with $\gamma = \|(\mathbf{M}_* - \mathbf{M}_{*0})\mathbf{X}_*\boldsymbol{\beta}\|^2/\sigma^2$, where $\mathbf{M}_*$ and $\mathbf{M}_{*0}$ are the orthogonal projections onto $\mathcal{C}(\mathbf{V}^{-1/2}\mathbf{X})$ and $\mathcal{C}(\mathbf{V}^{-1/2}\mathbf{X}_0)$. The noncentrality is zero iff $\mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0)$.

Proof. Pass to the whitened model Eq. 31.1.3, which satisfies the normal linear model Eq. 7.3.1 with model matrix $\mathbf{X}_*$ of rank r . As shown above, $\hat{\boldsymbol{\beta}}_{\mathbf{V}}$ is exactly a least squares estimate for $(\mathbf{Y}_*, \mathbf{X}_*)$, and the two models have the same estimable functions. Moreover

$$\text{SSE}_{\mathbf{V}} = \|\mathbf{Y}_* - \mathbf{X}_*\hat{\boldsymbol{\beta}}_{\mathbf{V}}\|^2 = \|(\mathbf{I} - \mathbf{M}_*)\mathbf{Y}_*\|^2$$

is the residual sum of squares of the whitened problem, because $\mathbf{V}^{-1/2}\hat{\boldsymbol{\varepsilon}}_{\mathbf{V}} = (\mathbf{I} - \mathbf{M}_*)\mathbf{Y}_*$ by Theorem 6.4.1, and $\mathbf{X}^\top \mathbf{V}^{-1}\mathbf{X} = \mathbf{X}_*^\top \mathbf{X}_*$.

Now apply Theorem 7.5.1 to $(\mathbf{Y}_*, \mathbf{X}_*)$. Part (a) of that theorem gives (a) here, since $\boldsymbol{\lambda}^\top (\mathbf{X}_*^\top \mathbf{X}_*)^{-1}\boldsymbol{\lambda} = \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{V}^{-1}\mathbf{X})^{-1}\boldsymbol{\lambda}$ and invariance of the estimate follows from Theorem 6.4.4 applied in the whitened model. Parts (b) and (c) of Theorem 7.5.1 give (b) here, noting that $\mathbf{X}\hat{\boldsymbol{\beta}}_{\mathbf{V}} = \mathbf{V}^{1/2}\mathbf{M}_*\mathbf{Y}_*$ is a function of $\mathbf{M}_*\mathbf{Y}_*$, and part (d) gives (c). Part (d) follows from (a) and (b) exactly as Theorem 12.1.1 does in the Euclidean case. For (e), $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ implies $\mathcal{C}(\mathbf{V}^{-1/2}\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{V}^{-1/2}\mathbf{X})$ with ranks $r_0 < r$, so Definition 11.1.1 holds for the whitened pair and Theorem 11.1.1 applies; $\text{SSE}_{\mathbf{V},0} = \|(\mathbf{I} - \mathbf{M}_{*0})\mathbf{Y}_*\|^2$ by the same computation. The noncentrality Eq. 11.1.2 is $\|(\mathbf{M}_* - \mathbf{M}_{*0})\mathbf{X}_*\boldsymbol{\beta}\|^2/\sigma^2$, and it vanishes iff $\mathbf{X}_*\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_{*0})$, that is, iff $\mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0)$ since $\mathbf{V}^{-1/2}$ is nonsingular. ■

The theorem is not a new theory: it is Parts II and III read in another coordinate system, and the proof is nothing but the dictionary. Under normality $\hat{\boldsymbol{\beta}}_{\mathbf{V}}$ also maximizes the likelihood (Exercise (B3)), and $s_{\mathbf{V}}^2$ has smallest variance among unbiased estimates of σ^2 , by Section 7.4 applied to the whitened model.

31.1.4 What changes, and what does not

The dictionary is exact, but several habits from Parts II and III do not survive translation.

Warning. Under Eq. 31.1.1 with $\mathbf{V} \neq \mathbf{I}$:

- The generalized residual is **not** orthogonal to $\mathcal{C}(\mathbf{X})$; what holds is $\mathbf{X}^\top \mathbf{V}^{-1}\hat{\boldsymbol{\varepsilon}}_{\mathbf{V}} = \mathbf{0}$. The entries of $\hat{\boldsymbol{\varepsilon}}_{\mathbf{V}}$ need not sum to zero even when the model has an intercept.
- $\text{SSE}_{\mathbf{V}}$ is **not** $\sum_i (y_i - \hat{y}_i)^2$, and the ordinary residual sum of squares of the generalized fit is necessarily *larger* than that of the ordinary fit, which minimizes it. A model comparison using $\sum_i (y_i - \hat{y}_i)^2$ always prefers ordinary least squares and proves nothing.
- R^2 has no agreed meaning: the squared-cosine reading of Theorem 6.7.2 holds in the $\mathbf{V}^{-1}$ geometry, not the Euclidean one.
- The diagonal entries of $\mathbf{A}_{\mathbf{V}}$ still sum to r , but they are not leverages in the sense of Proposition 6.8.1 and can fall outside $[0, 1]$ (Exercise (B2)).

What survives is everything inference needs: unbiasedness, optimality, the χ^2 , t and F distribu-

tions, the degrees of freedom $n - r$, and γ as a squared distance from the reduced model space, measured now in the $\mathbf{V}^{-1}$ metric.

Example. (A trend in sea surface temperature)

The El Niño data record the monthly averaged sea surface temperature of a region of the eastern Pacific for the 61 complete years 1950 to 2010, 732 observations in 61 blocks of 12. Fit a linear trend in time together with three harmonic pairs at one, two and three cycles per year, so $p = 8$. Warm and cold years are warm and cold in every month, so the natural working model is a random annual shock: equicorrelation ρ inside each year, independence across years. Take $\rho = 0.5$ as known for the moment.

Ordinary least squares gives a trend of 0.1349 degrees per decade with the usual standard error 0.0223; generalized least squares gives 0.1347 with standard error 0.0512, larger by a factor of 2.30. The estimates agree to three decimals, the standard errors not at all. The annual cycle tells the same story in reverse: the coefficient of $\sin(2\pi \text{ month}/12)$ is 2.7629 under both fits, with standard error 0.0554 from ordinary and 0.0354 from generalized least squares — this time the usual standard error is too *large*. [Section 31.2](#) explains both facts.

The F test of “no trend” is 36.7 if the annual shock is ignored and 6.92 once it is allowed for, on 1 and 724 degrees of freedom ($p = 0.0087$): still clear evidence, but with a tenth of the apparent weight. The test that the second and third harmonics are absent moves the other way, from 10.4 to 25.6, because the annual shock inflates s^2 and so deflates every F whose numerator lives inside years. [Figure 31.1.1](#)(a) shows the annual mean residuals, far too spread out for independent errors, and panel (b) the two confidence bands.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

frame = sm.datasets.elnino.load_pandas().data
years = frame["YEAR"].to_numpy()
temps = frame.iloc[:, 1:].to_numpy()           # 61 years by 12 months
G, m = temps.shape
n = G * m
y = temps.ravel()                             # the month varies fastest
year = np.repeat(years, m)
month = np.tile(np.arange(1, m + 1), G)
time = (year - 1980.0) + (month - 6.5) / 12.0   # decimal years, centred at
1980

cols = [np.ones(n), time / 10.0]               # the trend is per decade
for k in (1, 2, 3):
    cols += [np.cos(2 * np.pi * k * month / m), np.sin(2 * np.pi * k * month / m)]
X = np.column_stack(cols)
p = X.shape[1]

rho = 0.5                                     # taken as known for now

    return F, stats.f.sf(F, df1, df2)

F_trend_gls, p_trend_gls = f_test(X, y, [1], rho, m)
F_trend_ols, p_trend_ols = f_test(X, y, [1], 0.0, m)    # rho = 0 is ordinary least
               squares
F_harm_gls, p_harm_gls = f_test(X, y, [4, 5, 6, 7], rho, m)
F_harm_ols, p_harm_ols = f_test(X, y, [4, 5, 6, 7], 0.0, m)
print(f"trend:      F = {F_trend_ols:7.2f} (rho = 0)    F = {F_trend_gls:6.2f} (rho =
      0.5)")
print(f"harmonics:  F = {F_harm_ols:7.2f} (rho = 0)    F = {F_harm_gls:6.2f} (rho =
      0.5)")
```

Idea. Generalized least squares is one change of coordinates away from ordinary least squares, and everything in Parts II and III transfers — provided *all* of it does: the estimate, the residual sum of squares, the degrees of freedom and the sums of squares of every hypothesis. Mixing geometries, as in a generalized estimate with an ordinary standard error, is the one way to get this wrong.

31.1.5 Exercises

31.1.5.1 A. Check your understanding

Exercise A1.

Show that replacing $(\sigma^2, \mathbf{V})$ by $(\sigma^2/c, c\mathbf{V})$ for $c > 0$ leaves $\hat{\boldsymbol{\beta}}_{\mathbf{V}}$, $\mathbf{A}_{\mathbf{V}}$ and every statistic in [Theorem 31.1.1](#)(d), (e) unchanged, and multiplies $\text{SSE}_{\mathbf{V}}$ and $s_{\mathbf{V}}^2$ by $1/c$. Conclude that no normalization of $\mathbf{V}$ affects any inference about $\boldsymbol{\beta}$.

Solution. The criterion $Q_{c\mathbf{V}}(\mathbf{b}) = Q_{\mathbf{V}}(\mathbf{b})/c$ is minimized at the same $\mathbf{b}$, and $(c\mathbf{V})^{-1} = \mathbf{V}^{-1}/c$ cancels from [Eq. 31.1.2](#). Then $\text{SSE}_{c\mathbf{V}} = \text{SSE}_{\mathbf{V}}/c$ and $\boldsymbol{\lambda}^\top (\mathbf{X}^\top (c\mathbf{V})^{-1} \mathbf{X})^{-1} \boldsymbol{\lambda} = c \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \boldsymbol{\lambda}$, so the factors c cancel in the t statistic; in F they cancel between numerator and denominator.

Exercise A2.

Show that $\mathbf{1}^\top \hat{\boldsymbol{\epsilon}}_{\mathbf{V}} = 0$ for every $\mathbf{y}$ iff $\mathbf{1} \in \mathcal{C}(\mathbf{V}^{-1}\mathbf{X})$. Give an example with an intercept in which this fails.

31.1.5.2 B. Practice

Exercise B1.

Let $\mathbf{V}_0 = (1 - \rho)\mathbf{I}_m + \rho\mathbf{1}\mathbf{1}^\top$ with $-1/(m-1) < \rho < 1$. Verify [Eq. 31.1.4](#) by [Theorem 1.6.5](#), and show that $\mathbf{L}_0 = (\mathbf{I}_m - c\mathbf{1}\mathbf{1}^\top/m)/\sqrt{1-\rho}$ satisfies $\mathbf{L}_0\mathbf{V}_0\mathbf{L}_0^\top = \mathbf{I}_m$ for $c = 1 - \sqrt{(1-\rho)/(1+(m-1)\rho)}$. Deduce [Eq. 31.1.5](#).

Solution. Write $\mathbf{P} = \mathbf{1}\mathbf{1}^\top/m$, which is idempotent, so $\mathbf{V}_0 = (1 - \rho)\mathbf{I} + \rho m\mathbf{P}$. For any c , $(\mathbf{I} - c\mathbf{P})\mathbf{V}_0(\mathbf{I} - c\mathbf{P}) = (1 - \rho)\mathbf{I} + [(1 - \rho)(c^2 - 2c) + \rho m(1 - c)^2]\mathbf{P}$, using $\mathbf{P}^2 = \mathbf{P}$. Setting $a = 1 - \rho$ and $b = \rho m$, the bracket vanishes iff $(a + b)c^2 - 2(a + b)c + b = 0$, that is $c^2 - 2c + b/(a + b) = 0$, whose root in $[0, 1)$ is $c = 1 - \sqrt{a/(a + b)}$. Dividing by $1 - \rho$ gives $\mathbf{L}_0\mathbf{V}_0\mathbf{L}_0^\top = \mathbf{I}$. The Woodbury identity with $\mathbf{U} = \mathbf{1}$ gives [Eq. 31.1.4](#) directly. Applying $\mathbf{L}_0$ block by block is [Eq. 31.1.5](#), since $\mathbf{1}\mathbf{1}^\top\mathbf{y}_k/m = \bar{y}_k\mathbf{1}$.

Exercise B2.

Show that $\text{tr } \mathbf{A}_\mathbf{V} = r$ for every positive definite $\mathbf{V}$. Then take $n = 2$, $p = 1$,

$$\mathbf{X} = \begin{pmatrix} 1 \\ 2 \end{pmatrix}, \quad \mathbf{V} = \begin{pmatrix} 1 & 0.9 \\ 0.9 & 1 \end{pmatrix},$$

and show that the diagonal of $\mathbf{A}_\mathbf{V}$ is $(-4/7, 11/7)$. Why does this not contradict [Proposition 6.8.1](#)?

Exercise B3.

Show that $\hat{\boldsymbol{\varepsilon}}_\mathbf{V}^\top \hat{\boldsymbol{\varepsilon}}_\mathbf{V} \geq \hat{\boldsymbol{\varepsilon}}^\top \hat{\boldsymbol{\varepsilon}}$, where $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{y}$ is the ordinary residual, with equality iff $\mathbf{X}\hat{\boldsymbol{\beta}}_\mathbf{V} = \mathbf{M}\mathbf{y}$. Show also that $\hat{\boldsymbol{\varepsilon}}^\top \mathbf{V}^{-1} \hat{\boldsymbol{\varepsilon}} \geq \hat{\boldsymbol{\varepsilon}}_\mathbf{V}^\top \mathbf{V}^{-1} \hat{\boldsymbol{\varepsilon}}_\mathbf{V}$. Explain why neither inequality says anything about which fit is better.

Exercise B4.

Observations Y_{kj} , $j = 1, \dots, m_k$, $k = 1, \dots, G$, have mean μ and covariance $\sigma^2\mathbf{V}$ with $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top$, $\mathbf{Z}$ the cluster indicator matrix. Using [Eq. 31.1.4](#) cluster by cluster, show that

$$\hat{\mu}_\mathbf{V} = \frac{\sum_k w_k \bar{Y}_k}{\sum_k w_k}, \quad w_k = \frac{m_k}{1 - \rho + m_k \rho}, \quad (31.1.8)$$

with $\text{Var}(\hat{\mu}_\mathbf{V}) = \sigma^2 / \sum_k w_k$. Interpret the weights as $\rho \rightarrow 0$ and $\rho \rightarrow 1$.

Solution. With $\mathbf{V}$ block diagonal, $\mathbf{V}^{-1}$ is block diagonal with blocks $(\mathbf{I} - \frac{\rho}{1-\rho+m_k\rho}\mathbf{1}\mathbf{1}^\top)/(1-\rho)$. Hence $\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{1} = \sum_k (m_k - \rho m_k^2 / (1 - \rho + m_k \rho)) / (1 - \rho) = \sum_k w_k$, and $\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{y} = \sum_k w_k \bar{y}_k$ by the same computation. The generalized normal equation is $(\mathbf{1}^\top \mathbf{V}^{-1} \mathbf{1})\mu = \mathbf{1}^\top \mathbf{V}^{-1} \mathbf{y}$. As $\rho \rightarrow 0$, $w_k \rightarrow m_k$ and $\hat{\mu}_\mathbf{V} \rightarrow \bar{y}$; as $\rho \rightarrow 1$, $w_k \rightarrow 1$ and every cluster counts once, however large, because the extra observations only repeat the same shock.

31.1.5.3 C. Going deeper

Exercise C1.

Suppose $(\mathbf{Y}^\top, Y_0)^\top$ is jointly distributed with $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, $E(Y_0) = \mathbf{x}_0^\top \boldsymbol{\beta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{V}$, $\text{Cov}(\mathbf{Y}, Y_0) = \sigma^2 \mathbf{c}$ and $\text{Var}(Y_0) = \sigma^2 v_0$, with $\mathbf{V}$ positive definite and $\text{rank}(\mathbf{X}) = p$. Among predictors $\mathbf{a}^\top \mathbf{Y}$ with $E(\mathbf{a}^\top \mathbf{Y} - Y_0) = 0$ for all $\boldsymbol{\beta}$, show that the one minimizing $E(\mathbf{a}^\top \mathbf{Y} - Y_0)^2$ is

$$\hat{Y}_0 = \mathbf{x}_0^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}} + \mathbf{c}^\top \mathbf{V}^{-1}(\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{\mathbf{V}}),$$

with prediction error variance $\sigma^2[v_0 - \mathbf{c}^\top \mathbf{V}^{-1} \mathbf{c} + \mathbf{d}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{d}]$, $\mathbf{d} = \mathbf{x}_0 - \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{c}$. This is Goldberger's formula; [Chapter 32](#) recognizes it as the best linear unbiased predictor of a random effect.

Solution. Unbiasedness requires $\mathbf{X}^\top \mathbf{a} = \mathbf{x}_0$, and $E(\mathbf{a}^\top \mathbf{Y} - Y_0)^2 = \sigma^2(\mathbf{a}^\top \mathbf{V} \mathbf{a} - 2\mathbf{a}^\top \mathbf{c} + v_0)$. By [Proposition 1.11.3](#) with the positive definite $\mathbf{V}$, the minimizer is $\mathbf{a} = \mathbf{V}^{-1} \mathbf{c} + \mathbf{V}^{-1} \mathbf{X}(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{d}$, and collecting terms gives $\mathbf{a}^\top \mathbf{Y} = \mathbf{x}_0^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}} + \mathbf{c}^\top \mathbf{V}^{-1}(\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{\mathbf{V}})$; the minimum value is the stated variance. Setting $\mathbf{c} = \mathbf{0}$ recovers the ordinary prediction of [Chapter 12](#). A correlated future observation is predicted by correcting the fitted mean with the part of the current residual that predicts it.

Exercise C2.

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2 \mathbf{V}(\boldsymbol{\theta}))$ with $\text{rank}(\mathbf{X}) = p$. Show that for each fixed $\boldsymbol{\theta}$ the log-likelihood is maximized over $(\boldsymbol{\beta}, \sigma^2)$ at $\hat{\boldsymbol{\beta}}_{\mathbf{V}(\boldsymbol{\theta})}$ and $\hat{\sigma}^2(\boldsymbol{\theta}) = \text{SSE}_{\mathbf{V}(\boldsymbol{\theta})}/n$, and that the profile log-likelihood is

$$\ell_p(\boldsymbol{\theta}) = -\frac{n}{2} \log \hat{\sigma}^2(\boldsymbol{\theta}) - \frac{1}{2} \log \det \mathbf{V}(\boldsymbol{\theta}) + \text{const.}$$

Why does the determinant term make the normalization of $\mathbf{V}$ matter here, when [Exercise \(A1\)](#) says it does not matter for inference about $\boldsymbol{\beta}$?

31.2 When ordinary least squares is best

The analysis in [Example \(A trend in sea surface temperature\)](#) left a puzzle: the generalized and the ordinary estimates of the trend agreed to three decimals and the seasonal coefficients to four, yet their standard errors disagreed by a factor of more than two in one direction and by half as much again in the other. Both halves have one explanation, the subject of this section: for a large class of designs ordinary least squares is *already* the best linear unbiased estimator, or very nearly so, while its reported standard error is wrong all the same.

Throughout, $\mathbf{V}$ is nonnegative definite and may be singular, $\mathbf{M}$ is the orthogonal projection onto $\mathcal{C}(\mathbf{X})$, and “ $\mathbf{A}\mathbf{Y}$ is a BLUE of $\mathbf{X}\boldsymbol{\beta}$ ” means that $\boldsymbol{\rho}^\top \mathbf{A}\mathbf{Y}$ is best linear unbiased for $\boldsymbol{\rho}^\top \mathbf{X}\boldsymbol{\beta}$ at every $\boldsymbol{\rho} \in \mathbb{R}^n$.

31.2.1 A criterion for a best estimator

Everything in this section, and most of the next, rests on one small lemma, the covariance version of [Exercise \(C3\)](#): a linear estimator is best exactly when it is uncorrelated with every

linear statistic that estimates zero. What is new is that $\mathbf{V}$ may be singular, that the criterion is read off one vector $\mathbf{c}$ at a time, and that uniqueness holds on $\mathcal{C}(\mathbf{X} : \mathbf{V})$, not merely with probability one.

Lemma 31.2.1 — Criterion for a BLUE

Assume Eq. 31.1.1 with $\mathbf{V}$ nonnegative definite. Let $\mathbf{c} \in \mathbb{R}^n$ and $\boldsymbol{\lambda} = \mathbf{X}^\top \mathbf{c}$, so that $\mathbf{c}^\top \mathbf{Y}$ is a linear unbiased estimator of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$.

- (a) $\mathbf{c}^\top \mathbf{Y}$ is a BLUE of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ if and only if $\mathbf{V}\mathbf{c} \in \mathcal{C}(\mathbf{X})$.
- (b) Any two BLUEs of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ are equal with probability one. More precisely, if $\mathbf{c}^\top \mathbf{Y}$ and $\mathbf{b}^\top \mathbf{Y}$ are both BLUEs then $\mathbf{c}^\top \mathbf{y} = \mathbf{b}^\top \mathbf{y}$ for every $\mathbf{y} \in \mathcal{C}(\mathbf{X} : \mathbf{V})$.
- (c) A matrix estimator $\mathbf{A}\mathbf{Y}$ with $\mathbf{A}\mathbf{X} = \mathbf{X}$ is a BLUE of $\mathbf{X}\boldsymbol{\beta}$ if and only if $\mathbf{A}\mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$, equivalently $\mathcal{C}(\mathbf{V}\mathbf{A}^\top) \subseteq \mathcal{C}(\mathbf{X})$.

Proof.

- (a) Every linear unbiased estimator of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ is $(\mathbf{c} + \mathbf{d})^\top \mathbf{Y}$ with $\mathbf{X}^\top \mathbf{d} = \mathbf{0}$, that is, with $\mathbf{d} \in \mathcal{C}(\mathbf{X})^\perp$. For real t ,

$$\text{Var}((\mathbf{c} + t\mathbf{d})^\top \mathbf{Y}) = \sigma^2(\mathbf{c}^\top \mathbf{V}\mathbf{c} + 2t\mathbf{c}^\top \mathbf{V}\mathbf{d} + t^2\mathbf{d}^\top \mathbf{V}\mathbf{d}),$$

a quadratic in t with nonnegative leading coefficient. If $\mathbf{c}^\top \mathbf{Y}$ is best, this quadratic is minimized at $t = 0$ for every such $\mathbf{d}$, which forces $\mathbf{c}^\top \mathbf{V}\mathbf{d} = 0$. Conversely, if $\mathbf{c}^\top \mathbf{V}\mathbf{d} = 0$ for every $\mathbf{d} \perp \mathcal{C}(\mathbf{X})$, then $\text{Var}((\mathbf{c} + \mathbf{d})^\top \mathbf{Y}) = \text{Var}(\mathbf{c}^\top \mathbf{Y}) + \sigma^2\mathbf{d}^\top \mathbf{V}\mathbf{d} \geq \text{Var}(\mathbf{c}^\top \mathbf{Y})$. So $\mathbf{c}^\top \mathbf{Y}$ is best iff $\mathbf{V}\mathbf{c} \perp \mathcal{C}(\mathbf{X})^\perp$, which is $\mathbf{V}\mathbf{c} \in \mathcal{C}(\mathbf{X})$.

- (b) Let $\mathbf{c}^\top \mathbf{Y}$ and $\mathbf{b}^\top \mathbf{Y}$ be BLUEs, with common variance v and covariance κ . The average $\frac{1}{2}(\mathbf{c} + \mathbf{b})^\top \mathbf{Y}$ is unbiased, so $v \leq \frac{1}{4}(v + v + 2\kappa)$, that is $v \leq \kappa$. Therefore

$$\text{Var}((\mathbf{c} - \mathbf{b})^\top \mathbf{Y}) = 2v - 2\kappa \leq 0,$$

so it is zero, and $(\mathbf{c} - \mathbf{b})^\top \mathbf{Y}$ has mean zero and zero variance: it vanishes with probability one. For the deterministic statement, zero variance means $(\mathbf{c} - \mathbf{b})^\top \mathbf{V}(\mathbf{c} - \mathbf{b}) = 0$, hence $\mathbf{V}(\mathbf{c} - \mathbf{b}) = \mathbf{0}$ because $\mathbf{V}$ is nonnegative definite, so $\mathbf{c}$ and $\mathbf{b}$ agree on $\mathcal{C}(\mathbf{V})$; and $\mathbf{X}^\top(\mathbf{c} - \mathbf{b}) = \mathbf{0}$ makes them agree on $\mathcal{C}(\mathbf{X})$. They therefore agree on $\mathcal{C}(\mathbf{X}) + \mathcal{C}(\mathbf{V}) = \mathcal{C}(\mathbf{X} : \mathbf{V})$.

- (c) Apply (a) to $\mathbf{c} = \mathbf{A}^\top \boldsymbol{\rho}$, which satisfies $\mathbf{X}^\top \mathbf{A}^\top \boldsymbol{\rho} = (\mathbf{A}\mathbf{X})^\top \boldsymbol{\rho} = \mathbf{X}^\top \boldsymbol{\rho}$, so $\mathbf{c}^\top \mathbf{Y}$ is unbiased for $\boldsymbol{\rho}^\top \mathbf{X}\boldsymbol{\beta}$. The condition $\mathbf{V}\mathbf{A}^\top \boldsymbol{\rho} \in \mathcal{C}(\mathbf{X})$ for every $\boldsymbol{\rho}$ is $\mathcal{C}(\mathbf{V}\mathbf{A}^\top) \subseteq \mathcal{C}(\mathbf{X})$, which says $(\mathbf{I} - \mathbf{M})\mathbf{V}\mathbf{A}^\top = \mathbf{0}$; transposing gives $\mathbf{A}\mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$.

■

31.2.2 The characterization

Theorem 31.2.2 — When ordinary least squares is best

Assume Eq. 31.1.1 with $\mathbf{V}$ nonnegative definite, and let $\mathbf{W}$ be any $n \times (n - r)$ matrix with $\mathcal{C}(\mathbf{W}) = \mathcal{C}(\mathbf{X})^\perp$.

- (a) The following are equivalent.
- (i) $\mathbf{MY}$ is a BLUE of $\mathbf{X}\boldsymbol{\beta}$.
 - (ii) $\mathbf{MV}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$, equivalently $\mathbf{MV} = \mathbf{VM}$.
 - (iii) $\mathcal{C}(\mathbf{VX}) \subseteq \mathcal{C}(\mathbf{X})$.
 - (iv) $\mathbf{V} = \mathbf{XAX}^\top + \mathbf{WBW}^\top$ for some nonnegative definite $\mathbf{A}$ and $\mathbf{B}$.
 - (v) $\mathcal{C}(\mathbf{X})$ has an orthonormal basis of eigenvectors of $\mathbf{V}$.
- (b) For $\boldsymbol{\rho} \in \mathbb{R}^n$, the estimator $\boldsymbol{\rho}^\top \mathbf{MY}$ of $\boldsymbol{\rho}^\top \mathbf{X}\boldsymbol{\beta}$ is a BLUE if and only if $\mathbf{VM}\boldsymbol{\rho} \in \mathcal{C}(\mathbf{X})$. When $\text{rank}(\mathbf{X}) = p$ and $\boldsymbol{\lambda} \in \mathbb{R}^p$, this reads $\mathbf{VX}(\mathbf{X}^\top \mathbf{X})^{-1}\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X})$.
- (c) If $\mathbf{V}$ is positive definite, the conditions of (a) are also equivalent to $\mathbf{M}\mathbf{y} = \mathbf{A}_\mathbf{V}\mathbf{y}$ for every $\mathbf{y}$, and then ordinary and generalized least squares give the same fit, the same estimate of every estimable function, and the same $\text{SSE}_\mathbf{V}$.

Proof. For positive definite $\mathbf{V}$ the chain (i) $\Leftrightarrow$ (ii) $\Leftrightarrow$ (iii) is [Exercise \(C3\)](#); the argument below needs no invertibility.

- (a) (i) $\Leftrightarrow$ (ii). Take $\mathbf{A} = \mathbf{M}$ in [Lemma 31.2.1\(c\)](#), which applies because $\mathbf{MX} = \mathbf{X}$. For the second form of (ii): if $\mathbf{MV}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$ then $\mathbf{MV} = \mathbf{MVM}$, and $\mathbf{MVM}$ is symmetric, so $\mathbf{MV}$ is symmetric and equals $(\mathbf{MV})^\top = \mathbf{VM}$. Conversely $\mathbf{MV} = \mathbf{VM}$ gives $\mathbf{MV}(\mathbf{I} - \mathbf{M}) = \mathbf{VM} - \mathbf{VM} = \mathbf{0}$.
- (ii) $\Leftrightarrow$ (iii). If $\mathbf{MV} = \mathbf{VM}$ then $\mathbf{VX} = \mathbf{VMX} = \mathbf{MVX} \in \mathcal{C}(\mathbf{M}) = \mathcal{C}(\mathbf{X})$. Conversely, if $\mathcal{C}(\mathbf{VX}) \subseteq \mathcal{C}(\mathbf{X})$ then $\mathbf{MVX} = \mathbf{VX}$. Since $\mathcal{C}(\mathbf{M}) = \mathcal{C}(\mathbf{X})$, every column of $\mathbf{M}$ is a combination of columns of $\mathbf{X}$, so $\mathbf{MVM} = \mathbf{VM}$. The left side is symmetric, so $\mathbf{VM} = (\mathbf{VM})^\top = \mathbf{MV}$.
- (iii) $\Rightarrow$ (iv). Split the identity as $\mathbf{I} = \mathbf{M} + (\mathbf{I} - \mathbf{M})$:

$$\begin{aligned} \mathbf{V} &= \mathbf{MVM} + \mathbf{MV}(\mathbf{I} - \mathbf{M}) \\ &\quad + (\mathbf{I} - \mathbf{M})\mathbf{VM} + (\mathbf{I} - \mathbf{M})\mathbf{V}(\mathbf{I} - \mathbf{M}) \\ &= \mathbf{MVM} + (\mathbf{I} - \mathbf{M})\mathbf{V}(\mathbf{I} - \mathbf{M}), \end{aligned}$$

the cross terms vanishing by (ii). Now $\mathbf{M} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\mathbf{X}^\top$ by [Theorem 6.3.6](#), so $\mathbf{MVM} = \mathbf{XAX}^\top$ with $\mathbf{A} = (\mathbf{X}^\top \mathbf{X})^{-1}\mathbf{X}^\top \mathbf{VX}(\mathbf{X}^\top \mathbf{X})^{-1}$, which is nonnegative definite because $\mathbf{V}$ is. Likewise $\mathbf{I} - \mathbf{M} = \mathbf{W}(\mathbf{W}^\top \mathbf{W})^{-1}\mathbf{W}^\top$, since $\mathbf{W}$ has full column rank and spans $\mathcal{C}(\mathbf{X})^\perp$, so $(\mathbf{I} - \mathbf{M})\mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{WBW}^\top$ with $\mathbf{B} = (\mathbf{W}^\top \mathbf{W})^{-1}\mathbf{W}^\top \mathbf{VW}(\mathbf{W}^\top \mathbf{W})^{-1}$, also nonnegative definite.

- (iv) $\Rightarrow$ (iii). $\mathbf{W}^\top \mathbf{X} = \mathbf{0}$, so $\mathbf{VX} = \mathbf{XAX}^\top \mathbf{X} \in \mathcal{C}(\mathbf{X})$.
- (v) $\Leftrightarrow$ (v). Condition (iii) says $\mathcal{C}(\mathbf{X})$ is invariant under $\mathbf{V}$. If it is, the restriction of $\mathbf{V}$ to $\mathcal{C}(\mathbf{X})$ is a symmetric operator on that subspace, so by [Theorem 1.7.2](#) it has an orthonormal eigenbasis there, and these are eigenvectors of $\mathbf{V}$. Conversely, if $\mathcal{C}(\mathbf{X})$ is spanned by eigenvectors of $\mathbf{V}$ then $\mathbf{V}$ maps each of them, and hence $\mathcal{C}(\mathbf{X})$, into $\mathcal{C}(\mathbf{X})$.
- (b) By [Lemma 31.2.1\(a\)](#) with $\mathbf{c} = \mathbf{M}\boldsymbol{\rho}$, which satisfies $\mathbf{X}^\top \mathbf{M}\boldsymbol{\rho} = \mathbf{X}^\top \boldsymbol{\rho}$, so that $\boldsymbol{\rho}^\top \mathbf{MY}$ is unbiased for $\boldsymbol{\rho}^\top \mathbf{X}\boldsymbol{\beta}$. For the full-rank form, $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} = \boldsymbol{\rho}^\top \mathbf{MY}$ with $\boldsymbol{\rho} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\boldsymbol{\lambda}$, and then $\mathbf{M}\boldsymbol{\rho} = \boldsymbol{\rho}$.
- (c) With $\mathbf{V}$ positive definite, (iii) is Kruskal's condition, and [Theorem 6.9.3](#) says it holds iff $\mathbf{M}\mathbf{y} = \mathbf{A}_\mathbf{V}\mathbf{y}$ for every $\mathbf{y}$. Equal fits give equal estimates of every estimable function by [Theorem 6.4.4](#), and equal residuals, hence equal $\text{SSE}_\mathbf{V}$.

Form (iv) is Rao's **simple covariance structure**: the error splits as $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}_1 + \boldsymbol{\varepsilon}_2$ with $\boldsymbol{\varepsilon}_1 \in \mathcal{C}(\mathbf{X})$, $\boldsymbol{\varepsilon}_2 \perp \mathcal{C}(\mathbf{X})$ and the two parts uncorrelated ([Exercise \(B1\)](#)). Ordinary least squares is best exactly when the noise splits along the model space in this way, for then the residuals carry no usable information about $\boldsymbol{\beta}$. Form (v) is the one to check when the eigenstructure of $\mathbf{V}$ is known.

31.2.3 Balanced layouts and a common shock

The most important case in practice is a balanced layout whose errors share a shock at some level of the design.

Example. (Equicorrelation in a balanced layout)

Let the $n = Gm$ observations fall into G groups of equal size m , let $\mathbf{Z}$ be the $n \times G$ matrix of group indicators, and let $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top$, the covariance produced by a group-level shock. Since $\mathbf{Z}\mathbf{Z}^\top$ is m times the orthogonal projection onto the group-constant vectors, condition (iii) holds iff $\mathcal{C}(\mathbf{X})$ is closed under replacing a vector by its group means — which happens whenever $\mathcal{C}(\mathbf{X})$ is spanned by group-constant vectors together with vectors whose group means vanish, exactly what a balanced design gives through its between-group and within-group contrasts.

In the El Niño data of [Example \(A trend in sea surface temperature\)](#) the groups are years. If the seasonal part of the model is the full set of eleven month effects, every column of $\mathbf{X}$ splits into a year-level part and a part whose year means vanish, both again in $\mathcal{C}(\mathbf{X})$, so the condition holds *exactly*: the two fits agree to nine decimals, whatever ρ . Their standard errors do not. At $\rho = 0.5$ the root of the expected reported variance $E(s^2)\{(\mathbf{X}^\top\mathbf{X})^{-1}\}_{22}$ is only 0.391 of the true standard error of the trend.

The same argument covers randomized complete block designs with random blocks, and any design whose every regressor is constant within a block or sums to zero in each block. The analysis of variance tables of [Part IV](#) therefore survive random block effects as *point estimates*; only their error terms need rethinking, and [Chapter 33](#) develops the split-plot case, where condition (iv) becomes a decomposition into error strata. Incomplete block designs break the condition: between-block comparisons then carry treatment information that a within-block analysis discards, and recovering it — Yates's recovery of interblock information — is generalized least squares.

31.2.4 When some contrasts are best and others are not

Part (b) of [Theorem 31.2.2](#) is finer than part (a): even when $\mathbf{MY}$ is not best for $\mathbf{X}\boldsymbol{\beta}$ as a whole, particular functions still can be. The mechanism is easiest to see when the balance of [Example \(Equicorrelation in a balanced layout\)](#) is broken.

Figure 31.2.1: Efficiency of the ordinary least squares estimate of the overall level, for three cluster layouts with equicorrelation ρ inside clusters (solid). The balanced layout loses nothing at any ρ . The dotted curves are the Kantorovich bound of [Theorem 19.2.3](#) for the same $\mathbf{V}$, far below the efficiency the design actually attains.

Example. (Unequal clusters)

Take G clusters of sizes $m_1, \dots, m_G$, a covariate $\mathbf{w}$ centred inside every cluster, and the model $\mathbf{X} = [\mathbf{1}, \mathbf{w}]$ with $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top$. Because $\mathbf{1}^\top \mathbf{w} = 0$, the vector attached to the slope is $\mathbf{c} = \mathbf{w}/\mathbf{w}^\top \mathbf{w}$, and $\mathbf{Z}\mathbf{Z}^\top \mathbf{w} = \mathbf{0}$ because $\mathbf{w}$ has zero mean in each cluster; so $\mathbf{V}\mathbf{c} = (1 - \rho)\mathbf{c} \in \mathcal{C}(\mathbf{X})$ and the within-cluster slope is estimated best by ordinary least squares, for every ρ and every set of sizes.

The vector attached to the level is $\mathbf{c} = \mathbf{1}/n$, and $\mathbf{Z}\mathbf{Z}^\top \mathbf{1}$ is the vector whose entry for an observation in cluster k is m_k . That step function lies in $\mathcal{C}(\mathbf{X}) = \text{span}\{\mathbf{1}, \mathbf{w}\}$ only if all the m_k are equal, since $\mathbf{w}$ is not constant within clusters. So with unequal clusters the overall level is *not* estimated best by ordinary least squares; [Eq. 31.1.8](#) gives the estimator that is.

With sizes 2, 3, 6 and $\rho = 0.5$ the weights of [Eq. 31.1.8](#) are 1.333, 1.500 and 1.714, summing to 4.5476, so the generalized estimate of the level has variance $0.2199\sigma^2$ against $0.2479\sigma^2$ for the sample mean: an efficiency of 0.887, well above the Kantorovich bound 0.437 that [Proposition 31.2.3\(c\)](#) allows for the eigenvalues 3.500 and 0.500 of this $\mathbf{V}$. The slope loses nothing. Meanwhile the usual standard errors are wrong for both: the root of the expected reported variance is 0.563 of the true standard error for the level and 1.314 of it for the slope.

```
import numpy as np

sizes = [2, 3, 6]
w = np.array([-1.0, 1.0, -1.0, 0.0, 1.0, -3.0, -2.0, -1.0, 1.0, 2.0, 3.0])
n = len(w)
Z = np.zeros((n, len(sizes))) # cluster indicators
Z[np.arange(n), np.repeat(np.arange(len(sizes)), sizes)] = 1.0
X = np.column_stack([np.ones(n), w])
rho = 0.5
V = (1 - rho) * np.eye(n) + rho * Z @ Z.T
```

```

Ginv = np.linalg.inv(X.T @ X)
Cov_ols = Ginv @ X.T @ V @ X @ Ginv # sigma^2 = 1 throughout
Cov_gls = np.linalg.inv(X.T @ np.linalg.solve(V, X))
print("efficiency of OLS: level %.4f slope %.4f"
      % (Cov_gls[0, 0] / Cov_ols[0, 0], Cov_gls[1, 1] / Cov_ols[1, 1]))

```

31.2.5 How much is lost, and what is actually broken

Proposition 31.2.3 — The cost of ordinary least squares

Assume [Eq. 31.1.1](#) with $\mathbf{V}$ positive definite and $\text{rank}(\mathbf{X}) = p$. Write $\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}$ and let $\lambda_1 \geq \cdots \geq \lambda_n > 0$ be the eigenvalues of $\mathbf{V}$. For $\boldsymbol{\lambda} \neq \mathbf{0}$ define the efficiency $e(\boldsymbol{\lambda}) = \text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}) / \text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}})$.

- (a) $\text{Cov}(\hat{\boldsymbol{\beta}}) - \text{Cov}(\hat{\boldsymbol{\beta}}_{\mathbf{V}})$ is nonnegative definite, so $0 < e(\boldsymbol{\lambda}) \leq 1$ for every $\boldsymbol{\lambda}$.
- (b) $e(\boldsymbol{\lambda}) = 1$ if and only if $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} = \boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}$ with probability one, which by [Theorem 31.2.2\(b\)](#) happens iff $\mathbf{V}\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X})$.
- (c) $e(\boldsymbol{\lambda}) \geq 4\lambda_1\lambda_n/(\lambda_1 + \lambda_n)^2$ for every $\boldsymbol{\lambda}$ and every $\mathbf{X}$, and the bound is attained.

Proof.

- (a) Both $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}$ and $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}$ are linear unbiased estimators of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$, and the latter is best by [Corollary 7.2.3](#), so $\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}) \geq \text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}) > 0$. Taking $\boldsymbol{\lambda}$ over $\mathbb{R}^p$ gives $\boldsymbol{\lambda}^\top (\text{Cov}(\hat{\boldsymbol{\beta}}) - \text{Cov}(\hat{\boldsymbol{\beta}}_{\mathbf{V}})) \boldsymbol{\lambda} \geq 0$.
- (b) If $e(\boldsymbol{\lambda}) = 1$ then $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}$ attains the minimum variance and is therefore a BLUE, so it equals $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}$ with probability one by [Lemma 31.2.1\(b\)](#); the converse is immediate. The condition is part (b) of [Theorem 31.2.2](#).
- (c) This is [Theorem 19.2.3](#), proved in [Section 19.2](#) by a matrix form of Kantorovich's inequality, together with the design given there that attains it.

■

Part (c) is the worst case over all designs and all $\boldsymbol{\lambda}$. A determinant version is also known: if $p \leq n/2$, then

$$\frac{\det \text{Cov}(\hat{\boldsymbol{\beta}}_{\mathbf{V}})}{\det \text{Cov}(\hat{\boldsymbol{\beta}})} \geq \prod_{j=1}^p \frac{4\lambda_j\lambda_{n-j+1}}{(\lambda_j + \lambda_{n-j+1})^2},$$

with equality for a design built from the corresponding pairs of eigenvectors. This is the Bloomfield–Watson–Knott inequality, proved independently by Bloomfield and Watson (1975) and by Knott (1975) in back-to-back papers. We state it without proof; the argument needs more matrix theory than this book develops.

In practice the loss is far smaller, because real designs are not adversarial. The El Niño model with three harmonics is typical: Kruskal's condition fails, with $\max_{s,t} |\{(\mathbf{I} - \mathbf{M})\mathbf{V}\mathbf{X}\}_{st}| = 0.126$, yet the efficiency of the trend coefficient is 0.9996 and that of every seasonal coefficient is 1.0000 to four decimals. The intercept is exactly best, because $\mathbf{1}$ is orthogonal to every other column, so $\mathbf{c} = \mathbf{1}/n$ and $\mathbf{V}\mathbf{1} = \{1 + 11\rho\}\mathbf{1}$ is a multiple of $\mathbf{1}$. What is badly wrong is the standard

Figure 31.2.2: The El Niño model with three harmonics, as a function of the intraclass correlation ρ . The efficiency of the ordinary least squares trend estimate stays above 0.99, while the ratio of the reported to the true standard error falls to a third for the trend and rises past three for a seasonal coefficient.

error: the root of the expected value of $s^2\{(\mathbf{X}^\top \mathbf{X})^{-1}\}_{jj}$ is 0.390 of the true standard error for the trend and 1.406 of it for the first cosine, and Figure 31.2.2 shows both ratios running away as ρ grows while the efficiency never falls below 0.99.

Idea. Correlated errors damage the *standard error* far more than the *estimate*. [Theorem 19.2.3](#) bounds the efficiency below by a quantity depending only on the extreme eigenvalues of $\mathbf{V}$, and for ordinary designs the loss is a few per cent. Nothing bounds the error in $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$, which can be too small or too large by any factor. If only one of the two problems can be fixed, fix the standard error.

That is what the sandwich estimator of [Section 21.4](#) does. It leaves $\hat{\boldsymbol{\beta}}$ alone and replaces $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ by $(\mathbf{X}^\top \mathbf{X})^{-1}(\sum_k \mathbf{X}_k^\top \hat{\boldsymbol{\varepsilon}}_k \hat{\boldsymbol{\varepsilon}}_k^\top \mathbf{X}_k)(\mathbf{X}^\top \mathbf{X})^{-1}$, summed over units that can be treated as independent; for clustered data the unit is a cluster, and the argument of [Theorem 21.4.2](#) applies cluster by cluster rather than observation by observation. We do not prove that extension: [Theorem 21.4.2](#) assumes independent observations, consistency of the cluster form as the number of clusters grows is due to Liang and Zeger (1986), and [Exercise \(C1\)](#) derives the same matrix as a bootstrap covariance. It recovers no efficiency and needs many independent units, as [Section 31.4](#) shows; the two repairs are complementary.

31.2.6 Exercises

31.2.6.1 A. Check your understanding

Exercise A1.

Show directly from [Theorem 31.2.2\(a\)\(v\)](#) that ordinary least squares is best when the columns of $\mathbf{X}$ are eigenvectors of $\mathbf{V}$, and use this to recover the equicorrelation result of [Exercise \(A1\)](#).

Solution. If each column of $\mathbf{X}$ is an eigenvector of $\mathbf{V}$, then $\mathcal{C}(\mathbf{X})$ is spanned by eigenvectors, which is (v). For $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top$ the vector $\mathbf{1}$ is an eigenvector with eigenvalue $1 + (n - 1)\rho$ and every vector orthogonal to $\mathbf{1}$ is an eigenvector with eigenvalue $1 - \rho$. A model containing an intercept has $\mathcal{C}(\mathbf{X}) = \text{span}\{\mathbf{1}\} \oplus (\mathcal{C}(\mathbf{X}) \cap \mathbf{1}^\perp)$, a span of eigenvectors, so (v) holds.

Exercise A2.

Show that $\mathbf{M}\mathbf{V} = \mathbf{V}\mathbf{M}$ for every $\mathbf{X}$ if and only if $\mathbf{V}$ is a multiple of $\mathbf{I}$.

31.2.6.2 B. Practice

Exercise B1.

Assume the simple covariance structure $\mathbf{V} = \mathbf{X}\mathbf{A}\mathbf{X}^\top + \mathbf{W}\mathbf{B}\mathbf{W}^\top$ of [Theorem 31.2.2\(a\)\(iv\)](#). Show that $\text{Cov}(\mathbf{M}\mathbf{Y}, (\mathbf{I} - \mathbf{M})\mathbf{Y}) = \mathbf{0}$, and that the error can be written $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}_1 + \boldsymbol{\varepsilon}_2$ with $\boldsymbol{\varepsilon}_1 \in \mathcal{C}(\mathbf{X})$, $\boldsymbol{\varepsilon}_2 \in \mathcal{C}(\mathbf{X})^\perp$ and $\text{Cov}(\boldsymbol{\varepsilon}_1, \boldsymbol{\varepsilon}_2) = \mathbf{0}$ with probability one.

Solution. $\text{Cov}(\mathbf{M}\mathbf{Y}, (\mathbf{I} - \mathbf{M})\mathbf{Y}) = \sigma^2\mathbf{M}\mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$ by (ii). Put $\boldsymbol{\varepsilon}_1 = \mathbf{M}\boldsymbol{\varepsilon}$ and $\boldsymbol{\varepsilon}_2 = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$; these lie in the stated spaces, add to $\boldsymbol{\varepsilon}$, and have cross-covariance $\sigma^2\mathbf{M}\mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$. Their covariance matrices are $\sigma^2\mathbf{X}\mathbf{A}\mathbf{X}^\top$ and $\sigma^2\mathbf{W}\mathbf{B}\mathbf{W}^\top$.

Exercise B2.

Suppose $\text{Cov}(\mathbf{Y}) = \boldsymbol{\Sigma}(\boldsymbol{\theta})$ with $\boldsymbol{\theta}$ unknown, and that $\mathcal{C}(\boldsymbol{\Sigma}(\boldsymbol{\theta})\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ for every $\boldsymbol{\theta}$ in the parameter set. Show that $\mathbf{M}\mathbf{Y}$ is a BLUE for every $\boldsymbol{\theta}$, so that the best estimator is known even though the covariance is not. Give an example with two unknown variance components.

Exercise B3.

In [Example \(Unequal clusters\)](#) with two clusters of sizes m_1 and m_2 , show that the efficiency of the sample mean as an estimate of the level is

$$e = \frac{(m_1 + m_2)^2}{\{(1 - \rho)(m_1 + m_2) + \rho(m_1^2 + m_2^2)\}(w_1 + w_2)}, \quad w_k = \frac{m_k}{1 - \rho + m_k\rho}.$$

Show that $e = 1$ when $m_1 = m_2$, and find the limit as $\rho \rightarrow 1$ with $m_1 = 1$ and $m_2 = m$.

Solution. $\text{Var}(\bar{Y}) = \sigma^2\mathbf{1}^\top\mathbf{V}\mathbf{1}/n^2$ with $\mathbf{1}^\top\mathbf{V}\mathbf{1} = (1 - \rho)n + \rho\sum_k m_k^2$, and $\text{Var}(\hat{\mu}_{\mathbf{V}}) = \sigma^2/\sum_k w_k$ by [Eq. 31.1.8](#); divide. If $m_1 = m_2 = m$ both variances are $\sigma^2(1 - \rho + m\rho)/(2m)$, so $e = 1$. With $m_1 = 1$, $m_2 = m$ and $\rho \rightarrow 1$, $w_k \rightarrow 1$ and $e \rightarrow (1 + m)^2/\{2(1 + m^2)\}$, which falls to $1/2$ as m grows.

31.2.6.3 C. Going deeper

Exercise C1.

Let $\text{rank}(\mathbf{X}) = p$ and put $\mathcal{B} = \{\boldsymbol{\lambda} \in \mathbb{R}^p : \mathbf{V}\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X})\}$, the set of coefficient functions that ordinary least squares estimates best. Show that $\mathcal{B}$ is a subspace, that $\mathcal{B} = \mathbb{R}^p$ iff $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, and that $\dim \mathcal{B} = p - \text{rank}((\mathbf{I} - \mathbf{M})\mathbf{V}\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1})$. Evaluate it for [Example \(Unequal clusters\)](#).

Solution. A vector $\boldsymbol{\lambda}$ lies in $\mathcal{B}$ iff $(\mathbf{I} - \mathbf{M})\mathbf{V}\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\boldsymbol{\lambda} = \mathbf{0}$, so $\mathcal{B}$ is the null space of that matrix, hence a subspace, and [Theorem 1.2.2](#) gives its dimension. It is all of $\mathbb{R}^p$ iff the matrix is zero, which is $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ because $(\mathbf{X}^\top \mathbf{X})^{-1}$ is nonsingular. In [Example \(Unequal clusters\)](#), $p = 2$ and the map kills the slope direction but not the level direction, so $\dim \mathcal{B} = 1$: the functions estimated best are exactly the multiples of the slope.

Exercise C2.

Suppose $\mathbf{V}$ has only two distinct eigenvalues, λ_1 with multiplicity k and λ_2 with multiplicity $n - k$, and let $\mathcal{E}_1$ be the eigenspace of λ_1 . Show that $\mathbf{M}\mathbf{V} = \mathbf{V}\mathbf{M}$ iff $\mathcal{C}(\mathbf{X}) = (\mathcal{C}(\mathbf{X}) \cap \mathcal{E}_1) \oplus (\mathcal{C}(\mathbf{X}) \cap \mathcal{E}_1^\perp)$. Deduce that when this splitting holds every $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}$ has efficiency 1, and that when it fails there is a design attaining the bound $4\lambda_1\lambda_2/(\lambda_1 + \lambda_2)^2$.

31.3 Singular covariance matrices

A covariance matrix is nonnegative definite, not necessarily positive definite. When it is singular, some linear combination of the observations has zero variance and is therefore a *constant*: the data satisfy an exact linear relation. This is not a pathology to be regularized away — it happens whenever a linear operation has destroyed information — and it changes the theory, because some functions of $\boldsymbol{\beta}$ become known without error.

31.3.1 Where a singular covariance comes from

Three mechanisms cover most cases.

Constraints built into the data. Percentages adjusted to add to a hundred, effects reported under a sum-to-zero side condition ([Chapter 8](#)), residuals from an earlier fit: the reported vector satisfies an exact linear identity, and if $\mathbf{a}^\top \mathbf{Y}$ is constant then $\mathbf{V}\mathbf{a} = \mathbf{0}$ by [Theorem 2.2.3\(c\)](#).

A deterministic component. Some observations may be free of measurement error — a boundary value known exactly, a fitted value substituted for a missing one — and the corresponding rows and columns of $\mathbf{V}$ vanish. So is $\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}^\top$, the covariance of a random-effects model $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$ with no separate measurement error, as soon as $\mathbf{Z}$ has fewer columns than rows; [Chapter 32](#) studies that family.

Linear filtering with redundancy. Replacing uncorrelated observations by more linear combinations than the rank of the transformation — differences together with their total, overlapping averages together with the underlying ones — produces a singular covariance. Redundancy is what matters, not filtering: $n - 1$ successive differences of n uncorrelated observations have a

nonsingular tridiagonal covariance.

31.3.2 The consistency condition

Idea. A singular $\mathbf{V}$ confines the *errors* to a subspace: $\Pr(\boldsymbol{\varepsilon} \in \mathcal{C}(\mathbf{V})) = 1$. With $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X})$, this confines the data to $\mathcal{C}(\mathbf{X} : \mathbf{V}) = \mathcal{C}(\mathbf{X}) + \mathcal{C}(\mathbf{V})$ and $\mathbf{X}\boldsymbol{\beta}$ to the affine set $\mathbf{y} + \mathcal{C}(\mathbf{V})$. Estimation becomes a constrained problem: find the point of $\mathcal{C}(\mathbf{X})$ nearest $\mathbf{y}$ among those the data allow.

Write $\mathcal{C}(\mathbf{X} : \mathbf{V})$ for $\mathcal{C}(\mathbf{X}) + \mathcal{C}(\mathbf{V})$, the column space of $[\mathbf{X} \ \mathbf{V}]$. The following small lemma is used repeatedly.

Lemma 31.3.1

If $\mathbf{A}$ and $\mathbf{B}$ are nonnegative definite of the same order, then $\mathcal{C}(\mathbf{A} + \mathbf{B}) = \mathcal{C}(\mathbf{A}) + \mathcal{C}(\mathbf{B})$.

Proof. $(\mathbf{A} + \mathbf{B})\mathbf{w} = \mathbf{A}\mathbf{w} + \mathbf{B}\mathbf{w}$ shows $\mathcal{C}(\mathbf{A} + \mathbf{B}) \subseteq \mathcal{C}(\mathbf{A}) + \mathcal{C}(\mathbf{B})$. For the reverse, take $\mathbf{w} \perp \mathcal{C}(\mathbf{A} + \mathbf{B})$. Then $\mathbf{w}^\top \mathbf{A}\mathbf{w} + \mathbf{w}^\top \mathbf{B}\mathbf{w} = 0$, and both terms are nonnegative, so both vanish. By Theorem 1.7.6, $\|\mathbf{A}^{1/2}\mathbf{w}\|^2 = \mathbf{w}^\top \mathbf{A}\mathbf{w} = 0$, so $\mathbf{A}\mathbf{w} = \mathbf{A}^{1/2}\mathbf{A}^{1/2}\mathbf{w} = \mathbf{0}$, and likewise $\mathbf{B}\mathbf{w} = \mathbf{0}$. Hence $\mathbf{w} \perp \mathcal{C}(\mathbf{A})$ and $\mathbf{w} \perp \mathcal{C}(\mathbf{B})$, so $\mathcal{C}(\mathbf{A} + \mathbf{B})^\perp \subseteq (\mathcal{C}(\mathbf{A}) + \mathcal{C}(\mathbf{B}))^\perp$, which gives the inclusion. ■

31.3.3 The general theorem

Fix an orthogonal splitting adapted to $\mathbf{V}$: let $\mathbf{\Gamma}$ be $n \times q$ and $\mathbf{N}$ be $n \times (n - q)$ with orthonormal columns, $\mathcal{C}(\mathbf{\Gamma}) = \mathcal{C}(\mathbf{V})$ and $\mathcal{C}(\mathbf{N}) = \mathcal{C}(\mathbf{V})^\perp$, where $q = \text{rank}(\mathbf{V})$. Put $\mathbf{\Lambda} = \mathbf{\Gamma}^\top \mathbf{V} \mathbf{\Gamma}$, which is $q \times q$ positive definite, and let $\mathbf{V}^+$ be the Moore–Penrose inverse (Definition 1.3.2), so that $\mathbf{V}^+ = \mathbf{\Gamma} \mathbf{\Lambda}^{-1} \mathbf{\Gamma}^\top$. Write $r = \text{rank}(\mathbf{X})$ and $d = \dim(\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V}))$, and let $\mathbf{U}$ be any $n \times d$ matrix of full column rank with $\mathcal{C}(\mathbf{U}) = \mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V})$.

Theorem 31.3.2 — The general Gauss–Markov model

Assume Eq. 31.1.1 with $\mathbf{V}$ nonnegative definite of rank q .

- (a) (*Consistency.*) $\mathbf{N}^\top \mathbf{Y} = \mathbf{N}^\top \mathbf{X}\boldsymbol{\beta}$ with probability one; consequently $\Pr(\mathbf{Y} \in \mathcal{C}(\mathbf{X} : \mathbf{V})) = 1$ and $\Pr(\mathbf{X}\boldsymbol{\beta} \in \mathbf{Y} + \mathcal{C}(\mathbf{V})) = 1$.
- (b) (*Estimability and perfect estimation.*) $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ has a linear unbiased estimator iff $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$, exactly as when $\mathbf{V} = \mathbf{I}$. It has a linear unbiased estimator of variance zero iff $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top \mathbf{N})$, a subspace of dimension $r - d$, and then $\boldsymbol{\lambda}^\top \boldsymbol{\beta} = \mathbf{b}^\top \mathbf{N}^\top \mathbf{Y}$ with probability one for any $\mathbf{b}$ with $\mathbf{X}^\top \mathbf{N} \mathbf{b} = \boldsymbol{\lambda}$.
- (c) (*Rao’s unified formula.*) Let $\mathbf{T} = \mathbf{V} + \mathbf{X} \mathbf{X}^\top$. Then $\mathcal{C}(\mathbf{T}) = \mathcal{C}(\mathbf{X} : \mathbf{V})$, $\mathbf{T} \mathbf{T}^+ \mathbf{X} = \mathbf{X}$, and

$$\mathbf{A} = \mathbf{X}(\mathbf{X}^\top \mathbf{T}^+ \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{T}^+ \quad (31.3.1)$$

satisfies $\mathbf{AX} = \mathbf{X}$ and $\mathbf{AV}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$. Hence $\mathbf{AY}$ is a BLUE of $\mathbf{X}\boldsymbol{\beta}$.

- (d) (*Uniqueness.*) Every estimable $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ has a BLUE, and any two BLUEs of it agree for every $\mathbf{y} \in \mathcal{C}(\mathbf{X} : \mathbf{V})$, hence with probability one.
- (e) (*Projection form.*) Let $\mathbf{y} \in \mathcal{C}(\mathbf{X} : \mathbf{V})$. The set $\mathcal{F}(\mathbf{y}) = \{\mathbf{b} : \mathbf{y} - \mathbf{Xb} \in \mathcal{C}(\mathbf{V})\}$ is nonempty, and

$$\tilde{\boldsymbol{\beta}} \in \arg \min_{\mathbf{b} \in \mathcal{F}(\mathbf{y})} (\mathbf{y} - \mathbf{Xb})^\top \mathbf{V}^+ (\mathbf{y} - \mathbf{Xb}) \quad (31.3.2)$$

determines $\mathbf{X}\tilde{\boldsymbol{\beta}}$ uniquely; the map $\mathbf{y} \mapsto \mathbf{X}\tilde{\boldsymbol{\beta}}$ is linear and $\mathbf{X}\tilde{\boldsymbol{\beta}}$ is a BLUE of $\mathbf{X}\boldsymbol{\beta}$. Explicitly, with $\mathbf{K} = \mathbf{N}^\top \mathbf{X}$ and any generalized inverse $\mathbf{K}^-$,

$$\mathbf{X}\tilde{\boldsymbol{\beta}} = \mathbf{Xb}_* + \mathbf{U}(\mathbf{U}^\top \mathbf{V}^+ \mathbf{U})^{-1} \mathbf{U}^\top \mathbf{V}^+ (\mathbf{y} - \mathbf{Xb}_*), \quad \mathbf{b}_* = \mathbf{K}^- \mathbf{N}^\top \mathbf{y}. \quad (31.3.3)$$

- (f) (*Error sum of squares.*) Put $\hat{\boldsymbol{\varepsilon}} = \mathbf{Y} - \mathbf{X}\tilde{\boldsymbol{\beta}}$ and $\text{SSE}_{\mathbf{V}} = \hat{\boldsymbol{\varepsilon}}^\top \mathbf{V}^+ \hat{\boldsymbol{\varepsilon}}$. Then $E(\text{SSE}_{\mathbf{V}}) = \sigma^2(q - d)$, and $q - d = \text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$. If $\mathbf{Y}$ is normal, then $\text{SSE}_{\mathbf{V}}/\sigma^2 \sim \chi^2(q - d)$, independently of $\mathbf{X}\tilde{\boldsymbol{\beta}}$.

Proof.

- (a) By Theorem 2.2.3(d), $\Pr(\boldsymbol{\varepsilon} \in \mathcal{C}(\sigma^2 \mathbf{V})) = 1$, and $\mathcal{C}(\mathbf{V}) = \mathcal{C}(\mathbf{N})^\perp$, so $\mathbf{N}^\top \boldsymbol{\varepsilon} = \mathbf{0}$ almost surely, giving $\mathbf{N}^\top \mathbf{Y} = \mathbf{N}^\top \mathbf{X}\boldsymbol{\beta}$. Then $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \in \mathcal{C}(\mathbf{X}) + \mathcal{C}(\mathbf{V})$ and $\mathbf{X}\boldsymbol{\beta} = \mathbf{Y} - \boldsymbol{\varepsilon} \in \mathbf{Y} + \mathcal{C}(\mathbf{V})$.
- (b) $\mathbf{c}^\top \mathbf{Y}$ is unbiased for $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ for every $\boldsymbol{\beta}$ iff $\mathbf{X}^\top \mathbf{c} = \boldsymbol{\lambda}$, which is possible iff $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$. Its variance is $\sigma^2 \mathbf{c}^\top \mathbf{V} \mathbf{c}$, which vanishes iff $\mathbf{V} \mathbf{c} = \mathbf{0}$ (as in Lemma 31.3.1), that is iff $\mathbf{c} \in \mathcal{C}(\mathbf{V})^\perp = \mathcal{C}(\mathbf{N})$, say $\mathbf{c} = \mathbf{Nb}$. Then $\boldsymbol{\lambda} = \mathbf{X}^\top \mathbf{Nb}$ and $\mathbf{c}^\top \mathbf{Y} = \mathbf{b}^\top \mathbf{N}^\top \mathbf{Y}$, which equals $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ almost surely by (a). For the dimension, $\text{rank}(\mathbf{X}^\top \mathbf{N}) = \text{rank}(\mathbf{N}) - \dim\{\mathbf{b} : \mathbf{Nb} \perp \mathcal{C}(\mathbf{X})\}$ by Theorem 1.2.2, and $\{\mathbf{Nb} : \mathbf{Nb} \perp \mathcal{C}(\mathbf{X})\} = \mathcal{C}(\mathbf{V})^\perp \cap \mathcal{C}(\mathbf{X})^\perp = (\mathcal{C}(\mathbf{X} : \mathbf{V}))^\perp$, of dimension $n - \text{rank}(\mathbf{X} : \mathbf{V})$. Since $\text{rank}(\mathbf{X} : \mathbf{V}) = r + q - d$, we get $\text{rank}(\mathbf{X}^\top \mathbf{N}) = (n - q) - (n - r - q + d) = r - d$.
- (c) By Lemma 31.3.1 and $\mathcal{C}(\mathbf{X}\mathbf{X}^\top) = \mathcal{C}(\mathbf{X})$ (Corollary 6.2.4), $\mathcal{C}(\mathbf{T}) = \mathcal{C}(\mathbf{V}) + \mathcal{C}(\mathbf{X}) = \mathcal{C}(\mathbf{X} : \mathbf{V})$. Since $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{T})$, the system $\mathbf{TH} = \mathbf{X}$ is consistent (Theorem 1.4.1), so $\mathbf{X} = \mathbf{TH}$ for some $\mathbf{H}$ and $\mathbf{T}\mathbf{T}^+ \mathbf{X} = \mathbf{T}\mathbf{T}^+ \mathbf{TH} = \mathbf{TH} = \mathbf{X}$.

Write $\mathbf{T}^+ = \mathbf{L}\mathbf{L}^\top$, possible because $\mathbf{T}^+$ is symmetric nonnegative definite, and set $\mathbf{X}_* = \mathbf{L}^\top \mathbf{X}$, so that $\mathbf{X}^\top \mathbf{T}^+ \mathbf{X} = \mathbf{X}_*^\top \mathbf{X}_*$. If $\mathbf{X}_* \mathbf{w} = \mathbf{0}$ then $\mathbf{X}\mathbf{w} \in \mathcal{N}(\mathbf{L}^\top) = \mathcal{N}(\mathbf{T}^+) = \mathcal{C}(\mathbf{T})^\perp$, while $\mathbf{X}\mathbf{w} \in \mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{T})$; hence $\mathbf{X}\mathbf{w} = \mathbf{0}$. Every column of $\mathbf{I} - (\mathbf{X}_*^\top \mathbf{X}_*)^{-1} \mathbf{X}_*^\top \mathbf{X}_*$ lies in $\mathcal{N}(\mathbf{X}_*^\top \mathbf{X}_*) = \mathcal{N}(\mathbf{X}_*)$, so $\mathbf{X}(\mathbf{I} - (\mathbf{X}_*^\top \mathbf{X}_*)^{-1} \mathbf{X}_*^\top \mathbf{X}_*) = \mathbf{0}$, which is $\mathbf{AX} = \mathbf{X}(\mathbf{X}_*^\top \mathbf{X}_*)^{-1} \mathbf{X}_*^\top \mathbf{L}^\top \mathbf{X} = \mathbf{X}(\mathbf{X}_*^\top \mathbf{X}_*)^{-1} \mathbf{X}_*^\top \mathbf{X}_* = \mathbf{X}$.

For the second condition, let $\mathbf{d}$ satisfy $\mathbf{X}^\top \mathbf{d} = \mathbf{0}$. Using $\mathbf{V} = \mathbf{T} - \mathbf{X}\mathbf{X}^\top$ and the symmetry of $\mathbf{T}$ and $\mathbf{T}^+$,

$$\mathbf{X}^\top \mathbf{T}^+ \mathbf{V} \mathbf{d} = \mathbf{X}^\top \mathbf{T}^+ \mathbf{T} \mathbf{d} - \mathbf{X}^\top \mathbf{T}^+ \mathbf{X} \mathbf{X}^\top \mathbf{d} = (\mathbf{T}\mathbf{T}^+ \mathbf{X})^\top \mathbf{d} = \mathbf{X}^\top \mathbf{d} = \mathbf{0},$$

so $\mathbf{AVd} = \mathbf{0}$. As $\mathbf{d}$ ranges over $\mathcal{C}(\mathbf{X})^\perp$ this says $\mathbf{AV}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$. Now Lemma 31.2.1(c) makes $\mathbf{AY}$ a BLUE of $\mathbf{X}\boldsymbol{\beta}$.

- (d) Existence is (c): for estimable $\boldsymbol{\lambda}^\top \boldsymbol{\beta} = \boldsymbol{\rho}^\top \mathbf{X}\boldsymbol{\beta}$, the statistic $\boldsymbol{\rho}^\top \mathbf{AY}$ is a BLUE. Uniqueness is Lemma 31.2.1(b).
- (e) If $\mathbf{y} = \mathbf{Xb}_0 + \mathbf{v}$ with $\mathbf{v} \in \mathcal{C}(\mathbf{V})$ then $\mathbf{b}_0 \in \mathcal{F}(\mathbf{y})$, so $\mathcal{F}(\mathbf{y}) \neq \emptyset$; and $\mathbf{b} \in \mathcal{F}(\mathbf{y})$ iff $\mathbf{Kb} = \mathbf{N}^\top \mathbf{y}$, a consistent system, whose solutions are $\mathbf{K}^- \mathbf{N}^\top \mathbf{y}$ plus $\mathcal{N}(\mathbf{K})$. Since $\mathbf{X}\mathcal{N}(\mathbf{K}) = \{\mathbf{Xh} : \mathbf{N}^\top \mathbf{Xh} = \mathbf{0}\} = \mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V}) = \mathcal{C}(\mathbf{U})$, the fitted vectors available

are $\mathbf{X}\mathbf{b} = \mathbf{X}\mathbf{b}_* + \mathbf{U}\mathbf{c}$ with $\mathbf{b}_* = \mathbf{K}^{-1}\mathbf{N}^\top \mathbf{y}$ and $\mathbf{c} \in \mathbb{R}^d$ free. Also $\mathbf{y} - \mathbf{X}\mathbf{b}_* \in \mathcal{C}(\mathbf{V})$, and on $\mathcal{C}(\mathbf{V})$ the form $\mathbf{a}^\top \mathbf{V}^+ \mathbf{a}$ is positive definite; so minimizing over $\mathbf{c}$ is an ordinary generalized least squares problem in the $\mathbf{V}^+$ inner product with model matrix $\mathbf{U}$ of full column rank, whose unique solution is $\hat{\mathbf{c}} = (\mathbf{U}^\top \mathbf{V}^+ \mathbf{U})^{-1} \mathbf{U}^\top \mathbf{V}^+ (\mathbf{y} - \mathbf{X}\mathbf{b}_*)$. This gives Eq. 31.3.3, shows that $\mathbf{X}\tilde{\boldsymbol{\beta}}$ is unique and that the map is linear, say $\mathbf{X}\tilde{\boldsymbol{\beta}} = \mathbf{A}_* \mathbf{y}$.

It remains to check the two conditions of Lemma 31.2.1(c) for $\mathbf{A}_*$. If $\mathbf{y} = \mathbf{X}\boldsymbol{\beta}$ then $\mathbf{K}\mathbf{b}_* = \mathbf{N}^\top \mathbf{X}\boldsymbol{\beta}$ and $\mathbf{N}^\top (\mathbf{y} - \mathbf{X}\mathbf{b}_*) = \mathbf{0}$, so $\mathbf{y} - \mathbf{X}\mathbf{b}_* \in \mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V}) = \mathcal{C}(\mathbf{U})$; the $\mathbf{V}^+$ -projection onto $\mathcal{C}(\mathbf{U})$ leaves it fixed, and $\mathbf{A}_* \mathbf{X}\boldsymbol{\beta} = \mathbf{X}\mathbf{b}_* + (\mathbf{y} - \mathbf{X}\mathbf{b}_*) = \mathbf{X}\boldsymbol{\beta}$. Thus $\mathbf{A}_* \mathbf{X} = \mathbf{X}$. If $\mathbf{y} = \mathbf{V}\mathbf{d}$ with $\mathbf{X}^\top \mathbf{d} = \mathbf{0}$, then $\mathbf{N}^\top \mathbf{V}\mathbf{d} = \mathbf{0}$ so we may take $\mathbf{b}_* = \mathbf{0}$, and $\mathbf{U}^\top \mathbf{V}^+ \mathbf{V}\mathbf{d} = \mathbf{U}^\top \mathbf{\Gamma} \mathbf{\Gamma}^\top \mathbf{d} = \mathbf{U}^\top \mathbf{d} = \mathbf{0}$, using $\mathbf{V}^+ \mathbf{V} = \mathbf{\Gamma} \mathbf{\Gamma}^\top$, $\mathcal{C}(\mathbf{U}) \subseteq \mathcal{C}(\mathbf{V})$ and $\mathcal{C}(\mathbf{U}) \subseteq \mathcal{C}(\mathbf{X})$. So $\mathbf{A}_* \mathbf{V}\mathbf{d} = \mathbf{0}$, that is $\mathbf{A}_* \mathbf{V}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$.

- (f) Put $\mathbf{Z}_* = \mathbf{\Lambda}^{-1/2} \mathbf{\Gamma}^\top (\mathbf{I} - \mathbf{X}\mathbf{K}^{-1} \mathbf{N}^\top) \mathbf{Y}$, a random vector in $\mathbb{R}^q$. Because $\mathbf{V}\mathbf{N} = \mathbf{0}$, $(\mathbf{I} - \mathbf{X}\mathbf{K}^{-1} \mathbf{N}^\top) \mathbf{V}(\mathbf{I} - \mathbf{X}\mathbf{K}^{-1} \mathbf{N}^\top)^\top = \mathbf{V}$, so $\text{Cov}(\mathbf{Z}_*) = \sigma^2 \mathbf{\Lambda}^{-1/2} \mathbf{\Gamma}^\top \mathbf{V} \mathbf{\Gamma} \mathbf{\Lambda}^{-1/2} = \sigma^2 \mathbf{I}_q$. Its mean is $\mathbf{\Lambda}^{-1/2} \mathbf{\Gamma}^\top \mathbf{X}(\mathbf{I} - \mathbf{K}^{-1} \mathbf{K})\boldsymbol{\beta}$, which lies in $\mathbf{\Lambda}^{-1/2} \mathbf{\Gamma}^\top \mathcal{C}(\mathbf{U})$, a subspace of dimension d (the map $\mathbf{\Lambda}^{-1/2} \mathbf{\Gamma}^\top$ is injective on $\mathcal{C}(\mathbf{V}) \supseteq \mathcal{C}(\mathbf{U})$). By the computation in (e), $\text{SSE}_{\mathbf{V}} = \|(\mathbf{I} - \mathbf{M}_d) \mathbf{Z}_*\|^2$ where $\mathbf{M}_d$ is the orthogonal projection of $\mathbb{R}^q$ onto that d -dimensional subspace, and $\mathbf{X}\tilde{\boldsymbol{\beta}}$ is a fixed vector plus a function of $\mathbf{M}_d \mathbf{Z}_*$, since $\mathbf{N}^\top \mathbf{Y}$ is constant by (a). Now Theorem 2.3.1 gives $E(\text{SSE}_{\mathbf{V}}) = \sigma^2 \text{tr}(\mathbf{I} - \mathbf{M}_d) = \sigma^2(q - d)$ with no distributional assumption, and under normality Theorem 7.5.1 applied to $\mathbf{Z}_*$ gives the $\chi^2(q - d)$ law and the independence. Finally $\text{rank}(\mathbf{X} : \mathbf{V}) = r + q - d$ by the dimension formula for a sum of subspaces, so $q - d = \text{rank}(\mathbf{X} : \mathbf{V}) - r$.

■

The singular model is the nonsingular model with a deterministic layer on top. Part (b) isolates that layer, $r - d$ linear functions of $\boldsymbol{\beta}$ known exactly once the data are seen; part (e) pins down a particular solution with them and then does generalized least squares inside $\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V})$, the part of the model space the noise can still reach; part (f) counts what is left. If $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{V})$ then $d = r$, nothing is known exactly, and Eq. 31.3.3 is generalized least squares with $\mathbf{V}^+$ for $\mathbf{V}^{-1}$ on $q - r$ degrees of freedom; if $\mathbf{V}$ is nonsingular then $q = n$, $d = r$, and everything collapses to Theorem 31.1.1.

31.3.4 A worked example

Example. (Regression on estimated treatment effects)

A balanced one-way layout with a treatments and m observations each is analysed, and the estimated effects $\hat{\alpha}_1, \dots, \hat{\alpha}_a$ are reported under the side condition $\sum_k \hat{\alpha}_k = 0$ (Theorem 8.4.2). A second analyst, with access only to these numbers, regresses them on the dose x_k applied to treatment k , fitting $E(\hat{\alpha}_k) = \beta_0 + \beta_1 x_k$ with an intercept.

The reported vector has $\text{Cov}(\hat{\boldsymbol{\alpha}}) = \tau^2 \mathbf{V}$ with $\mathbf{V} = \mathbf{I}_a - \mathbf{1}\mathbf{1}^\top/a$ and $\tau^2 = \sigma^2/m$, because $\hat{\alpha}_k = \bar{Y}_k - \bar{Y}$ and the $\bar{Y}_k$ are uncorrelated with variance τ^2 . Here $q = a - 1$, $\mathcal{C}(\mathbf{V}) = \mathbf{1}^\perp$, and $\mathbf{N} = \mathbf{1}/\sqrt{a}$. With $\mathbf{1} \in \mathcal{C}(\mathbf{X})$ we get $d = 1$ and $r = 2$, so Theorem 31.3.2(b) gives exactly $r - d = 1$ perfectly known function: $\mathbf{X}^\top \mathbf{N} \propto (a, \sum_k x_k)^\top$, so

$$a\beta_0 + \left(\sum_k x_k\right)\beta_1 = \mathbf{1}^\top \mathbf{X}\boldsymbol{\beta} = \mathbf{1}^\top \hat{\boldsymbol{\alpha}} = 0$$

Figure 31.3.1: The geometry of a singular model with $n = 3$. The plane is $\mathcal{C}(\mathbf{X})$; $\mathcal{C}(\mathbf{V})$ is horizontal, so $\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V})$ is the lower line. The data $\mathbf{y}$ determine $\mathbf{N}^\top \mathbf{X}\boldsymbol{\beta}$ exactly, which confines $\mathbf{X}\boldsymbol{\beta}$ to the dashed line $\mathcal{C}(\mathbf{X}) \cap (\mathbf{y} + \mathcal{C}(\mathbf{V}))$; the estimate is the point of that line nearest $\mathbf{y}$ in the $\mathbf{V}^+$ geometry, and the residual lies in $\mathcal{C}(\mathbf{V})$.

with probability one. In words: the intercept is determined by the slope, $\beta_0 = -\bar{x}\beta_1$, and the data say so without error. Fitting an intercept was a mistake, and the model itself reveals it.

Everything else is unchanged. Because $\mathbf{V}\mathbf{X} = \mathbf{X} - \mathbf{1}(\mathbf{1}^\top \mathbf{X})/a$ has columns in $\mathcal{C}(\mathbf{X})$, [Theorem 31.2.2](#) applies and ordinary least squares is already best: $\hat{\beta}_1$ is the usual centred slope and $\hat{\beta}_0 = -\bar{x}\hat{\beta}_1$. Since $\mathbf{V}$ is idempotent, $\mathbf{V}^+ = \mathbf{V}$ and $\text{SSE}_{\mathbf{V}} = \hat{\mathbf{e}}^\top \hat{\mathbf{e}}$ is the usual residual sum of squares, on $q - d = a - 2$ degrees of freedom. What is *not* unchanged is the covariance matrix. Because $\mathbf{1}^\top \hat{\boldsymbol{\alpha}} = 0$ exactly,

$$\begin{aligned}\text{Var}(\hat{\beta}_1) &= \frac{\tau^2}{S_{xx}}, & \text{Var}(\hat{\beta}_0) &= \bar{x}^2 \text{Var}(\hat{\beta}_1), \\ \text{Cov}(\hat{\beta}_0, \hat{\beta}_1) &= -\bar{x} \text{Var}(\hat{\beta}_1),\end{aligned}$$

whereas the ordinary formula $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ reports $s^2(1/a + \bar{x}^2/S_{xx})$ for the intercept. With $a = 5$ doses 0, 1, 2, 4, 8, $m = 6$ replicates and $\sigma = 1.2$, so $\tau^2 = 0.24$, $\bar{x} = 3.0$ and $S_{xx} = 40.0$: the true variances are 0.00600 for the slope and 0.0540 for the intercept, while the ordinary formula reports 0.1020 on average for the intercept, too large by a factor of 1.89. A simulation of 200,000 layouts reproduces 0.00600 and 0.0540.

```
import numpy as np

dose = np.array([0.0, 1.0, 2.0, 4.0, 8.0])           # a = 5 treatments
a, reps, sigma = len(dose), 6, 1.2
X = np.column_stack([np.ones(a), dose])
V = np.eye(a) - np.ones((a, a)) / a                # Cov(effects) = (sigma^2/reps)
V                                                    # V is symmetric idempotent, so
V+ = V
N = np.ones((a, 1)) / np.sqrt(a)                   # an orthonormal basis of C(V)
N                                                    # perp
print("rank(V) =", np.linalg.matrix_rank(V), " rank([X V]) =",
      np.linalg.matrix_rank(np.column_stack([X, V])), " rank(X) =", np.linalg.
      matrix_rank(X))
print("the perfectly known function:", (X.T @ N).ravel())
```

```
rng = np.random.default_rng(3107)
trials = 200_000
cell = rng.normal(scale=sigma / np.sqrt(reps), size=(trials, a))   # treatment
cell += 0.35 * (dose - xbar)                                         # the true
cell                                     effects
effects = cell - cell.mean(axis=1, keepdims=True)                  # sum to zero
effects                                     exactly
B = effects @ np.linalg.solve(X.T @ X, X.T).T                      # ordinary
B                                     least squares

tau2 = sigma**2 / reps
print("Var(slope): %.5f simulated, %.5f from tau^2/Sxx" % (B[:, 1].var(), tau2 /
      Sxx))
print("Var(intercept): %.5f simulated, %.5f from xbar^2 tau^2/Sxx"
      % (B[:, 0].var(), xbar**2 * tau2 / Sxx))
```

```
print("what OLS reports for the intercept: %.5f" % (tau2 * (1 / a + xbar**2 / Sxx)))
```

The script behind [Example \(Regression on estimated treatment effects\)](#) also computes the estimate four ways — by [Eq. 31.3.2](#), by the closed form [Eq. 31.3.3](#), by [Eq. 31.3.1](#) with $\mathbf{T} = \mathbf{V} + \mathbf{X}\mathbf{X}^\top$, and by ordinary least squares — and checks that all four agree, as [Theorem 31.3.2\(d\)](#) requires, and that [Eq. 31.3.3](#) gives the same answer for two different generalized inverses $\mathbf{K}^-$.

Warning. Software that inverts $\mathbf{V}$ will fail here, and software that silently replaces $\mathbf{V}^{-1}$ by a pseudo-inverse solves the wrong problem: it minimizes the $\mathbf{V}^+$ criterion over all $\mathbf{b}$ instead of over $\mathcal{F}(\mathbf{y})$, which is what [Theorem 31.3.2\(e\)](#) is for, so the point estimate can be wrong. In [Example \(Regression on estimated treatment effects\)](#) the formula $(\mathbf{X}^\top \mathbf{V}^+ \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^+ \mathbf{y}$ always returns $\hat{\beta}_0 = 0$, contradicting $\mathbf{1}^\top \hat{\boldsymbol{\alpha}} = 0$. The smallest instance has two observations, the second measured without error: $\mathbf{V} = \text{diag}(1, 0)$, $\mathbf{X} = \mathbf{1}_2$, so $\beta = Y_2$ exactly, while the formula reports Y_1 . The degrees of freedom are wrong too: $n - r$ is not $q - d$. Here $a - 2 = 3$ happens to agree with $n - r$, but with a $\mathbf{V}$ of lower rank it would not; always compute $\text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$.

31.3.5 Testing

A reduced model $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ is tested as in [Theorem 31.1.1\(e\)](#), with two adjustments. The degrees of freedom are those of [Theorem 31.3.2\(f\)](#) for each model, $\nu = \text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$ and $\nu_0 = \text{rank}(\mathbf{X}_0 : \mathbf{V}) - \text{rank}(\mathbf{X}_0)$, so the numerator carries $\nu_0 - \nu$. And the reduced model can be *refuted with certainty*: if $\mathbf{Y} \notin \mathcal{C}(\mathbf{X}_0 : \mathbf{V})$ it is impossible and the test rejects at once. Otherwise [Eq. 31.1.7](#) has the $F(\nu_0 - \nu, \nu, \gamma)$ distribution; [Exercise \(C1\)](#) works through the argument.

31.3.6 Exercises

31.3.6.1 A. Check your understanding

Exercise A1.

Show that if $\mathbf{V}$ is singular with $\mathbf{V}\mathbf{a} = \mathbf{0}$, then $\mathbf{a}^\top \mathbf{Y}$ is the same number for every possible data vector, and identify that number in terms of $\boldsymbol{\beta}$. What does this say about $\mathbf{a}^\top \mathbf{X}\boldsymbol{\beta}$ when $\mathbf{X}^\top \mathbf{a} = \mathbf{0}$?

Exercise A2.

Verify $\text{rank}(\mathbf{X} : \mathbf{V}) = \text{rank}(\mathbf{X}) + \text{rank}(\mathbf{V}) - \dim(\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V}))$ and compute both sides for [Example \(Regression on estimated treatment effects\)](#).

Solution. This is the dimension formula for the sum of two subspaces, $\dim(\mathcal{S} + \mathcal{T}) = \dim \mathcal{S} + \dim \mathcal{T} - \dim(\mathcal{S} \cap \mathcal{T})$. In [Example \(Regression on estimated treatment effects\)](#), $\mathcal{C}(\mathbf{X}) + \mathcal{C}(\mathbf{V}) = \mathbb{R}^a$ because $\mathbf{1} \in \mathcal{C}(\mathbf{X})$ and $\mathcal{C}(\mathbf{V}) = \mathbf{1}^\perp$; so the left side is a , and the right side is $2 + (a - 1) - 1 = a$.

31.3.6.2 B. Practice

Exercise B1.

Three fractions of a sample are measured and then rescaled so that they add to one. Model $E(Y_k) = \mu + \delta_k$ with $\sum_k \delta_k = 0$ known, and suppose $\text{Cov}(\mathbf{Y}) = \sigma^2(\mathbf{I}_3 - \mathbf{1}\mathbf{1}^\top/3)$. Which function of $(\mu, \delta_1, \delta_2)$ is known exactly? Find the variance of $Y_1 - Y_2$ as an estimate of $\delta_1 - \delta_2$, and explain why no other linear unbiased estimate exists.

Solution. Here $\mathbf{N} = \mathbf{1}/\sqrt{3}$ and $\mathbf{X}^\top \mathbf{N} \propto \mathbf{X}^\top \mathbf{1}$; with the parameterization $\boldsymbol{\beta} = (\mu, \delta_1, \delta_2)^\top$ and $\delta_3 = -\delta_1 - \delta_2$, we get $\mathbf{X}^\top \mathbf{1} = (3, 0, 0)^\top$, so 3μ is known exactly: $\mu = \mathbf{1}^\top \mathbf{Y}/3 = 1/3$, the rescaling constant. Here $\text{rank}(\mathbf{X}) = 3 = n$, so $\mathbf{X}^\top$ is nonsingular and the unbiasedness equation $\mathbf{X}^\top \mathbf{c} = \boldsymbol{\lambda}$ has exactly one solution: every estimable function has a single linear unbiased estimate, which is therefore its BLUE. For $\delta_1 - \delta_2$ that solution is $\mathbf{c} = (1, -1, 0)^\top$, and $\text{Var}(Y_1 - Y_2) = \sigma^2 \mathbf{c}^\top \mathbf{V} \mathbf{c} = \sigma^2(2/3 + 2/3 + 2/3) = 2\sigma^2$.

Exercise B2.

Suppose the first observation is measured without error, so $\mathbf{V} = \begin{pmatrix} 0 & \mathbf{0}^\top \\ \mathbf{0} & \mathbf{V}_{22} \end{pmatrix}$ with $\mathbf{V}_{22}$ positive definite, and $\mathbf{X} = \begin{pmatrix} \mathbf{x}_{(1)}^\top \\ \mathbf{X}_2 \end{pmatrix}$. Show that $\mathbf{x}_{(1)}^\top \boldsymbol{\beta}$ is known exactly, and that the BLUE of any estimable $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ is the generalized least squares estimate from the remaining $n - 1$ observations *subject to* the constraint $\mathbf{x}_{(1)}^\top \mathbf{b} = y_1$.

Solution. $\mathbf{N} = \mathbf{e}_1$ spans $\mathcal{C}(\mathbf{V})^\perp$, so $\mathbf{N}^\top \mathbf{Y} = Y_1 = \mathbf{x}_{(1)}^\top \boldsymbol{\beta}$ with probability one. In Eq. 31.3.2 the feasible set is $\{\mathbf{b} : \mathbf{y} - \mathbf{X}\mathbf{b} \in \mathcal{C}(\mathbf{V})\} = \{\mathbf{b} : \mathbf{x}_{(1)}^\top \mathbf{b} = y_1\}$, and on $\mathcal{C}(\mathbf{V})$ the form $\mathbf{a}^\top \mathbf{V} \mathbf{a}$ is $\mathbf{a}_2^\top \mathbf{V}_{22}^{-1} \mathbf{a}_2$; so the criterion is the generalized least squares criterion of the last $n - 1$ observations, minimized subject to the constraint. This is restricted least squares (Theorem 9.2.5) in the $\mathbf{V}_{22}^{-1}$ geometry.

Exercise B3.

Verify directly from Eq. 31.3.3 that $\mathbf{X}\tilde{\boldsymbol{\beta}}$ does not depend on which generalized inverse $\mathbf{K}^-$ is used, given $\mathbf{y} \in \mathcal{C}(\mathbf{X} : \mathbf{V})$.

31.3.6.3 C. Going deeper**Exercise C1.**

In the setting of Theorem 31.3.2, let $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\nu_0 = \text{rank}(\mathbf{X}_0 : \mathbf{V}) - \text{rank}(\mathbf{X}_0)$ and $\nu = \text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$, and assume $\mathbf{Y}$ is normal and $\mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0 : \mathbf{V})$. Working in the coordinates $\mathbf{Z}_*$ of the proof of Theorem 31.3.2(f), show that $\text{SSE}_{\mathbf{V},0} - \text{SSE}_{\mathbf{V}}$ and $\text{SSE}_{\mathbf{V}}$ are independent with $(\text{SSE}_{\mathbf{V},0} - \text{SSE}_{\mathbf{V}})/\sigma^2 \sim \chi^2(\nu_0 - \nu, \gamma)$, and identify γ . Why is the assumption $\mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0 : \mathbf{V})$ needed?

Solution. Because $\mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0 : \mathbf{V})$ makes $\mathbf{N}^\top \mathbf{Y} \in \mathcal{C}(\mathbf{N}^\top \mathbf{X}_0)$, the same $\mathbf{b}_*$ is feasible in both models. In the coordinates $\mathbf{Z}_* \sim N_q(\boldsymbol{\mu}_*, \sigma^2 \mathbf{I})$ the two sums of squares are $\|(\mathbf{I} - \mathbf{M}_d)\mathbf{Z}_*\|^2$ and $\|(\mathbf{I} - \mathbf{M}_{d_0})\mathbf{Z}_*\|^2$ for nested subspaces of dimensions $d_0 \leq d$, with

$q - d = \nu$ and $q - d_0 = \nu_0$. Now [Theorem 11.1.1](#) applied to $\mathbf{Z}_*$ gives independence, the χ^2 laws and $\gamma = \|(\mathbf{M}_d - \mathbf{M}_{d_0})\boldsymbol{\mu}_*\|^2/\sigma^2$. If $\mathbf{X}\boldsymbol{\beta} \notin \mathcal{C}(\mathbf{X}_0 : \mathbf{V})$ the reduced model assigns probability zero to the observed $\mathbf{Y}$, so it is contradicted outright and no distribution theory is needed.

Exercise C2.

Call $\mathbf{X}\tilde{\boldsymbol{\beta}}$ a *least squares consistent estimate* when it minimizes the ordinary sum of squares $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ over $\mathcal{F}(\mathbf{y})$; this is the criterion used by Christensen (2020). Show that it agrees with [Eq. 31.3.2](#) when $\mathbf{V}$ is idempotent, and that in general the two differ. Show also that when $\mathcal{C}(\mathbf{V}\mathbf{U}) \subseteq \mathcal{C}(\mathbf{U})$ the least squares consistent estimate is a BLUE.

31.4 Estimated covariance: feasible generalized least squares

Nothing in the previous three sections is usable until $\mathbf{V}$ is known, and $\mathbf{V}$ is almost never known. The practical procedure is to choose a small family $\mathbf{V}(\boldsymbol{\theta})$, estimate $\boldsymbol{\theta}$, and proceed as if the estimate were the truth. That costs asymptotically nothing and, in small samples, a great deal — the damage falling on the standard errors rather than on the estimate.

31.4.1 The two-step estimator

Definition 31.4.1 — Feasible generalized least squares

Let $\{\mathbf{V}(\boldsymbol{\theta}) : \boldsymbol{\theta} \in \Theta\}$ be a family of positive definite $n \times n$ matrices, $\Theta \subseteq \mathbb{R}^k$, and let $\hat{\boldsymbol{\theta}}$ be an estimator of $\boldsymbol{\theta}$ computed from the data. The **feasible generalized least squares** estimator is

$$\hat{\boldsymbol{\beta}}_F = (\mathbf{X}^\top \mathbf{V}(\hat{\boldsymbol{\theta}})^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}(\hat{\boldsymbol{\theta}})^{-1} \mathbf{Y}, \quad (31.4.1)$$

for $\text{rank}(\mathbf{X}) = p$, with reported covariance matrix $s_F^2(\mathbf{X}^\top \mathbf{V}(\hat{\boldsymbol{\theta}})^{-1} \mathbf{X})^{-1}$, where s_F^2 is [Eq. 31.1.6](#) evaluated at $\mathbf{V}(\hat{\boldsymbol{\theta}})$.

The families that matter are small. Equicorrelation inside clusters, $\mathbf{V}(\rho) = (1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top$, and first-order autoregressive errors ([Definition 21.6.1](#)) both have $k = 1$; a variance function $\text{Var}(\varepsilon_i) = \sigma^2 \exp(\mathbf{z}_i^\top \boldsymbol{\gamma})$ has $k = \dim \boldsymbol{\gamma}$, the diagonal case treated in [Section 21.3](#); the linear mixed models of [Chapter 32](#) give $\mathbf{V}(\boldsymbol{\theta}) = \mathbf{Z}\mathbf{G}(\boldsymbol{\theta})\mathbf{Z}^\top + \mathbf{R}(\boldsymbol{\theta})$ with a handful of variance components. In every case k stays fixed while n grows; a family with k of the order of n cannot be estimated at all, which is why “estimate $\mathbf{V}$ freely” is not an option.

There are three routes to $\hat{\boldsymbol{\theta}}$. The **moment** route matches a few moments of the ordinary least squares residuals to the model, as in the analysis of variance estimate of an intraclass correlation used below. The **likelihood** route maximizes the profile log-likelihood of [Exercise \(C2\)](#), taken

up in [Chapter 32](#) with the restricted version that corrects its downward bias. The **iterative** route alternates between β and θ , as in the Cochrane–Orcutt procedure of [Theorem 21.6.1\(d\)](#). Only consistency is needed below.

One case needs no asymptotics. If $\mathcal{C}(\mathbf{V}(\theta)\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ for every θ , the best estimator is known even though the covariance is not ([Theorem 31.2.2](#), [Exercise \(B2\)](#)): in a balanced layout with random block effects, only the standard errors need $\hat{\theta}$.

31.4.2 Large-sample equivalence

Write $\mathbf{V} = \mathbf{V}(\theta_0)$ for the true covariance, $\hat{\beta}_{\mathbf{V}}$ for the infeasible generalized least squares estimator that uses it, and $\mathbf{D}(\theta) = \mathbf{V}(\theta)^{-1} - \mathbf{V}(\theta_0)^{-1}$. The whole question is whether replacing θ_0 by $\hat{\theta}$ disturbs the two quantities $n^{-1}\mathbf{X}^\top \mathbf{V}^{-1}\mathbf{X}$ and $n^{-1/2}\mathbf{X}^\top \mathbf{V}^{-1}\boldsymbol{\varepsilon}$ that determine $\hat{\beta}_{\mathbf{V}}$. The first is easy, because it does not involve the errors. The second is not, because $\hat{\theta}$ is computed from the same $\boldsymbol{\varepsilon}$.

Theorem 31.4.1 — Feasible generalized least squares

Assume [Eq. 31.1.1](#) with $\text{rank}(\mathbf{X}) = p$ fixed, and consider a sequence of models indexed by n . Suppose:

- (G1) there are constants $0 < c \leq C < \infty$ and a neighbourhood B of θ_0 such that every eigenvalue of $\mathbf{V}(\theta)$ lies in $[c, C]$ for all $\theta \in B$ and all n ;
- (G2) $\|\mathbf{D}(\theta)\|_2 \leq L\|\theta - \theta_0\|$ for $\theta \in B$, all n , with $\|\cdot\|_2$ the spectral norm;
- (G3) the rows of $\mathbf{X}$ satisfy $\|\mathbf{x}_{(i)}\| \leq K$, and $n^{-1}\mathbf{X}^\top \mathbf{V}^{-1}\mathbf{X} \rightarrow \mathbf{A}$ for a positive definite $\mathbf{A}$;
- (G4) $\hat{\theta} \rightarrow \theta_0$ in probability.

Then:

- (a) $n^{-1}\mathbf{X}^\top \mathbf{V}(\hat{\theta})^{-1}\mathbf{X} \rightarrow \mathbf{A}$ in probability, so the reported covariance factor is consistent up to the scale σ^2 .
- (b) If in addition $\sqrt{n}(\hat{\theta} - \theta_0) = O_p(1)$ and

- (G5) $\sup_{\|\theta - \theta_0\| \leq \delta} \|n^{-1/2}\mathbf{X}^\top \mathbf{D}(\theta)\boldsymbol{\varepsilon}\| = O_p(\delta)$ as $\delta \rightarrow 0$, uniformly in n ,

then $\sqrt{n}(\hat{\beta}_F - \hat{\beta}_{\mathbf{V}}) \rightarrow \mathbf{0}$ in probability. Consequently $\hat{\beta}_F$ has whatever limiting distribution $\hat{\beta}_{\mathbf{V}}$ has, and in particular $\sqrt{n}(\hat{\beta}_F - \beta) \rightarrow N_p(\mathbf{0}, \sigma^2 \mathbf{A}^{-1})$ whenever $\sqrt{n}(\hat{\beta}_{\mathbf{V}} - \beta)$ does.

Proof.

- (a) On the event $\hat{\theta} \in B$, whose probability tends to one by (G4),

$$\begin{aligned} \|n^{-1}\mathbf{X}^\top \mathbf{D}(\hat{\theta})\mathbf{X}\|_2 &\leq n^{-1}\|\mathbf{D}(\hat{\theta})\|_2\|\mathbf{X}\|_2^2 \\ &\leq n^{-1}L\|\hat{\theta} - \theta_0\| \cdot nK^2 = LK^2\|\hat{\theta} - \theta_0\|, \end{aligned}$$

using $\|\mathbf{X}\|_2^2 \leq \|\mathbf{X}\|_F^2 = \sum_i \|\mathbf{x}_{(i)}\|^2 \leq nK^2$. By (G4) this tends to zero in probability, and adding $n^{-1}\mathbf{X}^\top \mathbf{V}^{-1}\mathbf{X} \rightarrow \mathbf{A}$ gives (a).

(b) Write $\mathbf{A}_n(\boldsymbol{\theta}) = n^{-1} \mathbf{X}^\top \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{X}$ and $\mathbf{b}_n(\boldsymbol{\theta}) = n^{-1/2} \mathbf{X}^\top \mathbf{V}(\boldsymbol{\theta})^{-1} \boldsymbol{\varepsilon}$, so that

$$\begin{aligned}\sqrt{n}(\hat{\boldsymbol{\beta}}_F - \boldsymbol{\beta}) &= \mathbf{A}_n(\hat{\boldsymbol{\theta}})^{-1} \mathbf{b}_n(\hat{\boldsymbol{\theta}}), \\ \sqrt{n}(\hat{\boldsymbol{\beta}}_V - \boldsymbol{\beta}) &= \mathbf{A}_n(\boldsymbol{\theta}_0)^{-1} \mathbf{b}_n(\boldsymbol{\theta}_0).\end{aligned}$$

By (G1) and (G3), $E\|\mathbf{b}_n(\boldsymbol{\theta}_0)\|^2 = \sigma^2 \text{tr} \mathbf{A}_n(\boldsymbol{\theta}_0) \leq \sigma^2 p K^2 / c$ is bounded, so $\mathbf{b}_n(\boldsymbol{\theta}_0) = O_p(1)$. By (G5) with $\delta_n = \|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}_0\| = O_p(n^{-1/2})$,

$$\mathbf{b}_n(\hat{\boldsymbol{\theta}}) - \mathbf{b}_n(\boldsymbol{\theta}_0) = n^{-1/2} \mathbf{X}^\top \mathbf{D}(\hat{\boldsymbol{\theta}}) \boldsymbol{\varepsilon} = O_p(n^{-1/2}) = o_p(1),$$

so $\mathbf{b}_n(\hat{\boldsymbol{\theta}}) = \mathbf{b}_n(\boldsymbol{\theta}_0) + o_p(1)$ and both are $O_p(1)$. By (a), $\mathbf{A}_n(\hat{\boldsymbol{\theta}})$ and $\mathbf{A}_n(\boldsymbol{\theta}_0)$ both converge in probability to the invertible $\mathbf{A}$, and matrix inversion is continuous there, so $\mathbf{A}_n(\hat{\boldsymbol{\theta}})^{-1} - \mathbf{A}_n(\boldsymbol{\theta}_0)^{-1} = o_p(1)$. The difference of the two displays is therefore

$$\begin{aligned}&\{\mathbf{A}_n(\hat{\boldsymbol{\theta}})^{-1} - \mathbf{A}_n(\boldsymbol{\theta}_0)^{-1}\} \mathbf{b}_n(\hat{\boldsymbol{\theta}}) \\ &\quad + \mathbf{A}_n(\boldsymbol{\theta}_0)^{-1} \{\mathbf{b}_n(\hat{\boldsymbol{\theta}}) - \mathbf{b}_n(\boldsymbol{\theta}_0)\},\end{aligned}$$

a sum of products of $o_p(1)$ and $O_p(1)$ terms, hence $o_p(1)$. The last claim is Slutsky's theorem. ■

Condition (G5) is the substance of the theorem, and stating it as a hypothesis rather than proving it is the honest course: it separates “the weights are random” from “the weights might as well be fixed”, and it is not automatic. The naive bound $\|n^{-1/2} \mathbf{X}^\top \mathbf{D} \boldsymbol{\varepsilon}\| \leq n^{-1/2} L K \sqrt{n} \delta \|\boldsymbol{\varepsilon}\|$ is of order $\delta \sqrt{n}$, far too crude, because it ignores the cancellation among the n terms. The next lemma supplies that cancellation for one fixed $\boldsymbol{\theta}$ in the case that matters most, independent clusters of bounded size.

Lemma 31.4.2 — The drift term for independent clusters

Suppose the observations fall into G independent clusters of size at most $\bar{m}$, that $\mathbf{V}(\boldsymbol{\theta})$ is block diagonal with one block per cluster for every $\boldsymbol{\theta}$, and that (G1)–(G3) hold. Then for every fixed $\boldsymbol{\theta} \in B$,

$$E\|n^{-1/2} \mathbf{X}^\top \mathbf{D}(\boldsymbol{\theta}) \boldsymbol{\varepsilon}\|^2 \leq \sigma^2 \bar{m} K^2 L^2 C \|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|^2.$$

In particular $n^{-1/2} \mathbf{X}^\top \mathbf{D}(\boldsymbol{\theta}) \boldsymbol{\varepsilon} = O_p(\|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|)$.

Proof. Write $\mathbf{X}_k$, $\boldsymbol{\varepsilon}_k$ and $\mathbf{D}_k$ for the blocks belonging to cluster k , so that $\mathbf{X}^\top \mathbf{D} \boldsymbol{\varepsilon} = \sum_k \mathbf{X}_k^\top \mathbf{D}_k \boldsymbol{\varepsilon}_k$. The summands are independent with mean zero, so their covariance matrices add and

$$E\|n^{-1/2} \mathbf{X}^\top \mathbf{D} \boldsymbol{\varepsilon}\|^2 = \frac{1}{n} \sum_k E\|\mathbf{X}_k^\top \mathbf{D}_k \boldsymbol{\varepsilon}_k\|^2 \leq \frac{1}{n} \sum_k \|\mathbf{X}_k\|_2^2 \|\mathbf{D}_k\|_2^2 E\|\boldsymbol{\varepsilon}_k\|^2.$$

Now $\|\mathbf{X}_k\|_2^2 \leq m_k K^2$, $\|\mathbf{D}_k\|_2 \leq \|\mathbf{D}\|_2 \leq L \|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|$ by (G2), and $E\|\boldsymbol{\varepsilon}_k\|^2 = \sigma^2 \text{tr} \mathbf{V}_{kk} \leq \sigma^2 m_k C$ by (G1). Since $m_k \leq \bar{m}$ and $\sum_k m_k = n$, the sum is at most $\sigma^2 \bar{m} K^2 L^2 C \|\boldsymbol{\theta} - \boldsymbol{\theta}_0\|^2$. Chebyshev's inequality turns the moment bound into the stochastic order. ■

Remark. Lemma 31.4.2 gives the right order for each fixed θ ; (G5) asks for it *uniformly* over a shrinking ball, which is what allows θ to be replaced by the data-dependent $\hat{\theta}$. That passage is a stochastic equicontinuity argument we do not carry out: with θ of fixed dimension, a chaining bound over the ball converts the pointwise bound into the uniform one under mild smoothness of $\theta \mapsto \mathbf{V}(\theta)^{-1}$. Amemiya (1985, ch. 6) proves the conclusion of Theorem 31.4.1(b) for several concrete families, and Carroll and Ruppert (1988, ch. 3) for smooth variance functions; (G5) is verified there, not assumed away.

31.4.3 What goes wrong in small samples

Theorem 31.4.1 says that $\hat{\beta}_F$ and $\hat{\beta}_V$ are indistinguishable in large samples. It says nothing about finite n , where three things go wrong.

The estimator is no longer linear. $\hat{\beta}_F$ is a ratio of random quantities, so none of the exact theory of Theorem 31.1.1 applies. A symmetry argument rescues unbiasedness when $\hat{\theta}$ is an even function of the residuals and the errors are symmetric, exactly as in Theorem 21.3.1(c), whose argument goes through verbatim for a non-diagonal $\mathbf{V}(\hat{\theta})^{-1}$.

The variance exceeds the generalized least squares variance. Estimating θ adds noise, with an excess of order $1/G$ in the cluster setting; Kackar and Harville (1984) give the standard expansion of it.

The reported standard error ignores that noise. The matrix $s_F^2(\mathbf{X}^\top \mathbf{V}(\hat{\theta})^{-1} \mathbf{X})^{-1}$ is the covariance $\hat{\beta}_V$ would have had if $\hat{\theta}$ were the truth: it omits the extra variability, and is evaluated at a random $\hat{\theta}$ drawn towards values that make the fit look good. Tests are liberal and intervals too short.

Example. (How many clusters are enough?)

Simulate clusters of sizes 2, 4, 8 repeated 1, 2, 4, 8, 16, 32 times, with a cluster-level regressor z , a within-cluster regressor w , and equicorrelation $\rho = 0.6$ inside clusters. Estimate ρ by the analysis of variance moment estimator from the ordinary least squares residuals and form $\hat{\beta}_F$. Figure 31.4.1 shows 20,000 replications for each size.

The efficiency story is almost trivial. Ordinary least squares attains about 0.895 of the optimal precision for the coefficient of z — its variance is 1.12 times the optimal one — at every number of clusters, while feasible generalized least squares already reaches 0.987 with 3 clusters and 1.000 with 96. Estimating one smooth parameter costs almost nothing in efficiency, in sharp contrast with Example (Weights from a few replicates), where a separate variance was estimated in each of ten groups.

The inference story is the opposite. The nominal 95% interval based on $s_F^2(\mathbf{X}^\top \mathbf{V}(\hat{\rho})^{-1} \mathbf{X})^{-1}$ covers the truth in 0.728 of samples with 3 clusters, 0.916 with 12, and 0.944 with 96, while the interval that uses the true ρ covers 0.950 at three clusters and stays within simulation error of 95% at every size, as Theorem 31.1.1 guarantees. The cluster-robust interval built on $\hat{\beta}_F$ is uniformly a little better than the model-based one, but no cure when clusters are few — 0.764 at 3 — and the two become indistinguishable once there are several dozen, neither reaching the nominal level even at 96, where both stand at 0.944.

Figure 31.4.1: Feasible generalized least squares with equicorrelated clusters of sizes 2, 4, 8 and $\rho = 0.6$, for the coefficient of a cluster-level regressor (20,000 replications each). (a) Efficiency: the variance of generalized least squares with ρ known divided by the estimator's own variance. Feasible generalized least squares recovers essentially all of it at once. (b) Coverage of nominal 95% intervals: both intervals need dozens of clusters, and the cluster-robust one is no cure.

Idea. Estimating a covariance parameter buys back the efficiency almost at once and the correct standard error only slowly: efficiency depends on $\hat{\theta}$ through a function whose derivative vanishes at the optimum, so a mediocre $\hat{\theta}$ still gives nearly optimal weights, while the reported variance depends on $\hat{\theta}$ to first order and inherits all its error.

31.4.4 Which repair to use

Ordinary least squares with robust standard errors assumes nothing about the shape of $\mathbf{V}$, loses the few per cent bounded by [Proposition 31.2.3](#), and needs many clusters. *Feasible generalized least squares* recovers that efficiency, but only as far as $\mathbf{V}(\theta)$ is right; a wrong shape leaves the estimate unbiased — by the argument of [Theorem 21.3.1\(b\)](#), applied with $\mathbf{W} = \mathbf{V}(\theta_1)^{-1}$ for the limiting θ_1 — and the reported covariance wrong in an unknown direction. *Both*, a fitted $\mathbf{V}(\hat{\theta})$ with a robust standard error, is the modern default for clustered data, and [Chapter 33](#) develops it for longitudinal designs.

None of the three helps when the independent units are few: with three clusters $\hat{\rho}$ is hopeless and a sandwich with three terms is not a covariance estimate. The remedy is a better small-sample approximation — the Satterthwaite and Kenward–Roger degrees of freedom of [Chapter 32](#), or the bias-corrected sandwiches and cluster bootstrap of [Chapter 23](#) — or more clusters.

Example. (The El Niño trend without assuming ρ)

The analysis of [Example \(A trend in sea surface temperature\)](#) assumed $\rho = 0.5$. The moment estimator from the ordinary least squares residuals gives $\hat{\rho} = 0.610$, and the feasible generalized least squares fit then reports a trend of 0.1346 degrees per decade with standard error 0.0618. For comparison, the ordinary least squares trend, 0.1349, carries the usual standard error 0.0223 and a cluster-robust standard error of 0.0584 with years as clusters. The two honest routes agree closely and the naive one is out by a factor of nearly three. With 61 clusters both are in the range where [Example \(How](#)

many clusters are enough?) found them reliable.

31.4.5 Exercises

31.4.5.1 A. Check your understanding

Exercise A1.

Explain why $\hat{\beta}_F$ is not a linear function of $\mathbf{Y}$, and why this alone makes [Corollary 7.2.3](#) inapplicable to it. Which part of [Theorem 31.1.1](#) could still hold exactly if $\hat{\theta}$ happened to be independent of $\mathbf{Y}$?

Exercise A2.

Give a family $\mathbf{V}(\theta)$ with $k = 2$ for which no estimation of θ is needed to obtain the best estimator of $\mathbf{X}\beta$, and say what θ is still needed for.

31.4.5.2 B. Practice

Exercise B1.

For balanced clusters of size m with equicorrelation ρ , let B and W be the between- and within-cluster mean squares of the ordinary least squares residuals. Show that the moment estimator $\hat{\rho} = (B - W)/\{B + (m - 1)W\}$ is the solution of matching $E B$ and $E W$ to their model values when the model is fitted without regressors, and explain why $\hat{\rho}$ can be negative. What does truncating it at zero do to [Theorem 31.4.1](#)?

Solution. For a one-way layout with no regressors, $E W = \sigma^2(1 - \rho)$ and $E B = \sigma^2\{1 + (m - 1)\rho\}$ (this is [Exercise \(B1\)](#)). Solving $B = \sigma^2\{1 + (m - 1)\rho\}$, $W = \sigma^2(1 - \rho)$ for ρ gives the stated ratio. Since B and W are independent chi-squared multiples, $B < W$ happens with positive probability whenever ρ is small, so $\hat{\rho} < 0$ is possible; [Chapter 32](#) discusses negative variance-component estimates at length. Truncation leaves $\hat{\rho}$ consistent whenever $\rho > 0$, which is all (G4) requires; at $\rho = 0$ the truncated estimator is still consistent and still satisfies $\sqrt{n} \hat{\rho} = O_p(1)$, so [Theorem 31.4.1\(b\)](#) still applies to $\hat{\beta}_F$, but $\hat{\rho}$ itself is no longer asymptotically normal and the usual Wald theory for it fails.

Exercise B2.

Suppose $\mathbf{V}(\theta) = \text{diag}(1 + \theta z_1, \dots, 1 + \theta z_n)$ with known $z_i \geq 0$ and $\theta \geq 0$. Verify (G1) and (G2) on a neighbourhood of an interior θ_0 , giving explicit constants, and show that (G3) holds when the z_i and the rows of $\mathbf{X}$ are bounded.

Exercise B3.

In the balanced cluster model of [Exercise \(B4\)](#), all clusters of size m , consider estimating μ with weights built from a wrong value ρ_1 when the truth is ρ_0 . Show that the resulting estimator is $\bar{Y}$ for every ρ_1 , and hence that the efficiency is exactly 1. Contrast with the unbalanced case and explain the flat curve in [Figure 31.4.1\(a\)](#).

Solution. With equal sizes, Eq. 31.1.8 gives $w_k = m/(1 - \rho_1 + m\rho_1)$, the same for every k , so the weighted mean of the cluster means is $\bar{Y}$ whatever ρ_1 is: the estimator does not depend on the weights at all. With unequal sizes the weights do depend on ρ_1 , but only through the smooth ratio $m_k/(1 - \rho_1 + m_k\rho_1)$, and the variance of the resulting estimator is stationary at $\rho_1 = \rho_0$ because ρ_0 minimizes it. A first-order error in $\hat{\rho}$ therefore produces only a second-order loss of efficiency, which is why panel (a) is flat.

31.4.5.3 C. Going deeper

Exercise C1.

Show that the bound of Lemma 31.4.2 cannot be improved in order: construct a family with $k = 1$, independent clusters of size 1, and a design for which $E\|n^{-1/2}\mathbf{X}^\top \mathbf{D}(\theta)\boldsymbol{\varepsilon}\|^2$ is bounded below by a positive multiple of $(\theta - \theta_0)^2$.

Exercise C2.

Let $\hat{\boldsymbol{\theta}}$ be independent of $\mathbf{Y}$ with $E\hat{\boldsymbol{\theta}} = \boldsymbol{\theta}_0$, and write $g(\boldsymbol{\theta}) = \mathbf{a}^\top (\mathbf{X}^\top \mathbf{V}(\boldsymbol{\theta})^{-1} \mathbf{X})^{-1} \mathbf{a}$ for the reported variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}_F$ at scale $\sigma^2 = 1$, and $h(\boldsymbol{\theta})$ for its true variance. Show that $h(\boldsymbol{\theta}) \geq g(\boldsymbol{\theta}_0)$ for every $\boldsymbol{\theta}$, with equality at $\boldsymbol{\theta}_0$, and deduce that $Eg(\hat{\boldsymbol{\theta}})$ understates $Eh(\hat{\boldsymbol{\theta}})$ whenever g is concave near $\boldsymbol{\theta}_0$. Why does this not settle the question in general?

Solution. For fixed $\boldsymbol{\theta}$ the statistic $\mathbf{a}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}(\boldsymbol{\theta})}$ is a linear unbiased estimator of $\mathbf{a}^\top \boldsymbol{\beta}$, so Corollary 7.2.3 gives $h(\boldsymbol{\theta}) \geq h(\boldsymbol{\theta}_0) = g(\boldsymbol{\theta}_0)$, with equality at $\boldsymbol{\theta}_0$. Conditionally on $\hat{\boldsymbol{\theta}}$ the report is $g(\hat{\boldsymbol{\theta}})$ and the truth is $h(\hat{\boldsymbol{\theta}}) \geq g(\boldsymbol{\theta}_0)$; concavity of g and Jensen's inequality give $Eg(\hat{\boldsymbol{\theta}}) \leq g(\boldsymbol{\theta}_0)$. In general g need not be concave and $\hat{\boldsymbol{\theta}}$ is not independent of $\mathbf{Y}$; that dependence is what Example (How many clusters are enough?) measures.

31.5 Summary and Notes

31.5.1 Summary

Idea.

1. The general Gauss–Markov model Eq. 31.1.1 keeps $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ and replaces $\sigma^2\mathbf{I}$ by $\sigma^2\mathbf{V}$. Only the product is identified, so $\mathbf{V}$ carries the *shape* of the covariance and σ^2 its scale (Exercise (A1)).
2. With $\mathbf{V}$ known and positive definite, generalized least squares (Definition 31.1.1) is ordinary least squares on the whitened data Eq. 31.1.3, and everything in Parts II and III transfers: the χ^2 law of $\text{SSE}_{\mathbf{V}}$, the unbiased $s_{\mathbf{V}}^2$, t intervals and the F test of a reduced model, all on $n - r$ degrees of freedom (Theorem 31.1.1). What does not transfer is the Euclidean reading of the residual, which is $\mathbf{V}^{-1}$ -orthogonal to $\mathcal{C}(\mathbf{X})$; R^2 and leverage lose their meaning.
3. For structured $\mathbf{V}$ the whitening has a closed form. Equicorrelated clusters give the quasi-demeaning Eq. 31.1.5, which interpolates between doing nothing and fully

centring each cluster.

4. A linear unbiased estimator $\mathbf{c}^\top \mathbf{Y}$ of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ is best exactly when $\mathbf{V}\mathbf{c} \in \mathcal{C}(\mathbf{X})$, and any two best estimators agree on $\mathcal{C}(\mathbf{X} : \mathbf{V})$ (Lemma 31.2.1). This one criterion drives the rest of the chapter.
5. Ordinary least squares is best for *everything* iff $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, iff $\mathbf{M}\mathbf{V} = \mathbf{V}\mathbf{M}$, iff $\mathbf{V} = \mathbf{X}\mathbf{A}\mathbf{X}^\top + \mathbf{W}\mathbf{B}\mathbf{W}^\top$, iff $\mathcal{C}(\mathbf{X})$ is spanned by eigenvectors of $\mathbf{V}$ (Theorem 31.2.2). Balanced layouts with a shared shock satisfy it; unbalanced ones do not, and then some contrasts are still estimated best and others are not.
6. The efficiency lost by ignoring the covariance is bounded below by the Kantorovich ratio and is usually small (Proposition 31.2.3). The error in the reported standard error is not bounded at all and is usually large. Fix the standard error first.
7. When $\mathbf{V}$ is singular the errors live in $\mathcal{C}(\mathbf{V})$, so the data live in $\mathcal{C}(\mathbf{X} : \mathbf{V})$ and $r - d$ linear functions of $\boldsymbol{\beta}$ are known exactly (Theorem 31.3.2). The BLUE uses those functions to pin down a particular solution and then does generalized least squares inside $\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{V})$, or comes in closed form from Rao's formula Eq. 31.3.1. The residual degrees of freedom are $\text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$, not $n - r$.
8. When $\mathbf{V} = \mathbf{V}(\boldsymbol{\theta})$ must be estimated, the two-step estimator Eq. 31.4.1 is asymptotically equivalent to generalized least squares under stated regularity and a stochastic equicontinuity condition (Theorem 31.4.1, Lemma 31.4.2). In small samples the efficiency comes back almost at once while the reported standard error stays badly optimistic (Example (How many clusters are enough?)).

31.5.2 Notes and sources

Generalized least squares. The estimator and its optimality are due to Aitken (1935), who derived it by the same change of variables used here. Christensen (2020, §2.7) develops it coordinate-freely for arbitrary rank, the route Section 6.9 follows; Seber and Lee (2003, §3.10) and Rencher and Schaalje (2008, §7.8) give the full-rank version. That only $\sigma^2\mathbf{V}$ is a parameter is standard but often left implicit, so “normalizing $\mathbf{V}$ ” is sometimes mistaken for an assumption.

When least squares is best. The condition $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ has been found many times: Kruskal (1968) gave the coordinate-free statement that the two *fits* coincide, proved here as Theorem 6.9.3; Zyskind (1967) characterized through eigenvectors the covariance structures for which least squares is best, which is condition (v); and Rao (1967) gave the structural form $\mathbf{V} = \mathbf{X}\mathbf{A}\mathbf{X}^\top + \mathbf{W}\mathbf{B}\mathbf{W}^\top$ now usually called simple covariance structure. Watson (1955) first asked how much efficiency is lost when the condition fails; the sharp scalar bound follows from Kantorovich's inequality, proved as Theorem 19.2.3 in Section 19.2, and the determinant bound quoted in Section 31.2 was proved independently by Bloomfield and Watson (1975) and by Knott (1975). Puntanen and Styan (1989) survey the whole equivalence. Recovery of interblock information in incomplete block designs, the applied face of the failure of the condition, goes back to Yates (1940).

Singular covariance matrices. The systematic theory is due to Rao (1971, 1973), whose unified theory of linear estimation produced the formula Eq. 31.3.1 with $\mathbf{T} = \mathbf{V} + \mathbf{X}\mathbf{S}\mathbf{X}^\top$ for any nonnegative definite $\mathbf{S}$ with $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{T})$, and to Rao and Mitra (1971) for the generalized-inverse machinery. Christensen (2020, ch. 10) gives the vector-space treatment, including consistent estimation and the degrees-of-freedom count $\text{rank}(\mathbf{X} : \mathbf{V}) - \text{rank}(\mathbf{X})$. The proof given here is different: it splits the observation space orthogonally into $\mathcal{C}(\mathbf{V})$ and its complement, turning the model into an ordinary generalized least squares problem subject to exact linear

constraints, and then verifies the two conditions of [Lemma 31.2.1](#). Our [Theorem 31.3.2\(c\)](#) uses the Moore–Penrose inverse throughout, which keeps it short; with an arbitrary generalized inverse of $\mathbf{T}$ the same statements hold, but $\mathbf{T}\mathbf{T}^-\mathbf{X} = \mathbf{X}$ and the invariance of [Eq. 31.3.1](#) then have to be established separately.

Feasible generalized least squares. Two-step estimation with an estimated covariance is old; the econometric literature traces it through Cochrane and Orcutt (1949) for autoregressive errors and Zellner (1962) for seemingly unrelated regressions. Amemiya (1985, ch. 6) states and proves the asymptotic equivalence for several concrete families, and Carroll and Ruppert (1988, ch. 3) for smooth variance functions; both need a uniformity condition of the kind labelled (G5) in [Theorem 31.4.1](#), and our [Lemma 31.4.2](#) isolates the cancellation that makes such a condition plausible. The finite-sample deficiency of the plug-in covariance is quantified by Kackar and Harville (1984), whose correction underlies the Kenward–Roger adjustment of [Chapter 32](#). The complementary strategy of leaving the estimator alone and correcting the standard error is White (1980) and, for clustered data, Liang and Zeger (1986); it appears in this book as [Theorem 21.4.2](#).

What comes next. [Chapter 32](#) makes $\mathbf{V}$ the marginal covariance of a model with random effects, which supplies both a reason for a particular $\mathbf{V}(\boldsymbol{\theta})$ and better estimators of $\boldsymbol{\theta}$ than the moment estimators used here. [Chapter 33](#) applies the whole apparatus to split-plot, repeated-measures and longitudinal designs, where [Theorem 31.2.2](#) explains which classical analyses survive and which do not.

Chapter 32

Random Effects and Linear Mixed Models

Part IV treated the levels of a factor as chosen: five nitrogen rates, three machines, the treatments the experimenter cared about. Many factors are not like that. The twelve laboratories in a proficiency study, the eleven firms in a panel, the patients in a trial and the classrooms in a school district are a *sample* of levels, and the question is not how laboratory 3 compares with laboratory 7 but how much laboratories vary. Declaring such a factor random changes three things at once. The parameters of interest become variances. The individual levels are *predicted* rather than estimated, and the prediction is shrunk towards the overall mean. And the covariance of the response stops being $\sigma^2\mathbf{I}$: observations sharing a level are correlated, which is what Part VII is about. This chapter develops the model that results, the best linear unbiased predictor and Henderson's equations that compute it, restricted maximum likelihood, and what inference survives when the covariance itself has been estimated from the same data.

What you need. Chapter 6 (projections and generalized least squares, Definition 6.9.1, Theorem 6.9.3), Chapter 7 (the Gauss–Markov and Aitken theorems, Theorem 7.2.1 and Corollary 7.2.3; maximum likelihood, Theorem 7.3.1; the conjugate posterior, Theorem 7.6.2), Chapter 4 (distributions of quadratic forms, Theorem 4.3.2 and Theorem 4.4.2), Chapter 9 (expected mean squares, Theorem 9.6.1 and Exercise (B1)), Chapter 14 (best linear unbiased prediction, Theorem 14.2.8, resting on the best linear predictor Theorem 2.5.2 of Chapter 2), Section 15.1 (the one-way layout and the first look at random effects, Definition 15.1.1) and Chapter 16 (nested and crossed layouts, Theorem 16.5.1). From Part V, Section 21.3 (weighted least squares with estimated weights) and Section 23.3 (the parametric bootstrap, Proposition 23.3.3); from Part VI, Chapter 27 (ridge and empirical Bayes, Theorem 27.2.2 and Proposition 27.5.4) and Chapter 29 (AIC and BIC, Definition 29.2.2). The generalized least squares theory of Chapter 31 is used throughout.

32.0.1 Roadmap

- Random effects
- The linear mixed model
- Prediction: BLUP and Henderson's equations
- Maximum likelihood and REML
- Inference when the covariance is estimated

- [Bayesian thread III: mixed models as hierarchical models](#)
- [Summary and notes](#)

32.1 Random effects

A one-way layout ([Definition 15.1.1](#)) has g groups and g group means. In Part IV those means were the object of the study: the five nitrogen rates were chosen, and every conclusion was about them. [Section 15.1](#) previewed the other possibility and left it here; this section carries the preview through. Consider a study of a different shape. A reference material with a known lead content is sent to twelve accredited laboratories, each of which analyses four aliquots of it. Nobody cares whether laboratory 3 reads higher than laboratory 7. The question is how much accredited laboratories disagree with one another, because that number, and not the twelve particular deviations, is what a client using an unnamed laboratory faces. The twelve are a sample from a population of laboratories, and the conclusion must reach the population.

32.1.1 When a factor is random

The test, met first in [Section 15.1](#), is about the *scope of the conclusion*. If the levels in the data exhaust the levels you want to talk about, the factor is fixed; if they are a sample and the conclusion should extend to levels you did not observe, it is random. Doses, treatments, varieties and the two arms of a trial are almost always fixed; laboratories, batches of reagent, subjects, litters, classrooms and interviewers are usually random. Three things change when a factor is declared random.

- (1) **The parameters change.** The g group effects are replaced by a single number, their variance. A study with $g = 12$ laboratories estimates one variance, not twelve means, and its precision is governed by g , not by the total number of observations.
- (2) **Estimation becomes prediction.** The realized effect of laboratory 3 is a random variable, not a parameter. Asking for its value is a prediction problem, and [Section 32.3](#) shows that the best answer is not the laboratory's own average.
- (3) **The covariance changes.** Two aliquots analysed by the same laboratory share its effect, so they are correlated. The model is no longer a linear model with $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, and this is the reason the chapter belongs to Part VII.

Warning. A variance is estimated from the number of *levels*, not the number of observations. With $g = 3$ laboratories there are two degrees of freedom for the between-laboratory variance, and any interval for it is nearly useless however many aliquots each laboratory analyses. A treated and a control arm should never be a random factor: two levels carry no information about a population of levels, and there is no population. When a factor has few levels but its levels really are a sample, the honest options are to report the fixed-effect analysis alongside, or to supply prior information ([Section 32.6](#)).

32.1.2 The one-way random effects model

Definition 32.1.1 — One-way random effects model

Let $g \geq 2$ groups contain $n_k \geq 1$ observations each, with $n = \sum_k n_k$. The **one-way random effects model** is

$$Y_{kj} = \mu + a_k + \varepsilon_{kj}, \quad k = 1, \dots, g, \quad j = 1, \dots, n_k,$$

where μ is an unknown constant, the **group effects** $a_1, \dots, a_g$ are uncorrelated with mean 0 and variance $\sigma_a^2 \geq 0$, the errors ε_{kj} are uncorrelated with mean 0 and variance $\sigma^2 > 0$, and the two sets are uncorrelated with each other. In matrix form, with $\mathbf{Z}$ the $n \times g$ matrix of group indicators,

$$\mathbf{Y} = \mu \mathbf{1} + \mathbf{Z}\mathbf{a} + \boldsymbol{\varepsilon}.$$

The **normal** one-way random effects model adds $\mathbf{a} \sim N_g(\mathbf{0}, \sigma_a^2 \mathbf{I})$ independent of $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$. The layout is **balanced** if $n_1 = \dots = n_g = m$. The pair (σ_a^2, σ^2) are the **variance components**.

The model has three parameters whatever g is, where Definition 15.1.1 had $g + 1$. That is the economy of random effects, and also their risk: it is bought by assuming that the g effects are an uncorrelated sample from one distribution.

Proposition 32.1.1 — The one-way random effects model

In Definition 32.1.1, write $\gamma = \sigma_a^2/\sigma^2$ and let $\mathbf{M}$ be the projection onto $\mathcal{C}(\mathbf{Z})$, which replaces each entry by its group mean.

- (a) $E(\mathbf{Y}) = \mu \mathbf{1}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{Z}\mathbf{Z}^\top$, a block diagonal matrix whose k th block is $\sigma^2 \mathbf{I}_{n_k} + \sigma_a^2 \mathbf{1}\mathbf{1}^\top$.
- (b) (*Intraclass correlation.*) Observations in different groups are uncorrelated, and two observations in the same group have correlation

$$\rho = \frac{\sigma_a^2}{\sigma_a^2 + \sigma^2} = \frac{\gamma}{1 + \gamma} \in [0, 1).$$

- (c) (*Moment estimates.*) Let MSB and MSE be the between and within mean squares of the one-way analysis of variance, on $g - 1$ and $n - g$ degrees of freedom. Then $E(\text{MSE}) = \sigma^2$ and $E(\text{MSB}) = \sigma^2 + m_0 \sigma_a^2$ with

$$m_0 = \frac{1}{g-1} \left(n - \frac{\sum_k n_k^2}{n} \right), \quad (32.1.1)$$

which equals m in a balanced layout. Hence $\hat{\sigma}^2 = \text{MSE}$ and $\hat{\sigma}_a^2 = (\text{MSB} - \text{MSE})/m_0$ are unbiased.

- (d) (*Distributions, balanced and normal.*) If the layout is balanced and the model is normal, then with $\lambda_1 = \sigma^2 + m\sigma_a^2$,

$$\frac{\text{SSB}}{\lambda_1} \sim \chi^2(g-1) \quad \text{independently of} \quad \frac{\text{SSE}}{\sigma^2} \sim \chi^2(n-g),$$

and therefore $\text{MSB}/\text{MSE} \sim (1 + m\gamma) F(g-1, n-g)$.

Proof.

- (a) By [Theorem 2.2.1](#) applied to $\mathbf{Y} = \mu\mathbf{1} + [\mathbf{Z}, \mathbf{I}](\mathbf{a}^\top, \boldsymbol{\varepsilon}^\top)^\top$, $\text{Cov}(\mathbf{Y}) = \mathbf{Z}(\sigma_a^2\mathbf{I}_g)\mathbf{Z}^\top + \sigma^2\mathbf{I}$. The matrix $\mathbf{ZZ}^\top$ has (i, i') entry 1 when observations i and i' are in the same group and 0 otherwise, which is the block form stated.
- (b) Read off (a): the covariance of two distinct observations in group k is σ_a^2 and each variance is $\sigma_a^2 + \sigma^2$.
- (c) The two sums of squares are $\text{SSB} = \mathbf{Y}^\top(\mathbf{M} - \mathbf{P}_1)\mathbf{Y}$ and $\text{SSE} = \mathbf{Y}^\top(\mathbf{I} - \mathbf{M})\mathbf{Y}$, where $\mathbf{P}_1 = n^{-1}\mathbf{1}\mathbf{1}^\top$. Both projections annihilate $\mathbf{1}$, so [Theorem 2.3.1](#) leaves only the trace term. Since the columns of $\mathbf{ZZ}^\top$ lie in $\mathcal{C}(\mathbf{Z})$ we have $\mathbf{MZZ}^\top = \mathbf{ZZ}^\top$, and $(\mathbf{I} - \mathbf{M})\mathbf{Z} = \mathbf{0}$, so

$$\text{E}(\text{SSE}) = \sigma^2 \text{tr}(\mathbf{I} - \mathbf{M}) = \sigma^2(n - g),$$

while $\text{tr}(\mathbf{ZZ}^\top) = n$ and $\text{tr}(\mathbf{P}_1\mathbf{ZZ}^\top) = n^{-1}\mathbf{1}^\top\mathbf{ZZ}^\top\mathbf{1} = n^{-1}\sum_k n_k^2$ give

$$\text{E}(\text{SSB}) = \sigma^2(g - 1) + \sigma_a^2\left(n - \frac{\sum_k n_k^2}{n}\right).$$

Dividing by the degrees of freedom gives the two expectations, and unbiasedness of the two estimates follows by linearity. In a balanced layout $n = gm$ and $\sum_k n_k^2 = gm^2$, so $m_0 = \{gm - gm^2/(gm)\}/(g - 1) = m(g - 1)/(g - 1) = m$.

- (d) In the balanced case $\mathbf{ZZ}^\top = m\mathbf{M}$, so by (a)

$$\text{Cov}(\mathbf{Y}) = \lambda_1\mathbf{M} + \sigma^2(\mathbf{I} - \mathbf{M}), \quad (32.1.2)$$

a spectral decomposition into the two orthogonal pieces $\mathcal{C}(\mathbf{Z})$ and $\mathcal{C}(\mathbf{Z})^\perp$. Write $\boldsymbol{\Sigma} = \text{Cov}(\mathbf{Y})$. For the between projection $\mathbf{A} = \mathbf{M} - \mathbf{P}_1$, which satisfies $\mathbf{AM} = \mathbf{A}$ and $\mathbf{A}(\mathbf{I} - \mathbf{M}) = \mathbf{0}$, we get $\mathbf{A}\boldsymbol{\Sigma} = \lambda_1\mathbf{A}$, so $\mathbf{A}\boldsymbol{\Sigma}/\lambda_1 = \mathbf{A}$ is idempotent of rank $g - 1$ and $\mathbf{A}\boldsymbol{\mu} = \mathbf{0}$; [Theorem 4.3.2](#) gives $\text{SSB}/\lambda_1 \sim \chi^2(g - 1)$. For $\mathbf{B} = \mathbf{I} - \mathbf{M}$ we get $\mathbf{B}\boldsymbol{\Sigma} = \sigma^2\mathbf{B}$ and $\text{SSE}/\sigma^2 \sim \chi^2(n - g)$ in the same way. Independence follows from [Theorem 4.4.2](#), because $\mathbf{A}\boldsymbol{\Sigma}\mathbf{B} = \lambda_1\mathbf{AB} = \mathbf{0}$. The ratio of the two mean squares is then (λ_1/σ^2) times an $F(g - 1, n - g)$ variable, and $\lambda_1/\sigma^2 = 1 + m\gamma$. ■

Part (c) is [Exercise \(B1\)](#) carried to unbalanced layouts, and part (d) is the fact that makes the balanced case so pleasant: the same F ratio that tests equality of fixed group means tests $\sigma_a^2 = 0$, and it does more, because its distribution is known for every γ , not only at $\gamma = 0$. Inverting it gives an exact interval.

Corollary 32.1.2 — Exact interval for the variance ratio

In the balanced normal one-way random effects model, let $F = \text{MSB}/\text{MSE}$ and let F_q denote the q quantile of $F(g - 1, n - g)$. Then

$$\left[\frac{1}{m} \left(\frac{F}{F_{1-\alpha/2}} - 1 \right), \frac{1}{m} \left(\frac{F}{F_{\alpha/2}} - 1 \right) \right] \quad (32.1.3)$$

is an exact $1 - \alpha$ confidence interval for $\gamma = \sigma_a^2/\sigma^2$, and applying the increasing map $\gamma \mapsto \gamma/(1 + \gamma)$ to its endpoints gives an exact $1 - \alpha$ interval for the intraclass correlation

ρ . Endpoints below zero are replaced by zero.

Proof. By [Proposition 32.1.1\(d\)](#), $F/(1 + m\gamma) \sim F(g - 1, n - g)$, so $\Pr\{F_{\alpha/2} \leq F/(1 + m\gamma) \leq F_{1-\alpha/2}\} = 1 - \alpha$ whatever γ is. Solving the two inequalities for γ gives [Eq. 32.1.3](#), an event of the same probability. A strictly increasing transformation of both endpoints keeps the coverage, and $\rho = \gamma/(1 + \gamma)$ is strictly increasing on $[0, \infty)$. Truncating at zero can only raise the coverage, since $\gamma \geq 0$. ■

Notice what [Eq. 32.1.3](#) is not: it is an interval for the *ratio*. No exact interval of this kind exists for σ_a^2 alone, because $\hat{\sigma}_a^2$ is a difference of two mean squares with different scale factors and its distribution depends on both components separately. Approximate intervals for σ_a^2 come either from Satterthwaite's method ([Section 32.5](#)) or from the profile likelihood ([Section 32.4](#)).

Example. (A laboratory proficiency study)

Twelve laboratories each analyse four aliquots of one homogeneous batch of soil for lead, in mg/kg; the data are simulated so that the truth is known, with $\mu = 2.50$, $\sigma_a = 0.20$ and $\sigma = 0.25$, so that the population intraclass correlation is 0.390. The analysis of variance gives $MSB = 0.2166$ on 11 degrees of freedom and $MSE = 0.0620$ on 36, so

$$\hat{\sigma}^2 = 0.0620, \quad \hat{\sigma}_a^2 = \frac{0.2166 - 0.0620}{4} = 0.0386,$$

that is, a within-laboratory (repeatability) standard deviation of 0.249 and a between-laboratory standard deviation of 0.197. The estimated intraclass correlation is 0.384: about two fifths of the variation in a single measurement is attributable to which laboratory made it.

The F ratio is 3.49, and [Eq. 32.1.3](#) gives $\gamma \in (0.118, 2.439)$, that is $\rho \in (0.105, 0.709)$. Twelve laboratories and 48 measurements pin the intraclass correlation down only to a factor of seven. That is not a defect of the method; it is what 11 degrees of freedom buy.

```
import numpy as np
from scipy import stats

g, m = 12, 4                                # laboratories, aliquots each
n = g * m
mu, sigma_a, sigma = 2.50, 0.20, 0.25       # the values used to simulate

rng = np.random.default_rng(20320048)
lab_effect = sigma_a * rng.standard_normal(g)
y = mu + np.repeat(lab_effect, m) + sigma * rng.standard_normal(n)

Y = y.reshape(g, m)                         # one row per laboratory
lab_mean, grand_mean = Y.mean(axis=1), Y.mean()

ss_between = m * np.sum((lab_mean - grand_mean) ** 2)
ss_within = np.sum((Y - lab_mean[:, None]) ** 2)
ms_between = ss_between / (g - 1)
ms_within = ss_within / (n - g)
```

Figure 32.1.1: (a) The proficiency study: four aliquots in each of twelve laboratories, with the laboratory means (short bars) and the overall mean (dashed). (b) The probability that the moment estimate $\hat{\sigma}_a^2$ is negative, as a function of the intraclass correlation, for $g = 6, 12$ and 25 laboratories with $m = 4$ aliquots each.

```
sigma2_hat = ms_within                                # E(MS within) = sigma^2
sigma2_a_hat = (ms_between - ms_within) / m          # E(MS between) = sigma^2 + m
              sigma_a^2
icc_hat = sigma2_a_hat / (sigma2_a_hat + sigma2_hat)

print(f"MS between {ms_between:.4f}    MS within {ms_within:.4f}")
print(f"sigma^2 {sigma2_hat:.4f}    sigma_a^2 {sigma2_a_hat:.4f}    ICC {icc_hat:.3f}"
      )
```

```
f_obs = ms_between / ms_within                        # ~ (1 + m gamma) F(g-1, n-g)
gamma_lo = (f_obs / stats.f.ppf(0.975, g - 1, n - g) - 1) / m
gamma_hi = (f_obs / stats.f.ppf(0.025, g - 1, n - g) - 1) / m
icc_lo, icc_hi = gamma_lo / (1 + gamma_lo), gamma_hi / (1 + gamma_hi)

print(f"F = {f_obs:.2f};  gamma in ({gamma_lo:.3f}, {gamma_hi:.3f})")
print(f"intraclass correlation in ({icc_lo:.3f}, {icc_hi:.3f})")
```

32.1.3 Negative estimates

Nothing in [Proposition 32.1.1\(c\)](#) prevents MSB from falling below MSE, and then the unbiased estimate of a variance is negative. In the balanced normal model the probability is exactly

$$\Pr(\hat{\sigma}_a^2 < 0) = \Pr\left(F(g-1, n-g) < \frac{1}{1+m\gamma}\right), \quad (32.1.4)$$

by [Proposition 32.1.1\(d\)](#). Panel (b) of [Figure 32.1.1](#) plots it. With $g = 6$ laboratories, $m = 4$ aliquots and an intraclass correlation of 0.05 the probability is 0.453; when σ_a^2 is exactly zero it is 0.554, a little over one half, because $\Pr\{F(5, 18) < 1\}$ exceeds $1/2$. In the study of [Example \(A laboratory proficiency study\)](#), with twelve laboratories and a true correlation of 0.390, it is only 0.0143.

A negative estimate is not a computational failure but evidence, and there are three honest responses.

- (1) **Report it.** A meta-analysis that averages several studies needs the unbiased value, negative or not; truncating every study at zero and then averaging biases the average upwards.
- (2) **Truncate.** The estimate $\max(\hat{\sigma}_a^2, 0)$ is biased upwards but has smaller mean squared error for every parameter value ([Exercise \(C1\)](#)). Maximum likelihood and REML produce it automatically, since they maximize over $\sigma_a^2 \geq 0$.
- (3) **Question the model.** A persistently negative estimate can mean that observations within a group are genuinely *negatively* correlated, as happens when the group is a fixed resource the observations compete for: litter-mates sharing a food supply, or plots sharing water. The matrix $\sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{Z}\mathbf{Z}^\top$ with $\sigma_a^2 < 0$ is a perfectly good covariance as long as $\sigma^2 + m\sigma_a^2 > 0$, and fitting it as such is more honest than pretending a variance was estimated.

32.1.4 Unbalanced layouts, and beyond one way

Part (c) is the simplest instance of a general recipe: write down quadratic forms, equate them to their expectations, and solve. Henderson (1953) organized this into three methods for unbalanced layouts, of which the one used here is the first. The recipe always gives unbiased estimates and never needs normality, but it is not unique — different quadratic forms give different estimates, and in unbalanced layouts none of them is best. That is why [Section 32.4](#) turns to the likelihood.

The same calculation runs through any balanced layout. In the two-stage nested design of [Exercise \(C1\)](#), with a levels of A , b of B within each and m observations per cell, that exercise gave $E MS_{B(A)} = \sigma^2 + m\sigma_B^2$, so the inner component is estimated by $(MS_{B(A)} - MSE)/m$. Taking A random too, with effects of variance σ_A^2 , MS_A is bm times the sample variance of a independent group means of variance $\sigma_A^2 + \sigma_B^2/b + \sigma^2/(bm)$, so $E MS_A = \sigma^2 + m\sigma_B^2 + bm\sigma_A^2$ and the outer component is estimated by $(MS_A - MS_{B(A)})/(bm)$. Every mean square in a balanced layout turns out to estimate σ^2 plus a positive combination of the components nested inside its factor, a fact [Chapter 33](#) establishes and uses to read a split-plot analysis off its strata.

Finally, a warning about the grand mean. In the fixed-effects model $\text{Var}(\bar{Y}) = \sigma^2/n$, so precision is bought with observations. Here it is different: [Exercise \(C2\)](#) showed that

$$\text{Var}(\bar{Y}) = \frac{\sigma^2}{n} + \sigma_a^2 \frac{\sum_k n_k^2}{n^2} \xrightarrow{\text{balanced}} \frac{\sigma^2 + m\sigma_a^2}{gm},$$

which for fixed g is bounded below by σ_a^2/g however large m grows. Measuring the same twelve laboratories a thousand times each does not improve the estimate of the population mean beyond a limit set by $g = 12$. This is the commonest way of overstating precision in clustered data, and [Chapter 33](#) quantifies it as the design effect.

32.1.5 Exercises

32.1.5.1 A. Check your understanding

Exercise A1.

For each study, say whether the named factor is better treated as fixed or random, and

what the corresponding target of inference is. (a) Four fertilizer formulations compared on a research farm. (b) Twenty operators sampled from a factory's workforce, each measuring the same set of parts. (c) The two arms of a randomized trial. (d) Thirty schools sampled from a district, in a study of a teaching method. (e) Three furnaces, the only three the plant owns, in a study of their temperature uniformity.

32.1.5.2 B. Practice

Exercise B1.

Verify [Eq. 32.1.1](#) directly from the group means: show that $E\{\sum_k n_k (\bar{Y}_k - \bar{Y})^2\} = \sigma^2(g-1) + \sigma_a^2(n - \sum_k n_k^2/n)$ by computing $\text{Var}(\bar{Y}_k)$, $\text{Var}(\bar{Y})$ and $\text{Cov}(\bar{Y}_k, \bar{Y})$. Confirm that $m_0 = m$ when the layout is balanced, and that $m_0 \leq (n - \min_k n_k)/(g-1)$ in general.

Solution. $\bar{Y}_k = \mu + a_k + \bar{\varepsilon}_k$ has variance $\sigma_a^2 + \sigma^2/n_k$, and $\bar{Y} = \mu + \sum_k n_k a_k/n + \bar{\varepsilon}$ has variance $\sigma_a^2 \sum_k n_k^2/n^2 + \sigma^2/n$. Also $\text{Cov}(\bar{Y}_k, \bar{Y}) = \sigma_a^2 n_k/n + \sigma^2/n$. Hence $E(\bar{Y}_k - \bar{Y})^2 = \sigma_a^2(1 - 2n_k/n + \sum_j n_j^2/n^2) + \sigma^2(1/n_k - 1/n)$. Multiplying by n_k and summing, the σ^2 terms give $\sigma^2(g-1)$ and the σ_a^2 terms give $\sigma_a^2(n - 2\sum_k n_k^2/n + \sum_k n_k^2/n) = \sigma_a^2(n - \sum_k n_k^2/n)$. For the balanced case, $n = gm$ and $\sum_k n_k^2 = gm^2$, so $m_0 = (gm - m)/(g-1) = m$. In general $\sum_k n_k^2 \geq n \min_k n_k$, whence $m_0 \leq (n - \min_k n_k)/(g-1)$.

Exercise B2.

In the balanced normal model, use [Proposition 32.1.1\(d\)](#) to show that

$$\text{Var}(\hat{\sigma}_a^2) = \frac{2}{m^2} \left\{ \frac{(\sigma^2 + m\sigma_a^2)^2}{g-1} + \frac{\sigma^4}{n-g} \right\}.$$

With σ^2 and σ_a^2 fixed and $n = gm$ held constant, is the variance smaller with many small groups or few large ones?

Solution. MSB and MSE are independent, with $\text{Var}(\text{MSB}) = \lambda_1^2 \cdot 2/(g-1)$ and $\text{Var}(\text{MSE}) = \sigma^4 \cdot 2/(n-g)$, because a $\chi^2(r)$ variable has variance $2r$. The formula follows from $\hat{\sigma}_a^2 = (\text{MSB} - \text{MSE})/m$. Neither extreme answers the second question. With $g-1 \approx n/m$ and $n-g \approx n$,

$$\text{Var}(\hat{\sigma}_a^2) \approx \frac{2}{n} \left(\frac{\sigma^4}{m} + 2\sigma^2\sigma_a^2 + m\sigma_a^4 + \frac{\sigma^4}{m^2} \right),$$

a decreasing part plus an increasing one, minimized near $m = \sigma^2/\sigma_a^2$, that is at $m\gamma \approx 1$: many small groups win only once each group is large enough for MSB to stand clear of MSE. In the exact formula with $n = 100$ and $\sigma^2 = 1$, at $\sigma_a^2 = 0.01$ the variance is 0.0206, 0.0056, 0.0029 and 0.0017 for $m = 2, 5, 10, 25$ — four groups of twenty-five beat fifty pairs by a factor of twelve — while at $\sigma_a^2 = 1$ it is 0.1018, 0.1526 and 0.2691 for $m = 2, 5, 10$, and the small groups win. The extreme $m = 1$ always fails, because then the two components are not separately identified.

Exercise B3.

Using [Eq. 32.1.4](#), compute $\Pr(\hat{\sigma}_a^2 < 0)$ when $\sigma_a^2 = 0$, for $(g, m) = (5, 4)$ and $(g, m) =$

(25, 4). Explain why the probability does not tend to 0 as $g \rightarrow \infty$ with $\sigma_a^2 = 0$ fixed, and why it does tend to 0 for any fixed $\sigma_a^2 > 0$.

32.1.5.3 C. Going deeper

Exercise C1.

Let T be any estimator of $\sigma_a^2 \geq 0$ and $T^+ = \max(T, 0)$. Show that $E(T^+ - \sigma_a^2)^2 \leq E(T - \sigma_a^2)^2$, with strict inequality whenever $\Pr(T < 0) > 0$. Deduce that the truncated moment estimator dominates the unbiased one in mean squared error, and explain why this does not make the unbiased estimator useless.

Solution. On $\{T \geq 0\}$ the two estimators agree. On $\{T < 0\}$, $|T^+ - \sigma_a^2| = \sigma_a^2 \leq \sigma_a^2 - T = |T - \sigma_a^2|$, because $T < 0$ and $\sigma_a^2 \geq 0$; the inequality is strict unless $T = 0$ almost surely on that event. Taking expectations gives the claim. The unbiased estimator remains useful because unbiasedness is preserved by averaging: combining K independent studies, $K^{-1} \sum_k T_k$ is unbiased and consistent, whereas $K^{-1} \sum_k T_k^+$ is biased upwards by an amount that does not vanish as K grows.

Exercise C2.

Consider a balanced two-way layout with a levels of A , b levels of B , m observations per cell, and *all* effects random: $Y_{ijk} = \mu + \alpha_i + \beta_j + (\alpha\beta)_{ij} + \varepsilon_{ijk}$ with the four sets uncorrelated and variances $\sigma_A^2, \sigma_B^2, \sigma_{AB}^2, \sigma^2$. Using the Kronecker projections of [Section 16.3](#) and [Theorem 2.3.1](#), show that

$$E \text{MS}_A = \sigma^2 + m\sigma_{AB}^2 + bm\sigma_A^2, \quad E \text{MS}_{AB} = \sigma^2 + m\sigma_{AB}^2.$$

Which ratio tests $\sigma_A^2 = 0$? Contrast this with the fixed-effects analysis, where MS_A/MSE is the right ratio.

32.2 The linear mixed model

The one-way random effects model of [Section 32.1](#) has one random factor and no regressors. Real studies have both: a trial has fixed treatment effects and random patient effects, a panel has fixed economic regressors and random firm effects, a field trial has fixed varieties and random blocks. The model that holds them all keeps the usual fixed part and adds a second design matrix whose coefficients are random.

32.2.1 Definition and the marginal model

Definition 32.2.1 — Linear mixed model

Let $\mathbf{X}$ be a known $n \times p$ matrix and $\mathbf{Z}$ a known $n \times q$ matrix. The **linear mixed model** is

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon}, \quad (32.2.1)$$

where $\boldsymbol{\beta} \in \mathbb{R}^p$ is a vector of unknown constants, the **fixed effects**; $\mathbf{u}$ is a $q \times 1$ random vector, the **random effects**, with $E(\mathbf{u}) = \mathbf{0}$ and $\text{Cov}(\mathbf{u}) = \mathbf{G}$; $\boldsymbol{\varepsilon}$ is an $n \times 1$ random vector with $E(\boldsymbol{\varepsilon}) = \mathbf{0}$ and $\text{Cov}(\boldsymbol{\varepsilon}) = \mathbf{R}$; and $\text{Cov}(\mathbf{u}, \boldsymbol{\varepsilon}) = \mathbf{0}$. The matrices $\mathbf{G}$ and $\mathbf{R}$ are nonnegative definite and are known functions $\mathbf{G}(\boldsymbol{\theta})$, $\mathbf{R}(\boldsymbol{\theta})$ of an unknown parameter $\boldsymbol{\theta}$, the **variance components**. The **normal** linear mixed model adds $\mathbf{u} \sim N_q(\mathbf{0}, \mathbf{G})$ independent of $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \mathbf{R})$.

Taking expectations in Eq. 32.2.1 and using Theorem 2.2.1 gives the **marginal model**

$$E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}, \quad \text{Cov}(\mathbf{Y}) = \mathbf{V}(\boldsymbol{\theta}) = \mathbf{Z}\mathbf{G}\mathbf{Z}^\top + \mathbf{R}, \quad (32.2.2)$$

and under normality $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$. Everything Part VII knows about the general Gauss–Markov model applies to Eq. 32.2.2 at once. What distinguishes a mixed model from the general model of Chapter 31 is that $\mathbf{V}$ is not an arbitrary unknown matrix but is built from a handful of parameters by a structure the experiment dictates. An $n \times n$ covariance has $n(n+1)/2$ free entries; a random intercept model has two.

Remark (Conditional and marginal). Two means live in Eq. 32.2.1. Conditionally on the random effects, $E(\mathbf{Y} \mid \mathbf{u}) = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$: this is what the subjects in *this* sample did. Marginally, $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$: this is what the population does on average. In the linear model with normal errors the two lead to the same $\boldsymbol{\beta}$, and the distinction looks pedantic. It is not pedantic at all once the link is nonlinear. For a generalized linear mixed model (Chapter 40) the marginal mean of $g^{-1}(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u})$ is not $g^{-1}(\mathbf{X}\boldsymbol{\beta})$, and the subject-specific and population-averaged coefficients genuinely differ (Proposition 40.1.1).

Warning. The pair $(\mathbf{G}, \mathbf{R})$ is not identified by the marginal distribution; only $\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}^\top + \mathbf{R}$ is. In the one-way layout with $\mathbf{Z}$ the group indicators, the model with $\mathbf{G} = \sigma_a^2 \mathbf{I}_g$, $\mathbf{R} = \sigma^2 \mathbf{I}_n$ has exactly the same marginal distribution as the model with no random effects at all and $\mathbf{R} = \sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{Z}\mathbf{Z}^\top$, that is, with equicorrelated errors within groups. Every likelihood-based procedure in this chapter estimates $\mathbf{V}$, so it cannot tell the two apart. What the random-effects reading adds is a *target for prediction*: the vector $\mathbf{u}$, whose realized value Section 32.3 predicts. It also adds a constraint, since $\sigma_a^2 \geq 0$ forces a nonnegative intraclass correlation, whereas the equicorrelated model allows ρ down to $-1/(m-1)$.

32.2.2 Inverting the covariance matrix

Formulas in this chapter are written with $\mathbf{V}^{-1}$, which is $n \times n$. When q is much smaller than n , or when the data fall into independent clusters, $\mathbf{V}^{-1}$ never has to be formed.

Proposition 32.2.1 — The inverse and determinant of $\mathbf{V}$

Let $\mathbf{R}$ and $\mathbf{G}$ be positive definite in Definition 32.2.1. Then $\mathbf{V}$ is positive definite, and

$$\mathbf{V}^{-1} = \mathbf{R}^{-1} - \mathbf{R}^{-1}\mathbf{Z}(\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1}\mathbf{Z})^{-1}\mathbf{Z}^\top \mathbf{R}^{-1}, \quad (32.2.3)$$

$$\det \mathbf{V} = \det \mathbf{R} \det \mathbf{G} \det(\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1}\mathbf{Z}). \quad (32.2.4)$$

If in addition the observations fall into g clusters with $\mathbf{R} = \bigoplus_k \mathbf{R}_k$, $\mathbf{Z} = \bigoplus_k \mathbf{Z}_k$ and $\mathbf{G} = \bigoplus_k \mathbf{G}_k$ block diagonal, the last saying that different clusters' random effects are independent, then $\mathbf{V} = \bigoplus_k (\mathbf{Z}_k \mathbf{G}_k \mathbf{Z}_k^\top + \mathbf{R}_k)$ is block diagonal too, and everything decomposes cluster by cluster.

Proof. $\mathbf{V} = \mathbf{R} + \mathbf{Z}\mathbf{G}\mathbf{Z}^\top$ is a sum of a positive definite and a nonnegative definite matrix, hence positive definite. Now use [Theorem 1.6.5](#) with the roles $\mathbf{B} \mapsto \mathbf{R}$, $\mathbf{U} \mapsto \mathbf{Z}$, $\mathbf{C} \mapsto \mathbf{G}$ and (in the notation of that theorem) the second outer factor also $\mathbf{Z}$. The matrix $\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1}\mathbf{Z}$ is positive definite, hence nonsingular, so the hypothesis holds and [Eq. 1.6.6](#) is [Eq. 32.2.3](#). For the determinant, [Theorem 1.6.3\(c\)](#) with $\mathbf{B} = \mathbf{R}$, $\mathbf{U} = \mathbf{Z}\mathbf{G}$ and the second factor $\mathbf{Z}^\top$ gives

$$\begin{aligned} \det \mathbf{V} &= \det \mathbf{R} \det(\mathbf{I}_g + \mathbf{Z}^\top \mathbf{R}^{-1}\mathbf{Z}\mathbf{G}) \\ &= \det \mathbf{R} \det \mathbf{G} \det(\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1}\mathbf{Z}), \end{aligned}$$

the last step by $\det(\mathbf{I}_g + \mathbf{A}\mathbf{G}) = \det(\mathbf{G}^{-1} + \mathbf{A}) \det \mathbf{G}$. The block diagonal statement is immediate from the definitions. ■

A study of $n = 10^5$ pupils in $q = 500$ schools therefore needs a 500×500 inverse, not a $10^5 \times 10^5$ one, and if $\mathbf{R}$ is diagonal the rest of [Eq. 32.2.3](#) costs nothing. [Section 32.3](#) improves on this again.

32.2.3 Four examples

Example. (Random intercepts)

Observations are grouped, group k contributing n_k of them. Take $\mathbf{Z}$ to be the $n \times g$ matrix of group indicators, $\mathbf{G} = \sigma_a^2 \mathbf{I}_g$ and $\mathbf{R} = \sigma^2 \mathbf{I}_n$, so that $\mathbf{V} = \sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{Z}\mathbf{Z}^\top$ as in [Proposition 32.1.1\(a\)](#). The fixed part $\mathbf{X}\boldsymbol{\beta}$ may hold anything: an intercept alone, recovering [Definition 32.1.1](#); a treatment indicator constant within group, as in a cluster-randomized trial; or regressors that vary within a group, as in a longitudinal study. Each group's block of $\mathbf{V}$ is $\sigma^2 \mathbf{I}_{n_k} + \sigma_a^2 \mathbf{1}\mathbf{1}^\top$, the **compound symmetric** or **equicorrelated** form.

Example. (Random intercepts and slopes)

Subject i is measured at times $t_{i1}, \dots, t_{in_i}$, and each subject has its own intercept and its own slope in time:

$$Y_{ij} = \mathbf{x}_{(ij)}^\top \boldsymbol{\beta} + u_{0i} + u_{1i} t_{ij} + \varepsilon_{ij}, \quad \begin{pmatrix} u_{0i} \\ u_{1i} \end{pmatrix} \sim N_2(\mathbf{0}, \mathbf{D}),$$

independently across subjects, with $\boldsymbol{\varepsilon}_i \sim N_{n_i}(\mathbf{0}, \sigma^2 \mathbf{I})$. Here $\mathbf{Z}_i = [\mathbf{1}, \mathbf{t}_i]$, $\mathbf{G} = \mathbf{I}_N \otimes \mathbf{D}$ for N subjects, and subject i 's covariance block is $\mathbf{V}_i = \mathbf{Z}_i \mathbf{D} \mathbf{Z}_i^\top + \sigma^2 \mathbf{I}$, with entries

$$\text{Cov}(Y_{ij}, Y_{ij'}) = d_{11} + d_{12}(t_{ij} + t_{ij'}) + d_{22}t_{ij}t_{ij'} + \sigma^2 \mathbf{1}\{j = j'\}.$$

Two features deserve notice. The variance of a response is quadratic in time, so a random slope model necessarily says that subjects spread apart, or, if $d_{12} < 0$, first converge and then spread. And the correlation between two occasions depends on both times, not only on their separation: it is not stationary. Whether this is the right shape is a modelling question that [Chapter 33](#) takes up.

Example. (Nested and crossed random factors)

With pupils inside classrooms inside schools, write $\mathbf{Z} = [\mathbf{Z}_{\text{sch}}, \mathbf{Z}_{\text{cls}}]$ and $\mathbf{G} = \begin{pmatrix} \sigma_s^2 \mathbf{I} & \mathbf{0} \\ \mathbf{0} & \sigma_c^2 \mathbf{I} \end{pmatrix}$. Because every classroom belongs to exactly one school, $\mathbf{V}$ is block diagonal by school, and the analysis splits school by school; this is the covariance behind [Exercise \(C1\)](#). With subjects responding to items, each subject seeing every item, the two factors are **crossed**: $\mathbf{Z}_{\text{sub}}$ and $\mathbf{Z}_{\text{item}}$ generate overlapping patterns and $\mathbf{V}$ has no block diagonal form at all. Nothing in the theory changes, but the computation does, and crossed random effects are the reason modern software stores $\mathbf{Z}$ sparsely.

Example. (Grunfeld's panel with a random firm effect)

[Section 6.6](#) fitted gross investment on market value and capital stock for 11 US firms over 20 years, once with a separate intercept per firm (the within estimator) and once with a single intercept. The mixed model puts the firm effect in between: $\mathbf{X}$ holds the intercept, value and capital, $\mathbf{Z}$ holds the firm indicators, $\mathbf{G} = \sigma_f^2 \mathbf{I}_{11}$ and $\mathbf{R} = \sigma^2 \mathbf{I}$. Fitted by restricted maximum likelihood ([Section 32.4](#)), it gives $\hat{\sigma}^2 = 2527.6$ and $\hat{\sigma}_f^2 = 6740.9$, a firm standard deviation of 82.1 and an intraclass correlation of 0.727: most of the variation in investment is between firms. The coefficients are 0.1094 for value and 0.3082 for capital, against 0.1101 and 0.3100 for the within estimator and 0.1145 and 0.2275 with a single intercept. The mixed estimate has landed essentially on the within estimate, and [Section 32.3](#) explains why: with 20 years per firm, the weight the model gives to between-firm comparisons is $1 - 0.9816$, less than two per cent.

```
import numpy as np
import pandas as pd
import statsmodels.api as sm

df = sm.datasets.grunfeld.load_pandas().data.sort_values(["firm", "year"])
firms = df["firm"].unique()
y = df["invest"].to_numpy()
X = np.column_stack([np.ones(len(y)), df["value"], df["capital"]])
blocks = [np.where(df["firm"].to_numpy() == f)[0] for f in firms]
n, p, g = len(y), X.shape[1], len(firms)
print(f"{n} observations, {g} firms, {n // g} years each")
```

32.2.4 When ordinary least squares is already best

The marginal model [Eq. 32.2.2](#) is a general Gauss–Markov model, so [Corollary 7.2.3](#) says the best linear unbiased estimator of an estimable $\lambda^\top \beta$ is the generalized least squares estimate built from $\mathbf{V}^{-1}$, and [Theorem 31.2.2](#) says that ordinary least squares achieves this for every $\mathbf{y}$ exactly when $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$. Mixed models supply the standard examples on both sides of that line.

Example. (Cluster-constant regressors)

Take [Example \(Random intercepts\)](#) with a balanced layout, $n_k = m$, and suppose every column of $\mathbf{X}$ is constant within groups, so that $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$. By [Eq. 32.1.2](#), $\mathbf{V} = \lambda_1 \mathbf{M} + \sigma^2(\mathbf{I} - \mathbf{M})$ with $\mathbf{M}$ the projection onto $\mathcal{C}(\mathbf{Z})$, so $\mathbf{V}\mathbf{X} = \lambda_1 \mathbf{X}$ and $\mathcal{C}(\mathbf{V}\mathbf{X}) = \mathcal{C}(\mathbf{X})$. Ordinary least squares is therefore the best linear unbiased estimator, whatever the variance components are, and the analysis of a balanced cluster-randomized trial can be carried out on the cluster means without loss. The covariance of the estimate is *not* $\sigma^2(\mathbf{X}^\top \mathbf{X})^{-1}$, however: it is $\lambda_1(\mathbf{X}^\top \mathbf{X})^{-1}$, larger by the factor $1 + m\gamma$. Getting the point estimate right and the standard error wrong is the classic error in clustered data.

Example. (Regressors that vary within a cluster)

Keep the same $\mathbf{V}$, but let $\mathbf{X} = [\mathbf{1}, \mathbf{x}]$ with $\mathbf{x}$ varying within groups. Decomposing $\mathbf{x}$ into its between and within parts,

$$\mathbf{V}\mathbf{x} = \lambda_1 \mathbf{M}\mathbf{x} + \sigma^2(\mathbf{I} - \mathbf{M})\mathbf{x},$$

which lies in $\mathcal{C}(\mathbf{X})$ only if one of the two parts vanishes or $\lambda_1 = \sigma^2$. Ordinary least squares is then not efficient, and the reason is visible: generalized least squares downweights the between-group part of $\mathbf{x}$ by $\sigma^2/\lambda_1 = 1/(1 + m\gamma)$ relative to the within-group part, because between-group comparisons carry the extra variance σ_a^2 . The mixed estimate is a compromise between the within estimator of [Section 6.6](#), which uses only $(\mathbf{I} - \mathbf{M})\mathbf{x}$, and the between estimator, which uses only $\mathbf{M}\mathbf{x}$; as $m\gamma \rightarrow \infty$ the weight on the between part goes to zero. [Example \(Grunfeld’s panel with a random firm effect\)](#) is that limit in practice.

Idea. A random effect is a statement about *where the information is*. Declaring the grouping factor random says that comparisons between groups carry an extra variance σ_a^2 and should be downweighted accordingly, but not discarded. Fixed effects for the groups discard them entirely; ignoring the grouping keeps them at full weight. The mixed model interpolates, and the interpolation weight is estimated from the data.

The remaining difficulty is that $\mathbf{V}$ depends on the unknown θ . The estimator actually used is the feasible generalized least squares estimator of [Definition 31.4.1](#),

$$\hat{\beta}(\hat{\theta}) = (\mathbf{X}^\top \mathbf{V}(\hat{\theta})^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}(\hat{\theta})^{-1} \mathbf{Y}, \quad (32.2.5)$$

with $\hat{\theta}$ from [Section 32.4](#). [Theorem 31.4.1](#) gives the large-sample justification; [Section 32.5](#) asks what it costs in small samples, and the answer is: more than people usually allow for.

32.2.5 Exercises

32.2.5.1 A. Check your understanding

Exercise A1.

A study measures 3 subjects on 2 occasions each, with a random subject effect of variance σ_s^2 and independent errors of variance σ^2 . Write $\mathbf{Z}$, $\mathbf{G}$, $\mathbf{R}$ and $\mathbf{V}$ explicitly as 6×6 or 6×3 matrices, and check Eq. 32.2.3 numerically for $\sigma_s^2 = 2$, $\sigma^2 = 1$.

Exercise A2.

A colleague argues that in Example (Random intercepts) the two variance components cannot be separated, since raising σ_a^2 and lowering σ^2 both change the diagonal of $\mathbf{V}$ in the same direction. Is the argument right? What happens if every group has $n_k = 1$?

32.2.5.2 B. Practice

Exercise B1.

Specialize Eq. 32.2.3 to Example (Random intercepts) with group sizes n_k , and show that the k th block of $\mathbf{V}^{-1}$ is

$$\frac{1}{\sigma^2} \left(\mathbf{I}_{n_k} - \frac{\sigma_a^2}{\sigma^2 + n_k \sigma_a^2} \mathbf{1}\mathbf{1}^\top \right).$$

Deduce that the generalized least squares criterion is $\sigma^{-2} \sum_k \{ \sum_j r_{kj}^2 - w_k n_k \bar{r}_k^2 \}$ with $w_k = n_k \sigma_a^2 / (\sigma^2 + n_k \sigma_a^2)$, and interpret w_k .

Solution. Each block of $\mathbf{V}$ is $\sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{1}\mathbf{1}^\top$; apply Eq. 1.6.7 with $\mathbf{B} = \sigma^2 \mathbf{I}$, $\mathbf{u} = \mathbf{v} = \sigma_a \mathbf{1}$: the correction is $\sigma_a^2 \sigma^{-4} \mathbf{1}\mathbf{1}^\top / (1 + n_k \sigma_a^2 / \sigma^2)$, which rearranges to the stated form. The criterion $\mathbf{r}^\top \mathbf{V}^{-1} \mathbf{r}$ then equals $\sigma^{-2} \sum_k \{ \sum_j r_{kj}^2 - n_k \bar{r}_k^2 w_k \}$ after writing $\mathbf{1}^\top \mathbf{r}_k = n_k \bar{r}_k$. The weight $w_k \in (0, 1)$ increases with n_k : the model removes a fraction w_k of the group's mean residual from the criterion, because that part of the residual is explained by the group's random effect rather than counted against the fit.

Exercise B2.

Let $\mathbf{V} = \lambda_1 \mathbf{M} + \sigma^2 (\mathbf{I} - \mathbf{M})$ as in Eq. 32.1.2. Show that $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ holds if and only if $\mathcal{C}(\mathbf{X})$ decomposes as $(\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{Z})) \oplus (\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{Z})^\perp)$, that is, iff $\mathbf{M}$ maps $\mathcal{C}(\mathbf{X})$ into itself. Give an $\mathbf{X}$ with both between and within columns for which ordinary least squares is best.

Solution. $\mathbf{V}\mathbf{X} = \sigma^2 \mathbf{X} + (\lambda_1 - \sigma^2) \mathbf{M}\mathbf{X}$, so (assuming $\lambda_1 \neq \sigma^2$) $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ iff $\mathcal{C}(\mathbf{M}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, that is, $\mathbf{M}$ maps $\mathcal{C}(\mathbf{X})$ into itself. A subspace invariant under an orthogonal projection splits into its parts inside $\mathcal{C}(\mathbf{Z})$ and inside $\mathcal{C}(\mathbf{Z})^\perp$. Example: $\mathbf{X} = [\mathbf{1}, \mathbf{x}]$ with $\mathbf{1}$ constant within groups and $\mathbf{x}$ having zero mean *within every group*, so

$\mathbf{M}\mathbf{x} = \mathbf{0}$; then $\mathbf{MX} = [\mathbf{1}, \mathbf{0}]$ lies in $\mathcal{C}(\mathbf{X})$. A balanced split-plot design has exactly this structure, which is why [Chapter 33](#) can analyse it stratum by stratum.

32.2.5.3 C. Going deeper

Exercise C1.

Two crossed random factors with a and b levels and one observation per cell give $\mathbf{Z} = [\mathbf{Z}_A, \mathbf{Z}_B]$ with $n = ab$, $q = a + b$. Show that $\text{rank}(\mathbf{Z}) = a + b - 1$, so $\mathbf{Z}^\top \mathbf{Z}$ is singular, and explain why this causes no difficulty for [Eq. 32.2.2](#) but would if one tried to treat $\mathbf{u}$ as a parameter vector to be estimated. Compute $\mathbf{V}$ and show it is *not* block diagonal under any ordering of the observations when $a, b \geq 2$.

32.3 Prediction: BLUP and Henderson's equations

The twelve laboratories of [Example \(A laboratory proficiency study\)](#) each have a realized effect a_k . It is not a parameter but the value taken by a random variable, so asking for it is a prediction problem. The answer is worth the trouble of setting the problem up properly: it is not the laboratory's own average, and the difference is shrinkage of exactly the kind [Chapter 27](#) studied, arriving here without anybody having decided to be biased.

32.3.1 The criterion

Definition 32.3.1 — Mixed functions and linear predictors

In [Definition 32.2.1](#), a **mixed function** is a random variable $\tau = \boldsymbol{\lambda}^\top \boldsymbol{\beta} + \mathbf{c}^\top \mathbf{u}$ with known $\boldsymbol{\lambda} \in \mathbb{R}^p$ and $\mathbf{c} \in \mathbb{R}^q$. A **linear predictor** of τ is a statistic $t = \mathbf{a}^\top \mathbf{Y} + b$ with known $\mathbf{a}$ and b ; it is **unbiased** if $E(t) = E(\tau)$ for every $\boldsymbol{\beta} \in \mathbb{R}^p$. The **best linear unbiased predictor** (BLUP) of τ is the unbiased linear predictor minimizing the prediction mean squared error $E(t - \tau)^2$.

Since $E(t) = \mathbf{a}^\top \mathbf{X}\boldsymbol{\beta} + b$ and $E(\tau) = \boldsymbol{\lambda}^\top \boldsymbol{\beta}$, unbiasedness for every $\boldsymbol{\beta}$ forces $b = 0$ and $\mathbf{X}^\top \mathbf{a} = \boldsymbol{\lambda}$. So an unbiased linear predictor exists exactly when $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$, that is, when $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ is estimable in the sense of [Definition 8.2.1](#); the random part $\mathbf{c}^\top \mathbf{u}$ places no restriction at all, because its mean is zero whatever $\mathbf{c}$ is. Note also that the criterion averages over $\mathbf{u}$ as well as over $\boldsymbol{\epsilon}$. This is the decision that makes the problem solvable, and the warning in the next subsection says what it costs.

The problem has already been solved. [Theorem 14.2.8](#) of [Section 14.2](#) predicted a new response $y_0 = \mathbf{x}_0^\top \boldsymbol{\beta} + e_0$ whose error was correlated with the training errors, and $\mathbf{c}^\top \mathbf{u}$ is exactly such an e_0 . What follows is that theorem in mixed-model notation; its proof is the substitution, plus the uniqueness and the decomposition (c) that [Chapter 14](#) did not need.

Theorem 32.3.1 — Best linear unbiased prediction

In [Definition 32.2.1](#) let $\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}^\top + \mathbf{R}$ be positive definite and let $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$. Put

$$\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Y}, \quad \hat{\mathbf{u}} = \mathbf{G}\mathbf{Z}^\top \mathbf{V}^{-1} (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}). \quad (32.3.1)$$

- (a) The BLUP of $\tau = \boldsymbol{\lambda}^\top \boldsymbol{\beta} + \mathbf{c}^\top \mathbf{u}$ is $\hat{\tau} = \boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} + \mathbf{c}^\top \hat{\mathbf{u}}$. It does not depend on which generalized inverse is used, and it is the unique minimizer.
- (b) Its prediction error variance is

$$\mathbb{E}(\hat{\tau} - \tau)^2 = \mathbf{c}^\top (\mathbf{G} - \mathbf{G}\mathbf{Z}^\top \mathbf{V}^{-1} \mathbf{Z}\mathbf{G}) \mathbf{c} + \mathbf{d}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{d}, \quad (32.3.2)$$

where $\mathbf{d} = \boldsymbol{\lambda} - \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Z}\mathbf{G}\mathbf{c}$.

- (c) If $\boldsymbol{\beta}$ were known, the best linear predictor of τ would be $\boldsymbol{\lambda}^\top \boldsymbol{\beta} + \mathbf{c}^\top \mathbf{G}\mathbf{Z}^\top \mathbf{V}^{-1} (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$, with prediction error variance the first term of [Eq. 32.3.2](#). The second term is the price of estimating $\boldsymbol{\beta}$.

Proof. Apply [Theorem 14.2.8](#) to $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + (\mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon})$, whose error vector has covariance $\mathbf{V}$, with $\sigma^2 = 1$, $y_0 = \tau$, $\mathbf{x}_0 = \boldsymbol{\lambda}$ and $\mathbf{e}_0 = \mathbf{c}^\top \mathbf{u}$. Since $\text{Cov}(\mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon}, \mathbf{u}) = \mathbf{Z}\mathbf{G}$, the two covariance inputs of that theorem are

$$\mathbf{v}_0 = \text{Cov}(\mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon}, \mathbf{c}^\top \mathbf{u}) = \mathbf{Z}\mathbf{G}\mathbf{c} =: \mathbf{s}, \quad v_{00} = \text{Var}(\mathbf{c}^\top \mathbf{u}) = \mathbf{c}^\top \mathbf{G}\mathbf{c},$$

and its hypothesis $\mathbf{x}_0 \in \mathcal{C}(\mathbf{X}^\top)$ is our $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$. So [Eq. 14.2.3](#) reads $\hat{\tau} = \boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} + \mathbf{c}^\top \mathbf{G}\mathbf{Z}^\top \mathbf{V}^{-1} (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}) = \boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} + \mathbf{c}^\top \hat{\mathbf{u}}$, and its mean squared error is [Eq. 32.3.2](#), because the vector called $\mathbf{c}$ there is $\mathbf{x}_0 - \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{v}_0 = \boldsymbol{\lambda} - \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Z}\mathbf{G}\mathbf{c} = \mathbf{d}$ here. That is (a) and (b) apart from the two uniqueness claims.

For those, recall that an unbiased linear predictor is $t = \mathbf{a}^\top \mathbf{Y}$ with $\mathbf{X}^\top \mathbf{a} = \boldsymbol{\lambda}$, and that $t - \tau$ then has mean zero, so

$$\mathbb{E}(t - \tau)^2 = \text{Var}(\mathbf{a}^\top \mathbf{Y} - \mathbf{c}^\top \mathbf{u}) = \mathbf{a}^\top \mathbf{V} \mathbf{a} - 2\mathbf{a}^\top \mathbf{s} + \mathbf{c}^\top \mathbf{G}\mathbf{c}.$$

The last term does not involve $\mathbf{a}$ and $\mathbf{V}$ is positive definite, so this is a strictly convex function of $\mathbf{a}$ on the affine set $\{\mathbf{a} : \mathbf{X}^\top \mathbf{a} = \boldsymbol{\lambda}\}$, non-empty because $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$, and a strictly convex function has at most one minimizer on a convex set. So $\mathbf{a}$, and with it $\hat{\tau}$, is unique, by an argument that nowhere asks $\mathbf{X}^\top$ to have full row rank. The generalized inverse then cancels, as one can also see directly: $\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{X}(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Y}$ is the projection of $\mathbf{Y}$ onto $\mathcal{C}(\mathbf{X})$ in the $\mathbf{V}^{-1}$ inner product ([Definition 6.9.1](#)), and both $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} = \mathbf{r}^\top \mathbf{X}\hat{\boldsymbol{\beta}}$, for $\mathbf{r}$ with $\boldsymbol{\lambda} = \mathbf{X}^\top \mathbf{r}$, and $\hat{\mathbf{u}}$ involve $\hat{\boldsymbol{\beta}}$ only through $\mathbf{X}\hat{\boldsymbol{\beta}}$.

For (c), with $\boldsymbol{\beta}$ known the problem is unconstrained prediction of $\mathbf{c}^\top \mathbf{u}$ from $\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}$, whose solution is the best linear predictor of [Theorem 2.5.2](#): $\text{Cov}(\mathbf{c}^\top \mathbf{u}, \mathbf{Y}) \mathbf{V}^{-1} (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$, with error variance $\mathbf{c}^\top \mathbf{G}\mathbf{c} - \mathbf{s}^\top \mathbf{V}^{-1} \mathbf{s}$, which is the first term of [Eq. 32.3.2](#) because $\mathbf{s} = \mathbf{Z}\mathbf{G}\mathbf{c}$.

■

Two readings of [Eq. 32.3.1](#) are worth having. First, $\hat{\mathbf{u}}$ is the best linear predictor of $\mathbf{u}$ with $\boldsymbol{\beta}$ replaced by its generalized least squares estimate; the whole content of “BLUP” is that this substitution is optimal, not merely convenient. Second, if the model is normal then $\mathbb{E}(\mathbf{u} | \mathbf{Y}) =$

$\mathbf{GZ}^\top \mathbf{V}^{-1}(\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})$ by [Theorem 3.5.2](#), so the BLUP is the conditional mean with $\boldsymbol{\beta}$ estimated. That is the door into [Section 32.6](#).

32.3.2 Shrinkage

Specialize to the balanced one-way model of [Definition 32.1.1](#), with $\mathbf{X} = \mathbf{1}$, $\mathbf{Z}$ the group indicators, $\mathbf{G} = \sigma_a^2 \mathbf{I}_g$ and $\mathbf{R} = \sigma^2 \mathbf{I}$. By [Eq. 32.1.2](#), $\mathbf{V}^{-1} = \lambda_1^{-1} \mathbf{M} + \sigma^{-2}(\mathbf{I} - \mathbf{M})$ with $\lambda_1 = \sigma^2 + m\sigma_a^2$, and since $\mathbf{MZ} = \mathbf{Z}$ we have $\mathbf{Z}^\top \mathbf{V}^{-1} = \lambda_1^{-1} \mathbf{Z}^\top$. Also $\mathbf{1} \in \mathcal{C}(\mathbf{Z})$, so the generalized least squares estimate of μ is the ordinary mean $\bar{y}$ ([Example \(Cluster-constant regressors\)](#)). Hence

$$\hat{a}_k = \frac{m\sigma_a^2}{\sigma^2 + m\sigma_a^2} (\bar{y}_k - \bar{y}) = B (\bar{y}_k - \bar{y}), \quad B = \frac{m\gamma}{1 + m\gamma}, \quad (32.3.3)$$

with $\gamma = \sigma_a^2/\sigma^2$. The predicted group mean is $\bar{y} + B(\bar{y}_k - \bar{y})$: the group's own average pulled towards the overall average by $B \in (0, 1)$. The pull is strong when groups are small or when groups genuinely differ little, and it vanishes as either m or γ grows. Formula [Eq. 32.3.3](#) is the empirical Bayes shrinkage of [Proposition 27.5.4](#) with the prior variance supplied by the model, and it is a ridge estimate of the group effects with penalty σ^2/σ_a^2 ([Theorem 27.2.2](#)); the next subsection makes that identification exact.

Warning. Unbiasedness in [Definition 32.3.1](#) averages over $\mathbf{u}$. Conditionally on the realized effects it fails, and deliberately so: from [Eq. 32.3.3](#), $E(\hat{a}_k | a_1, \dots, a_g) = B(a_k - \bar{a})$, which is nearer zero than a_k . Predicted effects are *shrunk*, so their spread understates the spread of the true effects, and ranking groups by $\hat{a}_k$ is not the same as ranking them by a_k . A league table of hospitals or schools built from BLUPs will move small units towards the middle, which is right for predicting each unit's next observation and wrong if the question is "which unit is genuinely worst".

The shrinkage is paid for in mean squared error. Continuing the balanced one-way case, [Eq. 32.3.2](#) with $\boldsymbol{\lambda} = \mathbf{0}$ and $\mathbf{c} = \mathbf{e}_k$ gives, after substituting $\mathbf{G} - \mathbf{GZ}^\top \mathbf{V}^{-1} \mathbf{ZG} = \sigma_a^2 \sigma^2 \lambda_1^{-1} \mathbf{I}$ and $\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X} = n/\lambda_1$,

$$E(\hat{a}_k - a_k)^2 = \frac{\sigma_a^2}{\lambda_1} \left(\sigma^2 + \frac{m\sigma_a^2}{g} \right), \quad (32.3.4)$$

whereas the obvious predictor $\bar{y}_k - \bar{y}$ has mean squared error $\sigma^2(1 - 1/g)/m + \sigma_a^2/g$ ([Exercise \(B1\)](#)).

Example. (Shrinking twelve laboratories)

In [Example \(A laboratory proficiency study\)](#), $\hat{\sigma}^2 = 0.0620$ and $\hat{\sigma}_a^2 = 0.0386$ give a shrinkage factor $B = 0.714$. The laboratory deviations $\bar{y}_k - \bar{y}$ run from -0.450 to 0.250 ; the predicted effects run from -0.321 to 0.178 . Each has been pulled about 29 per cent of the way towards zero.

The gain is real. By [Eq. 32.3.4](#) the prediction error variance is 0.01336, a standard error of 0.1156, against 0.01743 for the raw deviation, a ratio of 1.30 in mean squared error. Panel (b) of [Figure 32.3.1](#) shows the comparison over the whole range of intraclass

Figure 32.3.1: (a) The twelve laboratory deviations $\bar{y}_k - \bar{y}$ and their predicted effects $\hat{a}_k$, sorted, with 95% prediction intervals from Eq. 32.3.4. (b) Mean squared error of the two predictors of a_k , as a function of the intraclass correlation, with $\sigma_a^2 + \sigma^2 = 1$, $g = 12$ and $m = 4$.

correlations: shrinkage helps most when the correlation is small, which is exactly when the raw deviations are mostly noise.

32.3.3 Henderson's mixed model equations

Formula Eq. 32.3.1 asks for $\mathbf{V}^{-1}$, an $n \times n$ inverse. Henderson (1950) found a system of size $p + q$ that delivers the generalized least squares estimate and the BLUP together, without ever forming $\mathbf{V}$.

Theorem 32.3.2 — Henderson's mixed model equations

Let $\mathbf{G}$ and $\mathbf{R}$ be positive definite and $\text{rank}(\mathbf{X}) = p$. Define

$$\mathbf{C} = \begin{pmatrix} \mathbf{X}^\top \mathbf{R}^{-1} \mathbf{X} & \mathbf{X}^\top \mathbf{R}^{-1} \mathbf{Z} \\ \mathbf{Z}^\top \mathbf{R}^{-1} \mathbf{X} & \mathbf{Z}^\top \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1} \end{pmatrix}, \quad \mathbf{h} = \begin{pmatrix} \mathbf{X}^\top \mathbf{R}^{-1} \mathbf{y} \\ \mathbf{Z}^\top \mathbf{R}^{-1} \mathbf{y} \end{pmatrix}. \quad (32.3.5)$$

- (a) $\mathbf{C}$ is positive definite, and the unique solution of $\mathbf{C}(\mathbf{b}^\top, \mathbf{v}^\top)^\top = \mathbf{h}$ is $\mathbf{b} = \hat{\boldsymbol{\beta}}$, the generalized least squares estimate, and $\mathbf{v} = \hat{\mathbf{u}}$, the BLUP of Eq. 32.3.1.
- (b) The same pair is the unique minimizer of the penalized least squares criterion

$$Q(\boldsymbol{\beta}, \mathbf{u}) = (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u})^\top \mathbf{R}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) + \mathbf{u}^\top \mathbf{G}^{-1} \mathbf{u}. \quad (32.3.6)$$

- (c) With $\mathbf{W} = \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}$, the blocks of $\mathbf{C}^{-1}$ are

$$\begin{aligned} (\mathbf{C}^{-1})_{11} &= \mathbf{W}^{-1}, & (\mathbf{C}^{-1})_{12} &= -\mathbf{W}^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Z} \mathbf{G}, \\ (\mathbf{C}^{-1})_{22} &= \mathbf{G} - \mathbf{G} \mathbf{Z}^\top \mathbf{V}^{-1} \mathbf{Z} \mathbf{G} + \mathbf{G} \mathbf{Z}^\top \mathbf{V}^{-1} \mathbf{X} \mathbf{W}^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Z} \mathbf{G}. \end{aligned}$$

Its leading block is $\text{Cov}(\hat{\boldsymbol{\beta}})$ and its trailing block is $\text{Cov}(\hat{\mathbf{u}} - \mathbf{u})$, the matrix whose quadratic forms are [Eq. 32.3.2](#).

Proof. We use repeatedly the *push-through identity*

$$(\mathbf{G}^{-1} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z})^{-1} \mathbf{Z}^{\top} \mathbf{R}^{-1} = \mathbf{G} \mathbf{Z}^{\top} \mathbf{V}^{-1}, \quad (32.3.7)$$

proved by multiplying on the right by $\mathbf{V} = \mathbf{R} + \mathbf{Z} \mathbf{G} \mathbf{Z}^{\top}$:

$$\begin{aligned} & (\mathbf{G}^{-1} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z})^{-1} (\mathbf{Z}^{\top} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z} \mathbf{G} \mathbf{Z}^{\top}) \\ &= (\mathbf{G}^{-1} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z})^{-1} (\mathbf{G}^{-1} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z}) \mathbf{G} \mathbf{Z}^{\top} \\ &= \mathbf{G} \mathbf{Z}^{\top}. \end{aligned}$$

(a) For $(\mathbf{b}^{\top}, \mathbf{v}^{\top}) \neq \mathbf{0}$,

$$(\mathbf{b}^{\top}, \mathbf{v}^{\top}) \mathbf{C} (\mathbf{b}^{\top}, \mathbf{v}^{\top})^{\top} = \|\mathbf{R}^{-1/2}(\mathbf{X}\mathbf{b} + \mathbf{Z}\mathbf{v})\|^2 + \mathbf{v}^{\top} \mathbf{G}^{-1} \mathbf{v},$$

which vanishes only if $\mathbf{v} = \mathbf{0}$ and $\mathbf{X}\mathbf{b} = \mathbf{0}$, hence only if $\mathbf{b} = \mathbf{0}$ by full column rank. So $\mathbf{C}$ is positive definite and the system has a unique solution. The second block row gives

$$\begin{aligned} \mathbf{v} &= (\mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1})^{-1} \mathbf{Z}^{\top} \mathbf{R}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}) \\ &= \mathbf{G} \mathbf{Z}^{\top} \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}) \end{aligned}$$

by [Eq. 32.3.7](#). Substituting into the first block row, and using the residual identity

$$\begin{aligned} \mathbf{y} - \mathbf{X}\mathbf{b} - \mathbf{Z}\mathbf{v} &= (\mathbf{I} - \mathbf{Z} \mathbf{G} \mathbf{Z}^{\top} \mathbf{V}^{-1}) (\mathbf{y} - \mathbf{X}\mathbf{b}) \\ &= (\mathbf{V} - \mathbf{Z} \mathbf{G} \mathbf{Z}^{\top}) \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}) \\ &= \mathbf{R} \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}), \end{aligned}$$

the first block row $\mathbf{X}^{\top} \mathbf{R}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b} - \mathbf{Z}\mathbf{v}) = \mathbf{0}$ becomes $\mathbf{X}^{\top} \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{0}$, the generalized normal equations of [Definition 6.9.1](#). Hence $\mathbf{b} = \hat{\boldsymbol{\beta}}$ and then $\mathbf{v} = \hat{\mathbf{u}}$.

(b) Q is a quadratic in $(\boldsymbol{\beta}, \mathbf{u})$ with matrix $\mathbf{C}$ and linear term $-2\mathbf{h}$, and the display in (a) shows it is strictly convex. By [Proposition 1.11.2](#) its unique minimizer solves $\mathbf{C}(\mathbf{b}^{\top}, \mathbf{v}^{\top})^{\top} = \mathbf{h}$, which is [Eq. 32.3.5](#), whose solution is $(\hat{\boldsymbol{\beta}}, \hat{\mathbf{u}})$ by part (a).

(c) Write $\mathbf{C}_{11} = \mathbf{X}^{\top} \mathbf{R}^{-1} \mathbf{X}$, $\mathbf{C}_{12} = \mathbf{X}^{\top} \mathbf{R}^{-1} \mathbf{Z}$ and $\mathbf{C}_{22} = \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z} + \mathbf{G}^{-1}$, so that by [Eq. 32.2.3](#) the Schur complement of $\mathbf{C}_{22}$ is

$$\begin{aligned} & \mathbf{C}_{11} - \mathbf{C}_{12} \mathbf{C}_{22}^{-1} \mathbf{C}_{12}^{\top} \\ &= \mathbf{X}^{\top} (\mathbf{R}^{-1} - \mathbf{R}^{-1} \mathbf{Z} (\mathbf{G}^{-1} + \mathbf{Z}^{\top} \mathbf{R}^{-1} \mathbf{Z})^{-1} \mathbf{Z}^{\top} \mathbf{R}^{-1}) \mathbf{X} \\ &= \mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{X} = \mathbf{W}. \end{aligned}$$

[Theorem 1.6.4](#) now gives $(\mathbf{C}^{-1})_{11} = \mathbf{W}^{-1}$ and $(\mathbf{C}^{-1})_{12} = -\mathbf{W}^{-1} \mathbf{C}_{12} \mathbf{C}_{22}^{-1} = -\mathbf{W}^{-1} \mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{Z} \mathbf{G}$, the last step being the transpose of [Eq. 32.3.7](#). For the trailing block,

$$\begin{aligned} (\mathbf{C}^{-1})_{22} &= \mathbf{C}_{22}^{-1} + \mathbf{C}_{22}^{-1} \mathbf{C}_{12}^{\top} \mathbf{W}^{-1} \mathbf{C}_{12} \mathbf{C}_{22}^{-1} \\ &= \mathbf{C}_{22}^{-1} + \mathbf{G} \mathbf{Z}^{\top} \mathbf{V}^{-1} \mathbf{X} \mathbf{W}^{-1} \mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{Z} \mathbf{G}, \end{aligned}$$

and $\mathbf{C}_{22}^{-1} = \mathbf{G} - \mathbf{GZ}^\top \mathbf{V}^{-1} \mathbf{ZG}$, because

$$\begin{aligned} & (\mathbf{G} - \mathbf{GZ}^\top \mathbf{V}^{-1} \mathbf{ZG})(\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1} \mathbf{Z}) \\ &= \mathbf{I} + \mathbf{GZ}^\top \mathbf{R}^{-1} \mathbf{Z} - \mathbf{GZ}^\top \mathbf{V}^{-1} (\mathbf{ZGZ}^\top + \mathbf{R}) \mathbf{R}^{-1} \mathbf{Z} = \mathbf{I}, \end{aligned}$$

using [Eq. 32.3.7](#) once more in the form $\mathbf{GZ}^\top \mathbf{V}^{-1} \mathbf{V} = \mathbf{GZ}^\top$. Finally, $\text{Cov}(\hat{\boldsymbol{\beta}}) = \mathbf{W}^{-1}$ is [Corollary 7.2.3](#), and the trailing block is [Eq. 32.3.2](#) with $\boldsymbol{\lambda} = \mathbf{0}$ read off entry by entry. ■

Idea. Henderson's system says that a mixed model is a penalized least squares problem ([Eq. 32.3.6](#)): fit the random effects as though they were free parameters, but charge $\mathbf{u}^\top \mathbf{G}^{-1} \mathbf{u}$ for using them. With $\mathbf{R} = \sigma^2 \mathbf{I}$ and $\mathbf{G} = \sigma_u^2 \mathbf{I}$ the criterion is $\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}\|^2 + \lambda \|\mathbf{u}\|^2$ with $\lambda = \sigma^2/\sigma_u^2$: ridge regression on the random-effect columns only ([Theorem 27.2.2](#)). The difference from [Chapter 27](#) is that the penalty is not chosen by cross-validation; it is estimated, because the model says what σ^2/σ_u^2 means. [Chapter 43](#) exploits the same equivalence in the other direction, writing a penalized spline as a mixed model so that its smoothing parameter can be estimated by REML ([Theorem 43.6.1](#)).

```

Two practical points close the section. First, $\mathbf{C}$ is sparse whenever $\mathbf{Z}$ is, which is always: each row of $\mathbf{Z}$ has one non-zero entry per random factor, so Eq. 32.3.5 can be solved by sparse Cholesky factorization, and a model with hundreds of thousands of random effects is routine. Second, $\mathbf{G}$ and $\mathbf{R}$ are unknown in practice and estimates are substituted; the result is called the **empirical** BLUP, and Eq. 32.3.2 is then too small, since it ignores the variability of the estimated covariance. Kackar and Harville (1984) identified the extra term, which returns in Section 32.5 as the Kenward–Roger correction and in Section 32.6 as the gap between posterior and plug-in standard errors.

32.3.4 Exercises

32.3.4.1 A. Check your understanding

Exercise A1.

In Eq. 32.3.3, what happens to B as (a) $m \rightarrow \infty$, (b) $\sigma_a^2 \rightarrow 0$, (c) $\sigma^2 \rightarrow 0$? Describe in words the predictor in each limit, and say which of the three limits makes the mixed model agree with a fixed-effects analysis.

32.3.4.2 B. Practice

Exercise B1.

Show that the predictor $\bar{Y}_k - \bar{Y}$ of a_k in the balanced one-way model has $E(\bar{Y}_k - \bar{Y} - a_k)^2 = \sigma^2(1 - 1/g)/m + \sigma_a^2/g$, and verify that Eq. 32.3.4 is smaller for every $\gamma > 0$. Where does the difference come from when γ is very small?

Solution. $\bar{Y}_k - \bar{Y} - a_k = \bar{\varepsilon}_k - \bar{\varepsilon} - \bar{a}$ with $\bar{a} = g^{-1} \sum_j a_j$. The three terms have variances σ^2/m , $\sigma^2/(gm)$ and σ_a^2/g , and $\text{Cov}(\bar{\varepsilon}_k, \bar{\varepsilon}) = \sigma^2/(gm)$, giving $\sigma^2/m - \sigma^2/(gm) + \sigma_a^2/g$ as stated. In terms of $\gamma = \sigma_a^2/\sigma^2$, Eq. 32.3.4 equals $\sigma^2\gamma(1 + m\gamma/g)/(1 + m\gamma)$ while the raw predictor's error is $\sigma^2\{(1 - 1/g)/m + \gamma/g\}$. Putting the two over the denominator $1 + m\gamma$ and cancelling, their difference is exactly

$$\frac{\sigma^2}{m} \left(1 - \frac{1}{g}\right) \frac{1}{1 + m\gamma} = \frac{\sigma^2}{m} \left(1 - \frac{1}{g}\right) (1 - B),$$

which is strictly positive for every γ . As $\gamma \rightarrow 0$ the BLUP's error tends to σ_a^2 while the raw predictor's tends to σ^2/m , which is much larger: the raw predictor pays the full measurement error even when there is nothing to predict, whereas the BLUP predicts 0 and pays only σ_a^2 .

Exercise B2.

Take $\tau = \mu + a_k$, the mean of group k in the balanced one-way model, so that $\boldsymbol{\lambda} = 1$ and $\mathbf{c} = \mathbf{e}_k$. Use [Eq. 32.3.1](#) and [Eq. 32.3.2](#) to show that the BLUP is $\bar{y} + B(\bar{y}_k - \bar{y})$ with prediction error variance $\sigma^2 B/m + (1 - B)^2 \lambda_1/n$. Show that this equals λ_1/n at $B = 0$ and σ^2/m at $B = 1$; that it is strictly below σ^2/m , the prediction error of the group's own mean; and that it is below λ_1/n as well exactly when $m\sigma_a^2 > \sigma^2(g - 2)$, so that it is no interpolation between the two — with $g = 3$, $m = 4$ and $\sigma^2 = \sigma_a^2 = 1$ it beats both.

Solution. The predictor is immediate from [Eq. 32.3.1](#). For the variance, $\mathbf{d} = 1 - \mathbf{1}^\top \mathbf{V}^{-1} \mathbf{Z} \mathbf{G} \mathbf{e}_k = 1 - m\sigma_a^2/\lambda_1 = 1 - B$, and $\mathbf{W}^- = \lambda_1/n$, so the second term of [Eq. 32.3.2](#) is $(1 - B)^2 \lambda_1/n$; the first term is $\sigma_a^2 \sigma^2/\lambda_1 = \sigma^2 B/m$ since $B = m\sigma_a^2/\lambda_1$. Setting $B = 0$ and $B = 1$ gives the two stated endpoints. For the comparisons, use $1 - B = \sigma^2/\lambda_1$ and $n = gm$ to collapse the whole expression to

$$\frac{\sigma^2}{\lambda_1} \left(\sigma_a^2 + \frac{\sigma^2}{gm} \right),$$

and note that $\sigma^2/m = (\sigma^2/\lambda_1)(\sigma_a^2 + \sigma^2/m)$, so the first comparison holds whenever $g > 1$. The second asks $\sigma^2 \sigma_a^2 gm + \sigma^4 < \lambda_1^2 = (\sigma^2 + m\sigma_a^2)^2$, which after cancelling σ^4 and dividing by $m\sigma_a^2$ is $\sigma^2 g < 2\sigma^2 + m\sigma_a^2$. In the numerical case the expression is $13/60$, below both $5/12$ and $1/4$: the quadratic in B is not an interpolation between two strategies but can beat both, and that gain is what the shrinkage buys.

Exercise B3.

Take $\mathbf{X}$ empty (no fixed effects), $\mathbf{R} = \sigma^2 \mathbf{I}$ and $\mathbf{G} = \sigma_u^2 \mathbf{I}$ in [Theorem 32.3.2](#). Show that $\hat{\mathbf{u}}$ is exactly the ridge estimate $(\mathbf{Z}^\top \mathbf{Z} + \lambda \mathbf{I})^{-1} \mathbf{Z}^\top \mathbf{y}$ with $\lambda = \sigma^2/\sigma_u^2$, and that [Eq. 32.3.2](#) becomes $\sigma_u^2 \mathbf{c}^\top (\mathbf{I} + \lambda^{-1} \mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{c}$. Compare with the mean squared error of ridge in [Theorem 27.2.2](#): which is the same quantity and which is not?

Solution. With no $\mathbf{X}$, [Eq. 32.3.5](#) reduces to $(\mathbf{Z}^\top \mathbf{Z}/\sigma^2 + \mathbf{I}/\sigma_u^2) \mathbf{v} = \mathbf{Z}^\top \mathbf{y}/\sigma^2$, that is $\mathbf{v} = (\mathbf{Z}^\top \mathbf{Z} + \lambda \mathbf{I})^{-1} \mathbf{Z}^\top \mathbf{y}$. By [Theorem 32.3.2\(c\)](#) the prediction error covariance is $\mathbf{C}^{-1} = \sigma^2 (\mathbf{Z}^\top \mathbf{Z} + \lambda \mathbf{I})^{-1} = \sigma_u^2 (\mathbf{I} + \lambda^{-1} \mathbf{Z}^\top \mathbf{Z})^{-1}$. The quantity computed here averages over $\mathbf{u}$; the mean squared error in [Theorem 27.2.2](#) is computed for a *fixed* $\boldsymbol{\beta}$ and is therefore a function of that fixed value. Averaging the ridge mean squared error over $\boldsymbol{\beta} \sim \mathbf{N}(\mathbf{0}, \sigma_u^2 \mathbf{I})$ reproduces the BLUP formula, which is the empirical Bayes reading of [Proposition 27.5.4](#).

32.3.4.3 C. Going deeper**Exercise C1.**

Show that the BLUP is invariant to reparameterization of the random effects: if $\mathbf{Z}^* = \mathbf{Z} \mathbf{T}^{-1}$ and $\mathbf{G}^* = \mathbf{T} \mathbf{G} \mathbf{T}^\top$ for a nonsingular $\mathbf{T}$, with $\mathbf{u}^* = \mathbf{T} \mathbf{u}$, then $\mathbf{V}$ is unchanged and $\hat{\mathbf{u}}^* = \mathbf{T} \hat{\mathbf{u}}$. What does this say about predicting a contrast $\mathbf{c}^\top \mathbf{u}$ directly versus predicting $\mathbf{u}$ and then forming the contrast?

Exercise C2.

Assume the normal mixed model and suppose $\boldsymbol{\beta}$ is known. Show that among *all* predictors $t(\mathbf{Y})$, linear or not, the conditional mean $E(\mathbf{c}^\top \mathbf{u} \mid \mathbf{Y})$ minimizes $E(t - \mathbf{c}^\top \mathbf{u})^2$, and that it coincides with the linear predictor of [Theorem 32.3.1\(c\)](#). Explain why the same argument does not show that $\hat{\tau}$ is optimal among all predictors when $\boldsymbol{\beta}$ is unknown.

32.4 Maximum likelihood and REML

Everything so far has treated the variance components as known. They never are. The moment estimates of [Section 32.1](#) work in balanced layouts and lose their footing in unbalanced ones, where no canonical set of quadratic forms presents itself. Under normality the likelihood has no such difficulty, but it has one defect, which this section diagnoses and repairs: maximum likelihood underestimates variance components, because it does not pay for the fixed effects it has fitted.

32.4.1 The likelihood and its profile

Under the normal linear mixed model, $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \mathbf{V})$ with $\mathbf{V} = \mathbf{V}(\boldsymbol{\theta})$, so by [Theorem 3.2.2](#)

$$\ell(\boldsymbol{\beta}, \boldsymbol{\theta}) = -\frac{1}{2} \{n \log 2\pi + \log \det \mathbf{V} + (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^\top \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})\}. \quad (32.4.1)$$

For fixed $\boldsymbol{\theta}$ only the last term involves $\boldsymbol{\beta}$, and it is the generalized least squares criterion of [Definition 6.9.1](#), minimized by $\hat{\boldsymbol{\beta}}(\boldsymbol{\theta})$. Writing

$$\mathbf{P} = \mathbf{V}^{-1} - \mathbf{V}^{-1} \mathbf{X} (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-} \mathbf{X}^\top \mathbf{V}^{-1}, \quad (32.4.2)$$

the profile log-likelihood of [Definition 7.3.1](#) is

$$\ell_P(\boldsymbol{\theta}) = -\frac{1}{2} \{n \log 2\pi + \log \det \mathbf{V} + \mathbf{y}^\top \mathbf{P} \mathbf{y}\}. \quad (32.4.3)$$

Lemma 32.4.1 — The residual operator $\mathbf{P}$

Let $\mathbf{V}$ be positive definite and $r = \text{rank}(\mathbf{X})$. The matrix $\mathbf{P}$ of [Eq. 32.4.2](#) does not depend on the choice of generalized inverse, and

- (a) $\mathbf{P}\mathbf{X} = \mathbf{0}$, $\mathbf{PVP} = \mathbf{P}$, $\mathbf{P}$ is symmetric and $\text{rank}(\mathbf{P}) = n - r$;
- (b) $\mathbf{P}\mathbf{y} = \mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})$ and $\mathbf{y}^\top \mathbf{P} \mathbf{y} = \min_{\mathbf{b}} (\mathbf{y} - \mathbf{X}\mathbf{b})^\top \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b})$;
- (c) if $\mathbf{V}$ depends smoothly on $\boldsymbol{\theta}$ and $\mathbf{V}_j = \partial \mathbf{V} / \partial \theta_j$, then $\partial \mathbf{P} / \partial \theta_j = -\mathbf{P} \mathbf{V}_j \mathbf{P}$.

Proof. Write $\mathbf{X}_* = \mathbf{V}^{-1/2} \mathbf{X}$ ([Theorem 1.7.6](#)). Then $\mathbf{P} = \mathbf{V}^{-1/2} (\mathbf{I} - \mathbf{M}_*) \mathbf{V}^{-1/2}$, where $\mathbf{M}_* = \mathbf{X}_* (\mathbf{X}_*^\top \mathbf{X}_*)^{-} \mathbf{X}_*^\top$ is the orthogonal projection onto $\mathcal{C}(\mathbf{X}_*)$, which by [Theorem 6.3.6](#) is the same for every generalized inverse and has rank r . Symmetry, $\mathbf{P}\mathbf{X} = \mathbf{V}^{-1/2} (\mathbf{I} -$

$\mathbf{M}_*)\mathbf{X}_* = \mathbf{0}$, $\mathbf{PVP} = \mathbf{V}^{-1/2}(\mathbf{I} - \mathbf{M}_*)^2\mathbf{V}^{-1/2} = \mathbf{P}$ and the rank statement follow at once, which is (a). For (b), $\mathbf{Py} = \mathbf{V}^{-1}\mathbf{y} - \mathbf{V}^{-1}\mathbf{X}\hat{\boldsymbol{\beta}}$ by the definition of $\hat{\boldsymbol{\beta}}$, and $\mathbf{y}^\top \mathbf{Py} = \|(\mathbf{I} - \mathbf{M}_*)\mathbf{V}^{-1/2}\mathbf{y}\|^2$, the squared distance from $\mathbf{V}^{-1/2}\mathbf{y}$ to $\mathcal{C}(\mathbf{X}_*)$, which is the stated minimum. Part (c) is proved after [Theorem 32.4.2](#), which supplies a shorter route. ■

32.4.2 Restricted maximum likelihood

The trouble with [Eq. 32.4.3](#) is visible in the simplest case. With $\mathbf{V} = \sigma^2\mathbf{I}$ it reduces to the profile of [Theorem 7.3.1](#), whose maximizer is $\hat{\sigma}^2 = \text{SSE}/n$, biased downwards by the factor $(n - p)/n$. The likelihood has spent p dimensions fitting $\boldsymbol{\beta}$ and then measured the spread of the data as if it had not. The repair is to compute the likelihood of a part of the data that never saw $\boldsymbol{\beta}$.

Definition 32.4.1 — Error contrasts and restricted maximum likelihood

Let $r = \text{rank}(\mathbf{X})$. An **error contrast** is a random variable $\mathbf{k}^\top \mathbf{Y}$ with $\mathbf{X}^\top \mathbf{k} = \mathbf{0}$; its distribution does not involve $\boldsymbol{\beta}$. A **maximal set** of error contrasts is $\mathbf{K}^\top \mathbf{Y}$ for an $n \times (n - r)$ matrix $\mathbf{K}$ of full column rank with $\mathcal{C}(\mathbf{K}) = \mathcal{C}(\mathbf{X})^\perp$. The **restricted** (or residual) **log-likelihood** is the log-likelihood of $\mathbf{K}^\top \mathbf{Y}$,

$$\ell_R(\boldsymbol{\theta}) = -\frac{1}{2} \left\{ (n - r) \log 2\pi + \log \det(\mathbf{K}^\top \mathbf{V} \mathbf{K}) + \mathbf{y}^\top \mathbf{K}(\mathbf{K}^\top \mathbf{V} \mathbf{K})^{-1} \mathbf{K}^\top \mathbf{y} \right\}, \quad (32.4.4)$$

and the **REML estimate** of $\boldsymbol{\theta}$ maximizes it over the parameter space.

Theorem 32.4.2 — The restricted likelihood

In [Definition 32.4.1](#), with $\mathbf{V}$ positive definite:

- (a) $\mathbf{K}^\top \mathbf{Y} \sim N_{n-r}(\mathbf{0}, \mathbf{K}^\top \mathbf{V} \mathbf{K})$ with $\mathbf{K}^\top \mathbf{V} \mathbf{K}$ positive definite, so [Eq. 32.4.4](#) is its log-likelihood.
- (b) $\mathbf{K}(\mathbf{K}^\top \mathbf{V} \mathbf{K})^{-1} \mathbf{K}^\top = \mathbf{P}$ for every admissible $\mathbf{K}$. In particular the quadratic form in [Eq. 32.4.4](#) equals $\mathbf{y}^\top \mathbf{Py}$ and does not depend on $\mathbf{K}$.
- (c) Two admissible $\mathbf{K}_1, \mathbf{K}_2$ give restricted log-likelihoods differing by a constant free of $\boldsymbol{\theta}$. Hence the REML estimate does not depend on which maximal set of error contrasts is used.
- (d) If $\text{rank}(\mathbf{X}) = p$, then for any admissible $\mathbf{K}$ with $\mathbf{K}^\top \mathbf{K} = \mathbf{I}$,

$$\det(\mathbf{K}^\top \mathbf{V} \mathbf{K}) = \frac{\det \mathbf{V} \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})}{\det(\mathbf{X}^\top \mathbf{X})}, \quad (32.4.5)$$

so that

$$\begin{aligned}\ell_R(\boldsymbol{\theta}) &= \ell_P(\boldsymbol{\theta}) + \frac{p}{2} \log 2\pi - \frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}) \\ &\quad + \frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{X}).\end{aligned}\tag{32.4.6}$$

Proof.

- (a) By [Theorem 3.3.1](#), $\mathbf{K}^\top \mathbf{Y}$ is normal with mean $\mathbf{K}^\top \mathbf{X}\boldsymbol{\beta} = \mathbf{0}$ and covariance $\mathbf{K}^\top \mathbf{V}\mathbf{K}$, which is positive definite because $\mathbf{K}$ has full column rank and $\mathbf{V}$ is positive definite. Its density is [Theorem 3.2.2](#).
- (b) Fix $\mathbf{y}$ and consider

$$\min\{\mathbf{z}^\top \mathbf{V}^{-1} \mathbf{z} : \mathbf{K}^\top \mathbf{z} = \mathbf{K}^\top \mathbf{y}\}.$$

The feasible set is $\mathbf{y} + \mathcal{C}(\mathbf{X})$: indeed $\mathbf{K}^\top(\mathbf{z} - \mathbf{y}) = \mathbf{0}$ says $\mathbf{z} - \mathbf{y} \in \mathcal{C}(\mathbf{K})^\perp = \mathcal{C}(\mathbf{X})$. So the minimum equals $\min_{\mathbf{b}} (\mathbf{y} - \mathbf{X}\mathbf{b})^\top \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{y}^\top \mathbf{P}\mathbf{y}$ by [Lemma 32.4.1\(b\)](#). On the other hand the constrained problem can be solved directly. The criterion is strictly convex, so by [Proposition 1.11.3](#) the minimizer satisfies $\mathbf{V}^{-1} \mathbf{z} = \mathbf{K}\boldsymbol{\theta}$, that is $\mathbf{z} = \mathbf{V}\mathbf{K}\boldsymbol{\theta}$; the constraint gives $\mathbf{K}^\top \mathbf{V}\mathbf{K}\boldsymbol{\theta} = \mathbf{K}^\top \mathbf{y}$, and the minimum value is $\boldsymbol{\theta}^\top \mathbf{K}^\top \mathbf{V}\mathbf{K}\boldsymbol{\theta} = \mathbf{y}^\top \mathbf{K}(\mathbf{K}^\top \mathbf{V}\mathbf{K})^{-1} \mathbf{K}^\top \mathbf{y}$. The two expressions agree for every $\mathbf{y}$, and both are quadratic forms with symmetric matrices, so the matrices coincide.

- (c) Since $\mathcal{C}(\mathbf{K}_1) = \mathcal{C}(\mathbf{K}_2)$ and both have $n - r$ columns of full rank, $\mathbf{K}_2 = \mathbf{K}_1 \mathbf{A}$ for a nonsingular $(n-r) \times (n-r)$ matrix $\mathbf{A}$. Then $\det(\mathbf{K}_2^\top \mathbf{V}\mathbf{K}_2) = (\det \mathbf{A})^2 \det(\mathbf{K}_1^\top \mathbf{V}\mathbf{K}_1)$, while the quadratic forms are equal by (b). So the two log-likelihoods differ by $-\log|\det \mathbf{A}|$, which does not involve $\boldsymbol{\theta}$.
- (d) Let $\mathbf{T} = [\mathbf{X}, \mathbf{K}]$, which is nonsingular. Because $\mathbf{X}^\top \mathbf{K} = \mathbf{0}$ and $\mathbf{K}^\top \mathbf{K} = \mathbf{I}$,

$$\det(\mathbf{T}^\top \mathbf{T}) = \det \begin{pmatrix} \mathbf{X}^\top \mathbf{X} & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{pmatrix} = \det(\mathbf{X}^\top \mathbf{X}),$$

so $(\det \mathbf{T})^2 = \det(\mathbf{X}^\top \mathbf{X})$ and $\det(\mathbf{T}^\top \mathbf{V}\mathbf{T}) = \det(\mathbf{X}^\top \mathbf{X}) \det \mathbf{V}$. Next, $\mathbf{T}^{-1}$ has rows $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top$ stacked on $\mathbf{K}^\top$, as one checks by multiplying. Hence the leading $p \times p$ block of $(\mathbf{T}^\top \mathbf{V}\mathbf{T})^{-1} = \mathbf{T}^{-1} \mathbf{V}^{-1} \mathbf{T}^{-\top}$ is $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}$. By [Theorem 1.6.4](#) that block is the inverse of the Schur complement of the trailing block $\mathbf{K}^\top \mathbf{V}\mathbf{K}$, so by [Theorem 1.6.3\(b\)](#),

$$\det(\mathbf{T}^\top \mathbf{V}\mathbf{T}) = \det(\mathbf{K}^\top \mathbf{V}\mathbf{K}) \cdot \frac{\det(\mathbf{X}^\top \mathbf{X})^2}{\det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})}.$$

Equating the two expressions for $\det(\mathbf{T}^\top \mathbf{V}\mathbf{T})$ gives [Eq. 32.4.5](#), and substituting it together with (b) into [Eq. 32.4.4](#) gives [Eq. 32.4.6](#). ■

The proof of [Lemma 32.4.1\(c\)](#) is now immediate: differentiating $\mathbf{P} = \mathbf{K}(\mathbf{K}^\top \mathbf{V}\mathbf{K})^{-1} \mathbf{K}^\top$ with $\mathbf{K}$ fixed gives $\partial \mathbf{P} / \partial \theta_j = -\mathbf{K}(\mathbf{K}^\top \mathbf{V}\mathbf{K})^{-1} \mathbf{K}^\top \mathbf{V}_j \mathbf{K}(\mathbf{K}^\top \mathbf{V}\mathbf{K})^{-1} \mathbf{K}^\top = -\mathbf{P} \mathbf{V}_j \mathbf{P}$.

Idea. REML fits $\boldsymbol{\theta}$ to the residual directions only. It is the general form of the familiar divisor $n-p$: with $\mathbf{V} = \sigma^2 \mathbf{I}$, $\text{rank}(\mathbf{X}) = p$ and an orthonormal $\mathbf{K}$ (that is $\mathbf{K}^\top \mathbf{K} = \mathbf{I}$, as in [Theorem 32.4.2\(d\)](#)), [Eq. 32.4.4](#) is the likelihood of $\mathbf{K}^\top \mathbf{Y} \sim N_{n-p}(\mathbf{0}, \sigma^2 \mathbf{I})$, maximized at $\hat{\sigma}^2 = \|\mathbf{K}^\top \mathbf{y}\|^2 / (n-p) = \text{SSE} / (n-p) = s^2$; by [Theorem 32.4.2\(c\)](#) any other admissible $\mathbf{K}$ gives the same answer. Ordinary maximum likelihood gives SSE / n . So s^2 , the estimator every earlier chapter used, was the REML estimator all along. Its bias in a genuine

mixed model is computed exactly in [Proposition 32.4.3](#).

Warning. Since $\mathbf{K}$ is determined by $\mathcal{C}(\mathbf{X})$, two models with *different fixed effects* have restricted likelihoods of different data, and comparing them is meaningless; [Section 32.5](#) makes the rule explicit. Worse, [Eq. 32.4.6](#) shows that the constant $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{X})$ is part of the definition, and software often omits it; then the reported restricted log-likelihood changes if a column of $\mathbf{X}$ is measured in thousands rather than units, by $\log|\det \mathbf{S}|$ for the rescaling matrix $\mathbf{S}$. Comparisons of covariance structures with the *same* $\mathbf{X}$ are unaffected, since the constant cancels.

32.4.3 Why maximum likelihood is biased, exactly

In the balanced one-way model both likelihoods can be maximized in closed form, and the bias can be computed rather than asserted.

Proposition 32.4.3 — Balanced one-way: ML and REML

In the balanced normal one-way random effects model, write $\lambda_1 = \sigma^2 + m\sigma_a^2$ and $\lambda_2 = \sigma^2$, and treat (λ_1, λ_2) with $\lambda_1 \geq \lambda_2 > 0$ as the parameters. Then, up to constants free of the parameters,

$$-2\ell_P = g \log \lambda_1 + (n - g) \log \lambda_2 + \frac{\text{SSB}}{\lambda_1} + \frac{\text{SSE}}{\lambda_2}, \quad (32.4.7)$$

$$-2\ell_R = (g - 1) \log \lambda_1 + (n - g) \log \lambda_2 + \frac{\text{SSB}}{\lambda_1} + \frac{\text{SSE}}{\lambda_2}. \quad (32.4.8)$$

The two criteria differ in one coefficient, but leave the interior of the parameter space at different moments.

- (a) When $\text{MSB} \geq \text{MSE}$, REML gives $\hat{\lambda}_1 = \text{MSB}$, $\hat{\lambda}_2 = \text{MSE}$, so $\hat{\sigma}^2 = \text{MSE}$ and $\hat{\sigma}_a^2 = (\text{MSB} - \text{MSE})/m$: the moment estimates of [Proposition 32.1.1\(c\)](#), which are unbiased.
- (b) When $\text{MSB} < g \text{MSE}/(g - 1)$, maximum likelihood gives $\hat{\lambda}_1 = \text{SSB}/g$, $\hat{\lambda}_2 = \text{MSE}$, so $\hat{\sigma}_{\text{ML}}^2 = \text{MSE}$ and

$$\hat{\sigma}_{a,\text{ML}}^2 = \frac{1}{m} \left(\frac{g-1}{g} \text{MSB} - \text{MSE} \right).$$

The right-hand side is the *unconstrained* maximizer whatever the data, it is non-negative exactly under the stated condition, and

$$\mathbb{E} \left\{ \frac{1}{m} \left(\frac{g-1}{g} \text{MSB} - \text{MSE} \right) \right\} - \sigma_a^2 = -\frac{\lambda_1}{gm}. \quad (32.4.9)$$

- (c) Otherwise the maximizer lies on the boundary $\lambda_1 = \lambda_2$ and the method returns $\hat{\sigma}_a^2 = 0$ with $\hat{\sigma}^2$ the pooled mean square: for REML when $\text{MSB} < \text{MSE}$, for maximum likelihood on the wider range $\text{MSB} < g \text{MSE}/(g - 1)$. Between the two thresholds the REML estimate of σ_a^2 is positive and the ML estimate is zero.

Proof. By Eq. 32.1.2, $\mathbf{V} = \lambda_1 \mathbf{M} + \lambda_2 (\mathbf{I} - \mathbf{M})$, so $\det \mathbf{V} = \lambda_1^g \lambda_2^{n-g}$ and $\mathbf{V}^{-1} = \lambda_1^{-1} \mathbf{M} + \lambda_2^{-1} (\mathbf{I} - \mathbf{M})$. Since $\mathbf{1} \in \mathcal{C}(\mathbf{Z})$, $\mathbf{V}^{-1} \mathbf{1} = \lambda_1^{-1} \mathbf{1}$, so the generalized least squares estimate of μ is $\bar{y}$ and the residual is $\mathbf{y} - \bar{y} \mathbf{1}$. Splitting it by Theorem 6.5.1 into its parts in $\mathcal{C}(\mathbf{Z}) \cap \mathbf{1}^\perp$ and $\mathcal{C}(\mathbf{Z})^\perp$,

$$\mathbf{y}^\top \mathbf{P} \mathbf{y} = (\mathbf{y} - \bar{y} \mathbf{1})^\top \mathbf{V}^{-1} (\mathbf{y} - \bar{y} \mathbf{1}) = \frac{\text{SSB}}{\lambda_1} + \frac{\text{SSE}}{\lambda_2}.$$

Substituting into Eq. 32.4.3 gives Eq. 32.4.7. For the restricted version, $\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X} = n/\lambda_1$ and $\mathbf{X}^\top \mathbf{X} = n$, so the correction in Eq. 32.4.6 is $-\frac{1}{2} \log(n/\lambda_1) + \frac{1}{2} \log n = \frac{1}{2} \log \lambda_1$, which converts the coefficient g of $\log \lambda_1$ into $g - 1$ after multiplying by -2 . That is Eq. 32.4.8.

Both right-hand sides have the form $c_1 \log \lambda_1 + S_1/\lambda_1$ plus $c_2 \log \lambda_2 + S_2/\lambda_2$, a sum of two functions of separate arguments, each strictly convex in $1/\lambda$ and minimized at $\lambda = S/c$. So without the constraint $\lambda_1 \geq \lambda_2$, REML gives $\hat{\lambda}_1 = \text{SSB}/(g - 1) = \text{MSB}$ and $\hat{\lambda}_2 = \text{SSE}/(n - g) = \text{MSE}$, while maximum likelihood gives $\hat{\lambda}_1 = \text{SSB}/g$ and the same $\hat{\lambda}_2$. These are feasible exactly when $\hat{\lambda}_1 \geq \hat{\lambda}_2$, that is when $\text{MSB} \geq \text{MSE}$ for REML and when $\text{SSB}/g = (g - 1)\text{MSB}/g \geq \text{MSE}$, i.e. $\text{MSB} \geq g \text{MSE}/(g - 1)$, for maximum likelihood. Translating back through $\sigma^2 = \lambda_2$ and $\sigma_a^2 = (\lambda_1 - \lambda_2)/m$ gives (a) and (b), except for Eq. 32.4.9. For that, use $E \text{MSB} = \lambda_1$ and $E \text{MSE} = \sigma^2$:

$$E \left\{ \frac{1}{m} \left(\frac{g-1}{g} \text{MSB} - \text{MSE} \right) \right\} = \frac{1}{m} \left(\frac{g-1}{g} \lambda_1 - \sigma^2 \right) = \sigma_a^2 - \frac{\lambda_1}{gm}.$$

For (c), suppose the unconstrained minimizer of one of the two objectives violates $\lambda_1 \geq \lambda_2$, which by the previous paragraph happens exactly on the stated range. Each objective is a sum of two terms, one in each argument, each strictly unimodal on $(0, \infty)$ and tending to $+\infty$ at both ends, so a constrained minimum exists; were it interior to $\{\lambda_1 > \lambda_2\}$ the gradient would vanish there, making it the infeasible unconstrained minimizer. Hence it lies on the boundary $\lambda_1 = \lambda_2 = \lambda$, where the objective becomes $c \log \lambda + (\text{SSB} + \text{SSE})/\lambda$ with $c = n$ for ML and $c = n - 1$ for REML, minimized at the corresponding pooled mean square. ■

The bias $-\lambda_1/(gm)$ is λ_1 divided by the total sample size: the price of the single degree of freedom used up by the grand mean, charged entirely to the between-group component. In the proficiency study, $\lambda_1 = \sigma^2 + m\sigma_a^2 = 0.25^2 + 4(0.20)^2 = 0.2225$ and $gm = 48$, so the bias is -0.0046 , which is 11.6 per cent of σ_a^2 . A simulation of 40 000 studies reproduces it to the last recorded digit. Both the formula Eq. 32.4.9 and that simulation describe the *interior* expression of Proposition 32.4.3(b); truncating it at zero, as the estimator itself does, can only raise the estimate, so the estimator's own bias is slightly smaller in modulus. Here the expression is negative in 2.0 per cent of the simulated studies and the truncated bias is -0.0045 . With p fixed effects instead of one the same calculation gives a bias of order $p/(gm)$, which is why REML matters most when the fixed-effects model is large relative to the data.

32.4.4 Score equations and algorithms

Proposition 32.4.4 — Score equations

Let $\mathbf{V}_j = \partial \mathbf{V} / \partial \theta_j$ and $\mathbf{P}$ be as in Eq. 32.4.2. Then

$$\begin{aligned}\frac{\partial \ell_P}{\partial \theta_j} &= -\frac{1}{2} \{ \text{tr}(\mathbf{V}^{-1} \mathbf{V}_j) - \mathbf{y}^\top \mathbf{P} \mathbf{V}_j \mathbf{P} \mathbf{y} \}, \\ \frac{\partial \ell_R}{\partial \theta_j} &= -\frac{1}{2} \{ \text{tr}(\mathbf{P} \mathbf{V}_j) - \mathbf{y}^\top \mathbf{P} \mathbf{V}_j \mathbf{P} \mathbf{y} \},\end{aligned}\tag{32.4.10}$$

The restricted score exceeds the profile score by $\frac{1}{2} \text{tr}\{(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{V}_j \mathbf{V}^{-1} \mathbf{X}\}$, which is nonnegative whenever $\mathbf{V}_j$ is nonnegative definite, as it is for a variance-component parameterization $\mathbf{V} = \sum_j \theta_j \mathbf{Z}_j \mathbf{Z}_j^\top$.

Proof. For the profile, $\partial \log \det \mathbf{V} / \partial \theta_j = \text{tr}(\mathbf{V}^{-1} \mathbf{V}_j)$ and $\partial(\mathbf{y}^\top \mathbf{P} \mathbf{y}) / \partial \theta_j = -\mathbf{y}^\top \mathbf{P} \mathbf{V}_j \mathbf{P} \mathbf{y}$ by Lemma 32.4.1(c). For the restricted version, write ℓ_R through Eq. 32.4.4 with a fixed $\mathbf{K}$: then $\partial \log \det(\mathbf{K}^\top \mathbf{V} \mathbf{K}) / \partial \theta_j = \text{tr}\{(\mathbf{K}^\top \mathbf{V} \mathbf{K})^{-1} \mathbf{K}^\top \mathbf{V}_j \mathbf{K}\} = \text{tr}(\mathbf{P} \mathbf{V}_j)$ by Theorem 32.4.2(b) and the cyclic property of the trace (Theorem 1.6.1), and the quadratic term differentiates as before. Subtracting, and using Eq. 32.4.2 for $\mathbf{P}$, gives the stated difference. Its value is the same for every generalized inverse, because $\mathcal{C}(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{V}_j \mathbf{V}^{-1} \mathbf{X}) \subset \mathcal{C}(\mathbf{X}^\top) = \mathcal{C}(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})$, so take the Moore–Penrose inverse, which is nonnegative definite; when $\mathbf{V}_j$ is nonnegative definite too, the difference is a trace of a product of two nonnegative definite matrices, hence nonnegative. ■

Setting Eq. 32.4.10 to zero gives equations that are not solvable in closed form outside balanced designs, and three families of algorithms are used.

Fisher scoring. The expected information for the restricted likelihood has entries $\frac{1}{2} \text{tr}(\mathbf{P} \mathbf{V}_j \mathbf{P} \mathbf{V}_k)$, so a Newton-type step costs one trace per pair of components. Convergence is fast near the maximum and unreliable far from it, and nothing keeps the iterates inside the parameter space.

Average information REML. Gilmour, Thompson and Cullis (1995) noticed that the average of the observed and expected information has entries $\frac{1}{2} \mathbf{y}^\top \mathbf{P} \mathbf{V}_j \mathbf{P} \mathbf{V}_k \mathbf{P} \mathbf{y}$, which need no traces at all. Average information REML is the workhorse of large animal-breeding and genomic analyses.

EM. Treat $\mathbf{u}$ as missing data (Dempster, Laird and Rubin, 1977). With $\mathbf{R} = \sigma^2 \mathbf{I}$ and $\mathbf{G} = \sigma_u^2 \mathbf{I}_q$, the complete-data maximum likelihood estimates are averages of squares, so the E-step and M-step give the maximum likelihood update

$$\begin{aligned}\sigma_u^{2,\text{new}} &= \frac{1}{q} \{ \|\hat{\mathbf{u}}\|^2 + \text{tr} \mathbf{S} \}, \\ \sigma^{2,\text{new}} &= \frac{1}{n} \{ \|\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}} - \mathbf{Z} \hat{\mathbf{u}}\|^2 + \text{tr}(\mathbf{Z} \mathbf{S} \mathbf{Z}^\top) \},\end{aligned}$$

because $E(\mathbf{u}^\top \mathbf{u} \mid \mathbf{y}) = \|\hat{\mathbf{u}}\|^2 + \text{tr} \mathbf{S}$ and $E(\boldsymbol{\varepsilon}^\top \boldsymbol{\varepsilon} \mid \mathbf{y}) = \|\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}} - \mathbf{Z} \hat{\mathbf{u}}\|^2 + \text{tr}(\mathbf{Z} \mathbf{S} \mathbf{Z}^\top)$, where

$$\mathbf{S} = \text{Cov}(\mathbf{u} \mid \mathbf{y}) = (\mathbf{G}^{-1} + \mathbf{Z}^\top \mathbf{R}^{-1} \mathbf{Z})^{-1} = \mathbf{G} - \mathbf{G} \mathbf{Z}^\top \mathbf{V}^{-1} \mathbf{Z} \mathbf{G}$$

is the inverse of the trailing block of $\mathbf{C}$ in Eq. 32.3.5, the matrix the push-through identity Eq. 32.3.7 was applied to. It is *not* the trailing block of $\mathbf{C}^{-1}$ in Theorem 32.3.2(c), which carries a third term because $\boldsymbol{\beta}$ has been estimated; that matrix gives an iteration maximizing neither likelihood. Each step is cheap, increases the likelihood and never leaves the parameter space; the price is slow convergence. A restricted version runs the same argument on the error contrasts.

Laird and Ware (1982) introduced this algorithm to longitudinal data analysis, and it remains the most reliable starting procedure.

Warning. One starting value is not enough. Fit the Grunfeld panel of [Example \(Grunfeld's panel with a random firm effect\)](#) with a random slope as well as a random intercept, on the logarithmic scale for the variances that keeps the iterates positive: a search begun with a negligible slope variance crawls along the boundary and stops at the random-intercept fit, with restricted log-likelihood -1176.53 against the maximum -1159.01 , a gap of 17.52 reported as successful convergence. Here thirty random starts all reach the same maximum, which is some evidence that it is the only one; but such likelihoods can also be genuinely multimodal, increasingly so as the covariance structure grows (Searle, Casella and McCulloch, 1992).

32.4.5 The proficiency study, computed

Example. (REML and ML for the twelve laboratories)

For the data of [Example \(A laboratory proficiency study\)](#), [Proposition 32.4.3](#) gives $\hat{\sigma}^2 = 0.0620$ by both methods, and

$$\hat{\sigma}_{a,\text{REML}}^2 = 0.0386, \quad \hat{\sigma}_{a,\text{ML}}^2 = 0.0341,$$

the maximum likelihood estimate being 0.883 of the restricted one, because it replaces MSB by $(g-1)\text{MSB}/g$ before subtracting MSE. The restricted log-likelihood at its maximum is -8.228 and the ordinary log-likelihood is -8.360 ; the two are not comparable, being likelihoods of 47 and 48 numbers respectively. Both agree with the general matrix formulas coded from [Eq. 32.4.3](#) and [Eq. 32.4.4](#), and with statsmodels' `MixedLM`.

[Figure 32.4.1](#) plots the two profiles against σ_a^2 , each with σ^2 maximized out: the same shape in different places, the restricted one flatter on the right, which is why REML intervals are wider. Cutting the restricted profile 1.92 units below its maximum gives $\sigma_a^2 \in (0.0086, 0.1275)$, an interval comparable to the exact one of [Corollary 32.1.2](#) and available in models where no exact interval exists.

```
import numpy as np

g, m = 12, 4
n = g * m
mu, sigma_a, sigma = 2.50, 0.20, 0.25          # the values used to simulate

rng = np.random.default_rng(20320048)
lab_effect = sigma_a * rng.standard_normal(g)
y = mu + np.repeat(lab_effect, m) + sigma * rng.standard_normal(n)

X = np.ones((n, 1))
Z = np.repeat(np.eye(g), m, axis=0)

def loglik(s2, s2a, reml=True):
    """Log-likelihood (reml=False) or restricted log-likelihood of the variances."""
    V = s2a * (Z @ Z.T) + s2 * np.eye(n)
    L = np.linalg.cholesky(V)
    Vi_X = np.linalg.solve(V, X)
    W = X.T @ Vi_X                                # X' V^{-1} X
```

Figure 32.4.1: Profile log-likelihoods of σ_a^2 for the proficiency study, with σ^2 maximized out and each curve shifted to have maximum zero. The horizontal line is 1.92 below the maximum, the cut that gives an approximate 95% interval.

```

r = y - X @ np.linalg.solve(W, Vi_X.T @ y) # GLS residual
quad = r @ np.linalg.solve(V, r)           # = y' P y
logdetV = 2 * np.sum(np.log(np.diag(L)))
out = -0.5 * (n * np.log(2 * np.pi) + logdetV + quad)
if reml:
    out += -0.5 * (np.linalg.slogdet(W)[1] - np.linalg.slogdet(X.T @ X)[1]
                  - X.shape[1] * np.log(2 * np.pi))
return out

```

```

Y = y.reshape(g, m)
lab_mean = Y.mean(axis=1)
ms_between = m * np.sum((lab_mean - Y.mean()) ** 2) / (g - 1)
ms_within = np.sum((Y - lab_mean[:, None]) ** 2) / (n - g)

reml_s2, reml_s2a = ms_within, (ms_between - ms_within) / m
ml_s2 = ms_within
ml_s2a = ((g - 1) / g * ms_between - ms_within) / m

print(f"REML  sigma^2 {reml_s2:.4f}  sigma_a^2 {reml_s2a:.4f}")
print(f"ML    sigma^2 {ml_s2:.4f}   sigma_a^2 {ml_s2a:.4f}")
print("restricted log-likelihood", round(loglik(reml_s2, reml_s2a), 4))
print("log-likelihood", round(loglik(ml_s2, ml_s2a, reml=False), 4))

```

Two hundred EM steps from a deliberately poor start reach those maximum likelihood values to nine decimal places, which is what a correct **S** buys; the trailing block of $\mathbf{C}^{-1}$ in its place converges instead to (0.0644, 0.0380), maximizing neither likelihood.

```

ZZt = Z @ Z.T
s2, s2a = 0.1, 0.1 # a deliberately poor starting value
for _ in range(200):
    V = s2a * ZZt + s2 * np.eye(n)
    Vi = np.linalg.inv(V)
    W = X.T @ Vi @ X
    beta_hat = np.linalg.solve(W, X.T @ Vi @ y)
    u_hat = s2a * Z.T @ Vi @ (y - X @ beta_hat)
    S = np.linalg.inv(np.eye(g) / s2a + Z.T @ Z / s2) # Cov(u | y), not (C^{-1})
    _22

```

```

resid = y - X @ beta_hat - Z @ u_hat
s2a = (u_hat @ u_hat + np.trace(S)) / g
s2 = (resid @ resid + np.trace(Z @ S @ Z.T)) / n

print(f"EM      sigma^2 {s2:.4f}  sigma_a^2 {s2a:.4f}")

```

32.4.6 Exercises

32.4.6.1 A. Check your understanding

Exercise A1.

Take $\mathbf{V} = \sigma^2 \mathbf{I}$ and $\text{rank}(\mathbf{X}) = p$. Show from [Eq. 32.4.6](#) that $-2\ell_R = (n - p) \log \sigma^2 + \text{SSE}/\sigma^2$ up to constants, and deduce that the REML estimate of σ^2 is s^2 . Then use [Proposition 7.3.2](#) to find which multiple of SSE has the smallest mean squared error, and show that the maximum likelihood estimator beats s^2 for some (n, p) and loses to it for others.

Solution. With $\mathbf{V} = \sigma^2 \mathbf{I}$: $\log \det \mathbf{V} = n \log \sigma^2$, $\mathbf{y}^\top \mathbf{P} \mathbf{y} = \text{SSE}/\sigma^2$ and $\det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}) = \sigma^{-2p} \det(\mathbf{X}^\top \mathbf{X})$, so $\log \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}) - \log \det(\mathbf{X}^\top \mathbf{X}) = -p \log \sigma^2$; adding this to $-2\ell_P = n \log \sigma^2 + \text{SSE}/\sigma^2$ leaves $(n - p) \log \sigma^2 + \text{SSE}/\sigma^2$. Its minimizer is $\text{SSE}/(n - p) = s^2$. By [Proposition 7.3.2](#) the best multiple of SSE is $\text{SSE}/(n - p + 2)$, which neither estimator in the question attains; writing $k = n - p$, the same proposition gives relative mean squared errors $2/k$ for s^2 and $(2k + p^2)/n^2$ for SSE/n . Multiplying out $n^2 = (k + p)^2$, the inequality $(2k + p^2)/n^2 \leq 2/k$ reduces to $k(p - 4) \leq 2p$. So maximum likelihood wins for every $p \leq 4$, whatever n , and loses once p is moderately large: with $n = 100$ and $p = 10$ it gives $(180 + 100)/100^2 = 0.0280$ against $2/90 = 0.0222$. Fitting many fixed effects and then dividing by n is the bad case, which is the case REML exists for.

Exercise A2.

A colleague reports two restricted log-likelihoods for the same model fitted to the same data, differing by 6.91, the only difference between the runs being that one measured a regressor in units and the other in thousands. Explain the discrepancy using [Eq. 32.4.6](#), and confirm the value 6.91.

32.4.6.2 B. Practice

Exercise B1.

Verify [Theorem 32.4.2\(b\)](#) directly in the simplest case: $n = 3$, $\mathbf{X} = \mathbf{1}_3$, $\mathbf{V} = \text{diag}(v_1, v_2, v_3)$. Choose a basis $\mathbf{K}$ of $\mathbf{1}^\perp$, compute $\mathbf{K}(\mathbf{K}^\top \mathbf{V} \mathbf{K})^{-1} \mathbf{K}^\top$ and $\mathbf{P}$, and check they agree. Then change $\mathbf{K}$ to a different basis and confirm that $\det(\mathbf{K}^\top \mathbf{V} \mathbf{K})$ changes by a factor free of $\mathbf{V}$.

Exercise B2.

Two groups of sizes n_1, n_2 have independent normal responses with a common mean and

variances σ^2 and $c\sigma^2$ with c known. Write down ℓ_P and ℓ_R for σ^2 , find both maximizers, and confirm that REML divides by $n_1 + n_2 - 1$ and ML by $n_1 + n_2$.

Exercise B3.

Specialize the score equations [Eq. 32.4.10](#) of [Proposition 32.4.4](#) to the balanced one-way model with $\boldsymbol{\theta} = (\lambda_1, \lambda_2)$, for which $\mathbf{V} = \lambda_1 \mathbf{M} + \lambda_2 (\mathbf{I} - \mathbf{M})$, $\mathbf{V}_1 = \mathbf{M}$ and $\mathbf{V}_2 = \mathbf{I} - \mathbf{M}$. Show that the restricted score equations are $\hat{\lambda}_1 = \text{MSB}$ and $\hat{\lambda}_2 = \text{MSE}$, recovering [Proposition 32.4.3\(a\)](#) without any optimization.

Solution. Here $\mathbf{P} = \lambda_1^{-1}(\mathbf{M} - \mathbf{P}_1) + \lambda_2^{-1}(\mathbf{I} - \mathbf{M})$, so $\mathbf{P}\mathbf{V}_1 = \lambda_1^{-1}(\mathbf{M} - \mathbf{P}_1)$ with trace $(g-1)/\lambda_1$, and $\mathbf{y}^\top \mathbf{P}\mathbf{V}_1 \mathbf{P}\mathbf{y} = \text{SSB}/\lambda_1^2$. The first equation in [Eq. 32.4.10](#) therefore reads $(g-1)/\lambda_1 = \text{SSB}/\lambda_1^2$, that is $\lambda_1 = \text{SSB}/(g-1)$. Likewise $\text{tr}(\mathbf{P}\mathbf{V}_2) = (n-g)/\lambda_2$ and $\mathbf{y}^\top \mathbf{P}\mathbf{V}_2 \mathbf{P}\mathbf{y} = \text{SSE}/\lambda_2^2$, giving $\lambda_2 = \text{SSE}/(n-g)$. Using $\mathbf{V}^{-1}$ instead of $\mathbf{P}$ replaces $g-1$ by $\text{tr}(\mathbf{V}^{-1}\mathbf{V}_1)\lambda_1 = g$, which is the ML answer.

32.4.6.3 C. Going deeper

Exercise C1.

Show that

$$\int \exp\{\ell(\boldsymbol{\beta}, \boldsymbol{\theta})\} d\boldsymbol{\beta} = \exp\{\ell_R(\boldsymbol{\theta})\}$$

when $\text{rank}(\mathbf{X}) = p$ and the constant $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{X})$ is dropped from [Eq. 32.4.4](#). (Hint: complete the square in $\boldsymbol{\beta}$ and use the normal integral.) This identity is the subject of [Section 32.6](#); state in words what it says about REML.

Solution. Write $(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^\top \mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) = \mathbf{y}^\top \mathbf{P}\mathbf{y} + (\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})^\top \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})$, which is the decomposition behind [Lemma 32.4.1\(b\)](#). Integrating $\exp\{-\frac{1}{2}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})^\top \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})\}$ over $\mathbb{R}^p$ gives $(2\pi)^{p/2} \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1/2}$. Hence

$$\begin{aligned} \int e^\ell d\boldsymbol{\beta} &= e^{-\frac{1}{2}\{n \log 2\pi + \log \det \mathbf{V} + \mathbf{y}^\top \mathbf{P}\mathbf{y}\}} \\ &\quad \times (2\pi)^{p/2} \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1/2}, \end{aligned}$$

whose logarithm is [Eq. 32.4.6](#) without the $\det(\mathbf{X}^\top \mathbf{X})$ term. In words: the restricted likelihood is the marginal likelihood of $\boldsymbol{\theta}$ after integrating the fixed effects out with a flat prior.

32.5 Inference when the covariance is estimated

Every formula in the last three sections assumed $\mathbf{V}$ known. In practice $\mathbf{V}(\hat{\boldsymbol{\theta}})$ is substituted, and the substitution is not free: it perturbs the estimator, it perturbs the estimator's covariance, and it destroys the exactness of the F and t distributions Part III relied on. Testing a variance

component raises a separate difficulty, since the null value sits on the boundary of the parameter space and the usual chi-square calibration is simply wrong; [Theorem 32.5.2](#) computes the right one exactly in the balanced layout.

32.5.1 Feasible generalized least squares is still unbiased

Proposition 32.5.1 — Fixed-effect inference with an estimated covariance

Consider the normal linear mixed model with $\text{rank}(\mathbf{X}) = p$, and write

$$\hat{\boldsymbol{\beta}}(\boldsymbol{\theta}) = (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{Y}$$

for the generalized least squares estimator.

- (a) (*Unbiasedness.*) Let $\hat{\boldsymbol{\theta}} = \hat{\boldsymbol{\theta}}(\mathbf{Y})$ be **translation invariant**, meaning $\hat{\boldsymbol{\theta}}(\mathbf{y} + \mathbf{X}\mathbf{b}) = \hat{\boldsymbol{\theta}}(\mathbf{y})$ for all $\mathbf{b}$, and **even**, meaning $\hat{\boldsymbol{\theta}}(-\mathbf{y}) = \hat{\boldsymbol{\theta}}(\mathbf{y})$. If $E\|\hat{\boldsymbol{\beta}}(\hat{\boldsymbol{\theta}})\| < \infty$, then $E\hat{\boldsymbol{\beta}}(\hat{\boldsymbol{\theta}}) = \boldsymbol{\beta}$. Both REML and maximum likelihood estimators of $\boldsymbol{\theta}$ have these two properties.
- (b) (*A design where everything is exact.*) Consider a balanced cluster-randomized trial: g clusters, $g/2$ assigned to each arm, m units per cluster, with a random cluster effect of variance σ_a^2 and independent errors of variance σ^2 . Let $\hat{\beta}$ be the difference of the two arms' means of cluster means, and let MS_C be the mean square between clusters within arms, on $g - 2$ degrees of freedom, and MSE the mean square within clusters. Then, with $\lambda_1 = \sigma^2 + m\sigma_a^2$, $\text{Var}(\hat{\beta}) = 4\lambda_1/(gm)$ and

$$\frac{\hat{\beta} - \beta}{\sqrt{4\text{MS}_C/(gm)}} \sim t(g - 2) \quad (32.5.1)$$

exactly. If $\text{MS}_C \geq \text{MSE}$ then MS_C is also the REML estimate of λ_1 ; otherwise the REML estimate lies on the boundary $\hat{\sigma}_a^2 = 0$, as in [Proposition 32.4.3\(c\)](#).

- (c) (*Satterthwaite's approximation.*) Let $U = \sum_i c_i \text{MS}_i > 0$, where the MS_i are independent and $\nu_i \text{MS}_i / E \text{MS}_i \sim \chi^2(\nu_i)$. The two-moment match of [Section 4.3](#), fitting $\nu U / E U \sim \chi^2(\nu)$ to the mean and variance of U , has

$$\nu = \frac{(EU)^2}{\sum_i c_i^2 (E \text{MS}_i)^2 / \nu_i}, \quad (32.5.2)$$

estimated in practice by replacing $E \text{MS}_i$ by MS_i .

The companion statement for the variance components themselves, where the null value sits on the boundary of the parameter space, is [Theorem 32.5.2](#) below.

Proof.

- (a) Write $\boldsymbol{\varepsilon} = \mathbf{Y} - \mathbf{X}\boldsymbol{\beta}$ and $\mathbf{A}(\boldsymbol{\theta}) = (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}^{-1}$, so that $\mathbf{A}(\boldsymbol{\theta})\mathbf{X} = \mathbf{I}$ and $\hat{\boldsymbol{\beta}}(\hat{\boldsymbol{\theta}}) - \boldsymbol{\beta} = \mathbf{A}(\hat{\boldsymbol{\theta}}(\mathbf{Y}))\boldsymbol{\varepsilon}$. Translation invariance gives $\hat{\boldsymbol{\theta}}(\mathbf{Y}) = \hat{\boldsymbol{\theta}}(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}) = \hat{\boldsymbol{\theta}}(\boldsymbol{\varepsilon})$, so $\hat{\boldsymbol{\beta}}(\hat{\boldsymbol{\theta}}) - \boldsymbol{\beta} = \mathbf{h}(\boldsymbol{\varepsilon})$ with $\mathbf{h}(\mathbf{e}) = \mathbf{A}(\hat{\boldsymbol{\theta}}(\mathbf{e}))\mathbf{e}$. Evenness gives $\mathbf{h}(-\mathbf{e}) = -\mathbf{h}(\mathbf{e})$, and $\boldsymbol{\varepsilon}$ has the same distribution as $-\boldsymbol{\varepsilon}$, so $E\mathbf{h}(\boldsymbol{\varepsilon}) = -E\mathbf{h}(\boldsymbol{\varepsilon})$ and the expectation is $\mathbf{0}$. This is the argument of [Theorem 21.3.1\(c\)](#) with the weights replaced by

a covariance. REML estimators are functions of $\mathbf{K}^\top \mathbf{y}$ alone, hence translation invariant, and Eq. 32.4.4 is unchanged by $\mathbf{y} \mapsto -\mathbf{y}$, hence even; the same holds for maximum likelihood, whose profile Eq. 32.4.3 depends on $\mathbf{y}$ only through $\mathbf{y}^\top \mathbf{P} \mathbf{y}$ and is translation invariant because $\mathbf{P} \mathbf{X} = \mathbf{0}$.

- (b) Both columns of $\mathbf{X} = [\mathbf{1}, \mathbf{T}]$ are constant within clusters, so by Example (Cluster-constant regressors) ordinary and generalized least squares agree and $\hat{\beta}$ is the difference of arm means of cluster means. The g cluster means $\bar{Y}_k$ are independent $N(\beta_0 + \beta T_k, \lambda_1/m)$, because $\text{Var}(\bar{Y}_k) = \sigma_a^2 + \sigma^2/m = \lambda_1/m$. Applying the exact normal theory of Chapter 11 to these g independent normal observations gives $\hat{\beta} \sim N(\beta, 4\lambda_1/(gm))$, since the two arm means are independent with variance $\lambda_1/(m \cdot g/2)$ each. The quadratic form $m \sum_k (\bar{Y}_k - \bar{Y}_{\text{arm}(k)})^2 / \lambda_1 = (g-2) \text{MS}_C / \lambda_1$ is the residual sum of squares of a two-group model fitted to the g cluster means, so it is $\chi^2(g-2)$ and is independent of the fitted arm means by Theorem 4.4.1. Dividing gives Eq. 32.5.1.

For the REML claim, the error contrast space $\mathcal{C}(\mathbf{X})^\perp$ decomposes orthogonally into $\mathcal{C}(\mathbf{Z}) \cap \mathcal{C}(\mathbf{X})^\perp$, of dimension $g-2$, on which $\mathbf{V}$ acts as $\lambda_1 \mathbf{I}$, and $\mathcal{C}(\mathbf{Z})^\perp$, of dimension $n-g$, on which $\mathbf{V}$ acts as $\sigma^2 \mathbf{I}$. Choosing $\mathbf{K}$ adapted to this decomposition, Eq. 32.4.4 becomes $-2\ell_R = (g-2) \log \lambda_1 + (n-g) \log \sigma^2 + \text{SS}_C / \lambda_1 + \text{SSE} / \sigma^2$ up to constants, to be minimized over $\lambda_1 \geq \sigma^2 > 0$, exactly as in Proposition 32.4.3. Its minimizers are $\hat{\lambda}_1 = \text{MS}_C$ and $\hat{\sigma}^2 = \text{MSE}$ when $\text{MS}_C \geq \text{MSE}$; otherwise the constraint binds, by the argument of Proposition 32.4.3(c).

- (c) The two-moment match of Section 4.3 gives $\nu = 2(\text{E } U)^2 / \text{Var}(U)$, and here $\text{Var}(U) = \sum_i c_i^2 \text{Var}(\text{MS}_i) = 2 \sum_i c_i^2 (\text{E } \text{MS}_i)^2 / \nu_i$, which is Eq. 32.5.2 — the calculation already made for a linear combination of independent variance estimates in Section 15.5.

■

Part (b) isolates the problem. The standard error a mixed-model program reports for this design is *exactly right*: it is $\sqrt{4 \text{MS}_C / (gm)}$ whenever the REML estimate of λ_1 is interior, that is, unless $\text{MS}_C < \text{MSE}$ — probability 0.157 in the design simulated below, and 0.558 when σ_a^2 is in fact zero. What is wrong is the reference distribution. Treating $\hat{\beta}/\text{se}$ as standard normal, which is what a Wald test does, ignores that MS_C came from $g-2$ degrees of freedom. With $g=8$ clusters that is six, and the t critical value 2.447 exceeds 1.96 by 25 per cent.

Example. (Eight clusters)

Simulate the trial with $g=8$ clusters of $m=5$, an intraclass correlation of 0.2, and no treatment effect. Over 200 000 trials, the nominal 95% normal Wald interval covers 0.901 of the time, while the $t(g-2)$ interval covers 0.949. Figure 32.5.1 traces the coverage against the number of clusters: 0.812 with four clusters, still 0.943 with forty. The normal interval's coverage is exactly $2F_{t(g-2)}(1.96) - 1$, which is why it approaches but never reaches 0.95.

The coverage study is the null one; take now a single data set simulated from the same design but with a true effect of 0.8. On it the estimated effect is 1.154 with standard error 0.479. The normal interval is 1.154 ± 0.940 , which excludes zero; the exact interval is 1.154 ± 1.173 , which does not. The whole difference between “significant” and “not” is the reference distribution.

```
import numpy as np
```

Figure 32.5.1: Coverage of a nominal 95% interval for the treatment effect in a balanced cluster-randomized trial with $m = 5$ units per cluster and intraclass correlation 0.2, against the number of clusters. The normal Wald interval treats the estimated covariance as known; the $t(g-2)$ interval is exact by Eq. 32.5.1.

```

from scipy import stats

def simulate(g, m, sigma_a, sigma, effect, B, seed):
    """B cluster-randomized trials; returns the estimate and its estimated variance.
    """
    rng = np.random.default_rng(seed)
    treat = np.tile([0.0, 1.0], g // 2)          # cluster k is treated if
    treat[k]=1
    Y = (effect * treat[:, None] + sigma_a * rng.standard_normal((B, g, 1))
          + sigma * rng.standard_normal((B, g, m)))
    cluster_mean = Y.mean(axis=2)
    diff = (cluster_mean[:, treat == 1].mean(axis=1)
            - cluster_mean[:, treat == 0].mean(axis=1))
    # mean square between clusters within arms, on g - 2 degrees of freedom
    centred = cluster_mean - np.where(treat == 1,
                                      cluster_mean[:, treat == 1].mean(axis=1,
                                      keepdims=True),
                                      cluster_mean[:, treat == 0].mean(axis=1,
                                      keepdims=True))
    lam1 = m * np.sum(centred**2, axis=1) / (g - 2)    # estimates sigma^2 + m
    sigma_a^2
    return diff, 4 * lam1 / (g * m)

g, m = 8, 5
# a shorter run than the 200 000 trials quoted in the text, so the cell finishes
quickly
diff, var_hat = simulate(g, m, 0.5, 1.0, 0.0, 20000, seed=5150)
t = diff / np.sqrt(var_hat)
print(f"normal interval covers {np.mean(np.abs(t) <= stats.norm.ppf(0.975)):.3f}")
print(f"t(g-2) interval covers {np.mean(np.abs(t) <= stats.t.ppf(0.975, g - 2)):.3f}")
")

```

32.5.2 Degrees of freedom in general

Outside designs as tidy as [Proposition 32.5.1\(b\)](#) there is no exact answer, and two approximations are in common use. Neither is proved here; both rest on simulation evidence rather than exact distribution theory.

Satterthwaite. The estimated variance $\lambda^\top (\mathbf{X}^\top \mathbf{V}(\hat{\boldsymbol{\theta}})^{-1} \mathbf{X})^{-1} \lambda$ is a smooth function of $\hat{\boldsymbol{\theta}}$. Approximating its distribution by a scaled chi-square and matching two moments, with the variance from the delta method and the asymptotic covariance of $\hat{\boldsymbol{\theta}}$, gives a denominator degrees of freedom that is in general not an integer. Giesbrecht and Burns (1985) developed this for mixed models; in the design of [Proposition 32.5.1\(b\)](#) it returns the exact $g - 2$ ([Exercise \(B1\)](#)).

Kenward and Roger. Satterthwaite corrects the reference distribution but not the variance estimate, and the variance estimate is biased downwards: the plug-in covariance $(\mathbf{X}^\top \mathbf{V}(\hat{\boldsymbol{\theta}})^{-1} \mathbf{X})^{-1}$ is what $\hat{\boldsymbol{\beta}}$ would have if $\hat{\boldsymbol{\theta}}$ were the truth, and the estimator actually used varies for a second reason, because $\hat{\boldsymbol{\theta}}$ itself varies, adding a nonnegative definite term. Kackar and Harville (1984) approximated it; Kenward and Roger (1997) add an estimate of it, then scale the F statistic and match two moments for its degrees of freedom. The correction is the default in several packages and performs well in small samples; [Example \(The proficiency study, four ways\)](#) exhibits the inflation.

Warning. Unlike [Proposition 32.5.1\(a\)](#), these are approximations with no finite-sample guarantee. When the design is small, unbalanced and the covariance structure rich, the safest calibration is a parametric bootstrap: simulate from the fitted model, refit, and use the simulated distribution of the statistic ([Proposition 23.3.3](#) and [Section 23.3](#)). It costs a few hundred fits and needs no asymptotics.

32.5.3 Comparing models

Two rules govern likelihood comparisons in mixed models, and both follow from [Section 32.4](#).

Different fixed effects: use maximum likelihood. Since $\mathbf{K}$ is determined by $\mathcal{C}(\mathbf{X})$, two fixed-effects structures give restricted likelihoods of different random vectors, and their difference means nothing. Likelihood ratio tests and information criteria across fixed-effects structures must use the ordinary likelihood [Eq. 32.4.1](#).

Same fixed effects, different covariance: REML is preferred. Here $\mathbf{K}$ is the same, the restricted likelihoods are likelihoods of the same data, and the additive constants of [Theorem 32.4.2\(c\)](#) cancel. Restricted likelihood ratio tests, and the AIC and BIC of [Definition 29.2.2](#) computed from ℓ_R with d_k the number of covariance parameters, are legitimate. For BIC the sample size to use is $n - p$, the dimension of the data actually modelled, not n , following Verbeke and Molenberghs (2000).

Example. (Do the firms' slopes differ?)

Continue [Example \(Grunfeld's panel with a random firm effect\)](#). Adding a firm-specific slope on market value, with variance σ_s^2 independent of the firm intercept, raises the restricted log-likelihood from -1176.53 to -1159.01 . The two models have the same fixed effects, so the comparison is legitimate: the statistic is 35.05 on one boundary parameter, far beyond any reasonable critical value, and AIC falls from 2357.1 to 2324.0, BIC from 2363.8 to 2334.2. The firms' responses to market value genuinely differ: the

Figure 32.5.2: Grunfeld's panel. (a) The coefficient of market value with 95% intervals under four analyses: one common intercept, firm indicators, a random firm intercept, and random firm intercepts and slopes. (b) Firm effects from the firm-indicator fit against the predicted firm effects of the random-intercept model; with twenty years per firm there is nothing left to shrink.

estimated standard deviation of the firm-specific slopes is 0.1492.

The consequence for inference is dramatic. In the random-intercept model the coefficient of market value is 0.1094 with standard error 0.0100; in the random-slope model it is 0.0127 with standard error 0.0562, five and a half times larger. Nothing about the data changed. Two things did. The standard error grew because the effective sample size for a *population-average* slope is 11 firms, not 220 firm-years. The estimate moved because the two models estimate different functionals. Firm-specific intercepts and slopes with a common capital coefficient give eleven slopes of mean -0.0009 and standard deviation 0.198: their spread dwarfs their average. The random-slope model estimates that average; the random-intercept model, forced to give every firm the same slope, reports a precision-weighted blend instead. Panel (a) of Figure 32.5.2 shows the four analyses side by side; panel (b) shows that with 20 years per firm the predicted firm effects are indistinguishable from the firm-indicator estimates.

```
import numpy as np
import pandas as pd

```

32.5.4 Testing a variance component

The hypothesis $\sigma_a^2 = 0$ sits on the edge of the parameter space, so the usual chi-square calibration of a likelihood ratio statistic does not apply: the standard argument expands the log-likelihood about an *interior* maximum, and here the unconstrained maximum falls outside the parameter space about half the time. In the balanced one-way model the correct answer can be computed exactly.

Theorem 32.5.2 — Exact null distribution of the restricted likelihood ratio

In the balanced normal one-way random effects model with $n = gm$, let

$$L = 2 \left\{ \sup_{\sigma_a^2 \geq 0} \ell_R - \sup_{\sigma_a^2 = 0} \ell_R \right\}$$

be the restricted likelihood ratio statistic for $H_0 : \sigma_a^2 = 0$, and write $F = \text{MSB}/\text{MSE}$, $a = (g - 1)/(n - 1)$, $b = (n - g)/(n - 1)$. Then

$$L = \begin{cases} 0, & F \leq 1, \\ (n - 1) \log(aF + b) - (g - 1) \log F, & F > 1. \end{cases} \quad (32.5.3)$$

Under H_0 , $F \sim F(g - 1, n - g)$, so the null distribution of L is free of σ^2 and exactly computable. In particular L is a nondecreasing function of F and

$$\Pr(L = 0) = \Pr\{F(g - 1, n - g) \leq 1\},$$

a probability that tends to $\frac{1}{2}$ as g and $n - g$ grow.

Proof. By Eq. 32.4.8, $-2\ell_R = (g - 1) \log \lambda_1 + (n - g) \log \lambda_2 + \text{SSB}/\lambda_1 + \text{SSE}/\lambda_2$ up to a constant, over the region $\lambda_1 \geq \lambda_2 > 0$. Under H_0 the region collapses to $\lambda_1 = \lambda_2 = \lambda$, where the objective is $(n - 1) \log \lambda + (\text{SSB} + \text{SSE})/\lambda$, minimized at $\hat{\lambda} = (\text{SSB} + \text{SSE})/(n - 1) = \text{MST}$, with minimum $(n - 1) \log \text{MST} + (n - 1)$.

If $\text{MSB} \geq \text{MSE}$ the unrestricted maximizers of Proposition 32.4.3(a) are feasible, and the minimum of $-2\ell_R$ is $(g - 1) \log \text{MSB} + (n - g) \log \text{MSE} + (n - 1)$. Subtracting,

$$L = (n - 1) \log \text{MST} - (g - 1) \log \text{MSB} - (n - g) \log \text{MSE}.$$

Dividing inside every logarithm by MSE , which is legitimate because the coefficients $(n - 1)$, $-(g - 1)$ and $-(n - g)$ sum to zero, and using $\text{MST}/\text{MSE} = aF + b$, gives Eq. 32.5.3. If $\text{MSB} < \text{MSE}$ then by Proposition 32.4.3(c) the constrained maximizer is on the boundary, which is the null model, so $L = 0$.

Under H_0 the distribution of F is $F(g - 1, n - g)$ by Proposition 32.4.3 and Proposition 32.1.1(d) with $\gamma = 0$, and L is a function of F alone. It is nondecreasing in F because, using $(n - 1)a = g - 1$ and then $1 - a = b$,

$$\begin{aligned} \frac{dL}{dF} &= \frac{(n - 1)a}{aF + b} - \frac{g - 1}{F} = \frac{(g - 1)\{F - (aF + b)\}}{F(aF + b)} \\ &= \frac{(g - 1)b(F - 1)}{F(aF + b)} \geq 0 \end{aligned}$$

for $F \geq 1$. Hence $\{L = 0\} = \{F \leq 1\}$. Finally, as $r = g - 1$ and $s = n - g$ grow, $\log F$ is asymptotically normal with variance $2/r + 2/s \rightarrow 0$ and mean of order $1/r + 1/s$, which is small compared with the standard deviation; so $\Pr(\log F \leq 0) \rightarrow 1/2$. ■

Remark (Sketch of the chi-bar-squared limit). The exact result explains the shape of the general answer. Put $\delta = F - 1$ and expand Eq. 32.5.3 for small $\delta > 0$: $\log(1 + a\delta) = a\delta - a^2\delta^2/2 + O(\delta^3)$ and $\log(1 + \delta) = \delta - \delta^2/2 + O(\delta^3)$. Using $(n - 1)a = g - 1$ and $(n - 1)a^2 = (g - 1)a$, the first-order terms cancel and

$$L = \frac{1}{2}(g - 1)(1 - a)\delta^2 + O((n - 1)\delta^3).$$

Under H_0 , $\delta = F - 1$ has, to first order, the variance of $\log F$, namely $\tau^2 = 2/(g - 1) + 2/(n - g) = 2(n - 1)/\{(g - 1)(n - g)\}$, and δ/τ is asymptotically standard normal. Since $(g - 1)(1 - a) = (g - 1)(n - g)/(n - 1)$, the product $(g - 1)(1 - a)\tau^2$ equals 2 exactly, so $L \approx Z^2$ on $\{\delta > 0\}$ for a standard normal Z , while $L = 0$ on $\{\delta \leq 0\}$, an event of limiting probability $1/2$. So L converges in distribution to $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$, the **chi-bar-squared** mixture: a point mass at zero of weight one half, plus one half of a chi-square on one degree of freedom. This is a sketch, not a proof; the expansions above are heuristic. The general theorem, covering several variance components on the boundary simultaneously with weights given by the geometry of the constraint cone, is due to Self and Liang (1987), with the mixed-model case worked out by Stram and Lee (1994).

Figure 32.5.3: Null tail probabilities of the restricted likelihood ratio statistic for $\sigma_a^2 = 0$ in a balanced one-way layout, on a logarithmic scale: exact (Eq. 32.5.3), the chi-bar-squared mixture, and $\chi^2(1)$. The mixture is conservative for small g and accurate for large g .

Example. (What the calibration costs)

Take $g = 6$ groups of $m = 4$. Exactly 0.554 of the null distribution of L sits at zero, and a simulation of 200 000 data sets puts 0.554 there. Referring L to the chi-bar-squared mixture, whose 5 per cent point is the 90 per cent point 2.706 of $\chi^2(1)$, gives an actual size of 0.0411: slightly conservative. Referring it to $\chi^2(1)$, with critical value 3.841, gives 0.0204, badly conservative — the test throws away about half its power. With $g = 40$ groups the mixture is nearly exact, at 0.0462. Figure 32.5.3 compares the three tail functions.

```
import numpy as np
from scipy import stats

def lrt_from_f(f, g, m):
    """Restricted likelihood ratio statistic for sigma_a^2 = 0, from the F ratio."""
    n = g * m
    a, b = (g - 1) / (n - 1), (n - g) / (n - 1)
    return np.where(f <= 1, 0.0,
                    (n - 1) * np.log(a * np.maximum(f, 1) + b) - (g - 1) * np.log(np
                    .maximum(f, 1)))

g, m = 6, 4
n = g * m
p_zero = stats.f.cdf(1.0, g - 1, n - g)
crit_mix = stats.chi2.ppf(0.90, 1)
print(f"g = {g}, m = {m}: P(L = 0) = {p_zero:.3f}, 5% point of the mixture {
    crit_mix:.3f}")
```

Crainiceanu and Ruppert (2004) showed that for models with a single variance component the exact null distribution can be computed in general, not only in the balanced case, and that the chi-bar-squared approximation can be poor when the design is unbalanced. Where their results do not apply, the parametric bootstrap is again the practical answer.

32.5.5 Intervals for variance components

Three routes, in decreasing order of reliability. In balanced designs, [Corollary 32.1.2](#) gives exact intervals for ratios of variance components and for the intraclass correlation. In general, the profile restricted likelihood of [Example \(REML and ML for the twelve laboratories\)](#) gives an interval by cutting 1.92 units below the maximum; it respects the boundary and is asymmetric, as the likelihood is. Last and least, the Wald interval from the inverse information matrix is symmetric, frequently includes negative values, and is badly calibrated whenever $\hat{\sigma}_a^2$ is near zero. [Burdick and Graybill \(1992\)](#) is a book-length treatment of what can and cannot be done exactly.

32.5.6 Exercises

32.5.6.1 A. Check your understanding

Exercise A1.

In [Proposition 32.5.1\(b\)](#), the reported standard error is exactly right and the test is still wrong. Explain in one or two sentences what “exactly right” means here and what is wrong, and say why the problem gets worse as the intraclass correlation grows with n fixed.

Exercise A2.

A colleague tests whether a regressor belongs in the fixed part of a mixed model by comparing restricted log-likelihoods with and without it, referring twice the difference to $\chi^2(1)$. Give two separate reasons why this is wrong, and say what to do instead.

32.5.6.2 B. Practice

Exercise B1.

Apply [Eq. 32.5.2](#) to the estimated variance $4\text{MS}_C/(gm)$ of [Proposition 32.5.1\(b\)](#), a single multiple of one mean square, and confirm that it returns $\nu = g - 2$ exactly. Then apply it to $\hat{\sigma}_a^2 = (\text{MSB} - \text{MSE})/m$ in the balanced one-way model and write down the resulting degrees of freedom.

Solution. With one term, $U = c \text{MS}_1$, [Eq. 32.5.2](#) gives $\nu = c^2(\text{E MS}_1)^2 / \{c^2(\text{E MS}_1)^2 / \nu_1\} = \nu_1 = g - 2$. For the variance component, $c_1 = 1/m$ with $\nu_1 = g - 1$ and $c_2 = -1/m$ with $\nu_2 = n - g$, so

$$\hat{\nu} = \frac{(\hat{\sigma}_a^2)^2}{(\text{MSB}/m)^2/(g-1) + (\text{MSE}/m)^2/(n-g)}.$$

Note that this can be far below $g - 1$ when MSB and MSE are close, which is the usual situation when σ_a^2 is small.

Exercise B2.

Verify directly that the function $F \mapsto (n-1)\log(aF+b) - (g-1)\log F$ in [Eq. 32.5.3](#)

vanishes at $F = 1$, is increasing for $F > 1$ and tends to infinity as $F \rightarrow \infty$. What does the last fact say about the power of the test when σ_a^2 is large?

Exercise B3.

In the balanced one-way model, compute the Wald interval $\hat{\sigma}_a^2 \pm 1.96 \text{se}$ for the proficiency study using [Exercise \(B2\)](#) for the standard error with the estimates plugged in, and compare it with the exact interval implied by [Corollary 32.1.2](#) and with the profile interval (0.0086, 0.1275) of [Example \(REML and ML for the twelve laboratories\)](#). Comment.

32.5.6.3 C. Going deeper

Exercise C1.

Consider testing $\sigma_a^2 = 0$ when a second variance component $\sigma_b^2 > 0$ is present and is *not* on the boundary. Argue informally that the limiting null distribution is still $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$, and explain why testing *both* components simultaneously gives a mixture over $\chi^2(0), \chi^2(1), \chi^2(2)$ with weights determined by the probability that the unconstrained maximizer lands in each orthant. Which weights arise if the two estimates are asymptotically independent?

Solution. Locally the log-likelihood is approximately quadratic in the parameter, so the likelihood ratio behaves like the squared distance from the unconstrained maximizer to the constrained set, measured in the information metric. With one parameter on the boundary, the constraint acts only in that coordinate: half the time the unconstrained maximizer already satisfies it and the ratio is zero, half the time the constrained maximum is on the face and the ratio is a squared standard normal. With two parameters constrained, the ratio is zero when the maximizer lies in the nonnegative orthant, a $\chi^2(1)$ when it lies in one of the two adjacent orthants, and a $\chi^2(2)$ when it lies in the fully negative orthant. If the two coordinates are asymptotically independent, those four orthants have probabilities $1/4, 1/4, 1/4, 1/4$, giving weights $1/4$ for $\chi^2(0)$, $1/2$ for $\chi^2(1)$ and $1/4$ for $\chi^2(2)$.

Exercise C2.

[Proposition 32.5.1\(a\)](#) needs the error distribution to be symmetric about zero. Give an example of a translation-invariant, even $\hat{\boldsymbol{\theta}}$ and a skewed error distribution for which $\hat{\boldsymbol{\beta}}(\hat{\boldsymbol{\theta}})$ is biased, and explain why symmetry cannot simply be dropped. (Compare the discussion after [Theorem 21.3.1](#).)

32.6 Bayesian thread III: mixed models as hierarchical models

The Bayesian thread began in [Section 7.6](#) with a conjugate prior on $(\boldsymbol{\beta}, \sigma^2)$ and continued in [Section 12.6](#) with credible sets and predictive distributions. Mixed models are where the two traditions meet most closely, because a random effect *is* a prior: the statement $\mathbf{u} \sim N_q(\mathbf{0}, \mathbf{G})$ is formally indistinguishable from a normal prior on q unknown constants. What separates the methods of [Section 32.4](#) from a fully Bayesian analysis is only that they estimate $\mathbf{G}$ and then treat it as known, which is empirical Bayes ([Proposition 27.5.4](#)), while a Bayesian puts a prior on $\mathbf{G}$ too and integrates.

32.6.1 The hierarchical reading

Write the model in three levels:

$$\mathbf{Y} \mid \boldsymbol{\beta}, \mathbf{u}, \boldsymbol{\theta} \sim N_n(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}, \mathbf{R}), \quad \mathbf{u} \mid \boldsymbol{\theta} \sim N_q(\mathbf{0}, \mathbf{G}), \quad (\boldsymbol{\beta}, \boldsymbol{\theta}) \sim \pi. \quad (32.6.1)$$

Level one is a linear model with known coefficients; level two is the prior on $\mathbf{u}$ that the experiment's sampling of levels supplies; level three is the part that is genuinely a matter of choice.

Proposition 32.6.1 — BLUP as a posterior mean, REML as a marginal posterior

Consider [Eq. 32.6.1](#) with $\mathbf{G}$ and $\mathbf{R}$ positive definite and $\text{rank}(\mathbf{X}) = p$.

- (a) (*BLUP is a posterior mean.*) Fix $\boldsymbol{\theta}$ and take the improper flat prior $\pi(\boldsymbol{\beta}) \propto 1$. Then the joint posterior of $(\boldsymbol{\beta}, \mathbf{u})$ is

$$\begin{pmatrix} \boldsymbol{\beta} \\ \mathbf{u} \end{pmatrix} \mid \mathbf{y} \sim N_{p+q} \left(\begin{pmatrix} \hat{\boldsymbol{\beta}} \\ \hat{\mathbf{u}} \end{pmatrix}, \mathbf{C}^{-1} \right),$$

with $\hat{\boldsymbol{\beta}}, \hat{\mathbf{u}}$ and $\mathbf{C}$ as in [Theorem 32.3.2](#). In particular $E(\mathbf{u} \mid \mathbf{y}) = \hat{\mathbf{u}}$ is the BLUP, $E(\boldsymbol{\beta} \mid \mathbf{y}) = \hat{\boldsymbol{\beta}}$ is the generalized least squares estimate, and $\text{Cov}(\mathbf{u} \mid \mathbf{y})$ is the prediction error covariance of [Eq. 32.3.2](#).

- (b) (*REML is a marginal posterior.*) With the flat prior on $\boldsymbol{\beta}$ and any prior $\pi(\boldsymbol{\theta})$, the marginal posterior of the variance components is

$$\pi(\boldsymbol{\theta} \mid \mathbf{y}) \propto \pi(\boldsymbol{\theta}) \exp\{\ell_R(\boldsymbol{\theta})\}, \quad (32.6.2)$$

with ℓ_R the restricted log-likelihood of [Definition 32.4.1](#). The REML estimate is therefore the mode of the marginal posterior under a flat prior on $\boldsymbol{\theta}$.

- (c) (*What the plug-in leaves out.*) Under (a) with $\boldsymbol{\theta}$ replaced by an estimate, the reported posterior variance is $\text{Cov}(\mathbf{u} \mid \mathbf{y}, \hat{\boldsymbol{\theta}})$, whereas the correct marginal posterior variance is $E\{\text{Cov}(\mathbf{u} \mid \mathbf{y}, \boldsymbol{\theta}) \mid \mathbf{y}\} + \text{Cov}\{E(\mathbf{u} \mid \mathbf{y}, \boldsymbol{\theta}) \mid \mathbf{y}\}$. The plug-in omits the second term, so it is too small.

Proof.

- (a) With $\pi(\boldsymbol{\beta}) \propto 1$ and $\boldsymbol{\theta}$ fixed, the joint density of $(\mathbf{y}, \mathbf{u})$ times the prior is proportional to $\exp\{-\frac{1}{2}Q(\boldsymbol{\beta}, \mathbf{u})\}$ with Q the penalized criterion [Eq. 32.3.6](#), because $-2 \log f(\mathbf{y} \mid \boldsymbol{\beta}, \mathbf{u}) = (\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u})^\top \mathbf{R}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u})$ and $-2 \log f(\mathbf{u}) = \mathbf{u}^\top \mathbf{G}^{-1}\mathbf{u}$, up to terms free of $(\boldsymbol{\beta}, \mathbf{u})$. By [Theorem 32.3.2\(b\)](#), Q is a quadratic in $\mathbf{w} = (\boldsymbol{\beta}^\top, \mathbf{u}^\top)^\top$ with positive definite matrix $\mathbf{C}$, minimized at $\hat{\mathbf{w}} = (\hat{\boldsymbol{\beta}}^\top, \hat{\mathbf{u}}^\top)^\top$, so $Q(\mathbf{w}) = (\mathbf{w} - \hat{\mathbf{w}})^\top \mathbf{C}(\mathbf{w} - \hat{\mathbf{w}}) + Q(\hat{\mathbf{w}})$. The posterior is therefore $N_{p+q}(\hat{\mathbf{w}}, \mathbf{C}^{-1})$, and [Theorem 32.3.2\(c\)](#) identifies the blocks.
- (b) The joint posterior is $\pi(\boldsymbol{\beta}, \boldsymbol{\theta} \mid \mathbf{y}) \propto \pi(\boldsymbol{\theta}) \exp\{\ell(\boldsymbol{\beta}, \boldsymbol{\theta})\}$ with ℓ the marginal log-likelihood [Eq. 32.4.1](#), the random effects having already been integrated out in [Eq. 32.2.2](#). Completing the square as in [Lemma 32.4.1\(b\)](#),

$$(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^\top \mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) = \mathbf{y}^\top \mathbf{P}\mathbf{y} + (\boldsymbol{\beta} - \hat{\boldsymbol{\beta}})^\top \mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}),$$

so integrating over $\boldsymbol{\beta} \in \mathbb{R}^p$ contributes the factor $(2\pi)^{p/2} \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1/2}$ and

$$\begin{aligned} \int e^{\ell(\boldsymbol{\beta}, \boldsymbol{\theta})} d\boldsymbol{\beta} &= \exp\left[-\frac{1}{2}\{(n-p) \log 2\pi + \log \det \mathbf{V} \right. \\ &\quad \left. + \log \det(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X}) + \mathbf{y}^\top \mathbf{P}\mathbf{y}\}\right]. \end{aligned}$$

By [Eq. 32.4.5](#) the exponent is $\ell_R(\boldsymbol{\theta})$ up to the additive constant $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{X})$, which does not involve $\boldsymbol{\theta}$. That is [Eq. 32.6.2](#).

- (c) This is the decomposition of a variance into the mean of the conditional variance plus the variance of the conditional mean ([Proposition 2.5.4](#)), applied to the posterior distribution with $\boldsymbol{\theta}$ as the conditioning variable. The second term is nonnegative definite. ■

Part (b) is Harville's (1974) observation, and it settles a question that the frequentist derivation leaves slightly mysterious. REML looked like a technical device for recovering lost degrees of freedom; it is in fact the exact marginal likelihood of the variance components once the fixed effects have been integrated out with a flat prior. The " $n - p$ " is not a correction but a consequence.

Idea. Three readings of the same computation. Frequentist: $\hat{\mathbf{u}}$ minimizes prediction mean squared error among unbiased linear predictors. Penalized: it minimizes a sum of squares with a ridge penalty on $\mathbf{u}$. Bayesian: it is the posterior mean of $\mathbf{u}$ under a normal prior with covariance $\mathbf{G}$. Henderson's equations compute all three at once, and the three readings differ only in what they say about $\mathbf{G}$: a covariance to be estimated, a penalty to be tuned, or a prior to be chosen.

32.6.2 Priors for variance components

The conditional distributions in [Eq. 32.6.1](#) make the conjugate choices obvious. Given $\mathbf{u}$ and $\boldsymbol{\beta}$, the sum of squares $\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}\|^2$ is an ordinary normal likelihood for σ^2 , so an inverse gamma prior is conjugate; given $\mathbf{u}$, the sum $\|\mathbf{u}\|^2$ plays the same role for σ_a^2 . This is what makes the Gibbs sampler below so short. What is not obvious is which inverse gamma.

Warning. The prior $\sigma_a^2 \sim \text{IG}(\epsilon, \epsilon)$ with ϵ small is often described as non-informative. It is not, and the limit does not exist. The marginal (restricted) likelihood $\exp\{\ell_R\}$ is continuous and *strictly positive* at $\sigma_a^2 = 0$, because $\sigma_a^2 = 0$ is a perfectly good model. Any prior density whose integral diverges at the origin, such as $\pi(\sigma_a^2) \propto 1/\sigma_a^2$ — equivalently a flat prior on $\log \sigma_a$ — therefore gives an improper posterior: $\int \pi(\sigma_a^2) e^{\ell_R} d\sigma_a^2 = \infty$. For small ϵ the $\text{IG}(\epsilon, \epsilon)$ posterior is proper but arbitrarily close to improper, and with few groups the answer depends on ϵ . Gelman (2006) made this point and recommended instead a prior that is flat or half- t on the *standard deviation* σ_a , which has finite mass near zero.

A convenient weakly informative default is the half-Cauchy on σ_a with scale A , chosen large relative to the plausible size of a group effect. It keeps the Gibbs sampler conjugate through the scale-mixture representation

$$\sigma_a^2 \mid \xi \sim \text{IG}(\tfrac{1}{2}, 1/\xi), \quad \xi \sim \text{IG}(\tfrac{1}{2}, 1/A^2),$$

whose marginal for σ_a is half-Cauchy(0, A). The auxiliary variable ξ is sampled alongside everything else.

32.6.3 A Gibbs sampler in a dozen lines

For the one-way model with a flat prior on μ , the four full conditionals are all standard. Given $\mu, \sigma^2, \sigma_a^2$, the effects are independent with

$$a_k \mid \text{rest} \sim N\left(\frac{(m/\sigma^2)(\bar{y}_k - \mu)}{m/\sigma^2 + 1/\sigma_a^2}, \frac{1}{m/\sigma^2 + 1/\sigma_a^2}\right),$$

which is [Eq. 32.3.3](#) with the current parameter values; given the effects, $\mu \sim N(\overline{y - \mathbf{Za}}, \sigma^2/n)$; and the two variances have inverse gamma conditionals with shapes $n/2$ and $g/2$ plus their prior shapes. Nothing needs tuning.

```
import numpy as np

g, m = 12, 4
n = g * m
mu, sigma_a, sigma = 2.50, 0.20, 0.25          # the values used to simulate

rng = np.random.default_rng(20320048)
lab_effect = sigma_a * rng.standard_normal(g)
y = mu + np.repeat(lab_effect, m) + sigma * rng.standard_normal(n)

Y = y.reshape(g, m)                            # the REML fit of Section 32.4
ms_between = m * np.sum((Y.mean(axis=1) - Y.mean()) ** 2) / (g - 1)
ms_within = np.sum((Y - Y.mean(axis=1)[:, None]) ** 2) / (n - g)
reml_s2, reml_s2a = ms_within, (ms_between - ms_within) / m

def gibbs(y, g, m, draws=40000, burn=2000, prior="inverse-gamma", A=1.0, seed=0):
    """Posterior draws of (mu, sigma^2, sigma_a^2, a) with a flat prior on mu."""
    rng = np.random.default_rng(seed)
    Y = y.reshape(g, m)
    n = g * m
    mu_, s2, s2a, xi = Y.mean(), Y.var(), 0.1, 1.0
    out = np.empty((draws, 3 + g))
    for t in range(draws + burn):
```

```

prec = m / s2 + 1 / s2a                                # a_k / rest
a = rng.normal((m / s2) * (Y.mean(axis=1) - mu_) / prec, np.sqrt(1 / prec))
mu_ = rng.normal((y - np.repeat(a, m)).mean(), np.sqrt(s2 / n)) # mu /
rest
resid = y - mu_ - np.repeat(a, m)
s2 = 1 / rng.gamma(0.001 + n / 2, 1 / (0.001 + resid @ resid / 2))
if prior == "inverse-gamma":                            # sigma_a^2 / rest
    s2a = 1 / rng.gamma(0.001 + g / 2, 1 / (0.001 + a @ a / 2))
else:                                                    # half-Cauchy(0, A)
    s2a = 1 / rng.gamma((g + 1) / 2, 1 / (1 / xi + a @ a / 2))
    xi = 1 / rng.gamma(1.0, 1 / (1 / A**2 + 1 / s2a))
if t >= burn:
    out[t - burn] = np.concatenate([[mu_, s2, s2a], a])
return out

```

```

# a shorter run than the 40 000 draws quoted in the text, so the cell finishes
quickly
short = gibbs(y, g, m, draws=4000, burn=500, prior="half-Cauchy", seed=12)
print(f"posterior median of sigma_a^2 {np.median(short[:, 2]):.4f}")
print(f"posterior mean of mu {short[:, 0].mean():.4f}")
print(f"REML estimate of sigma_a^2 {reml_s2a:.4f}")

```

Example. (The proficiency study, four ways)

Run the sampler for 40 000 draws on the data of [Example \(A laboratory proficiency study\)](#). Under the $\text{IG}(0.001, 0.001)$ prior the posterior median of σ_a^2 is 0.0356; under the half-Cauchy prior with $A = 1$ it is 0.0438. The REML estimate 0.0386 sits between them. The two priors therefore disagree by about a fifth of the estimate, with twelve laboratories — which is already a reason to report the prior.

The posterior means of the twelve effects track the BLUPs closely: their correlation exceeds 0.99 and the largest in absolute value is 0.294 against the BLUP's 0.321, slightly more shrunk — not because the posterior sits below the REML estimate, since its mean 0.0431 is above it, but because the shrinkage factor $B = m\sigma_a^2 / (\sigma^2 + m\sigma_a^2)$ is concave in σ_a^2 : averaging B over a posterior with mass near zero weights the data less than $\hat{\sigma}_a^2$ does. Their posterior standard deviations average 0.1218, against the plug-in prediction standard error 0.1156 of [Eq. 32.3.4](#): 5 per cent wider, which is the uncertainty about σ_a^2 that the plug-in throws away, exactly as [Proposition 32.6.1\(c\)](#) says. The same happens for the fixed effect: the posterior standard deviation of μ is 0.0709, against the plug-in $\sqrt{\hat{\lambda}_1/n} = 0.0672$.

Panel (b) of [Figure 32.6.1](#) repeats the analysis on the first 5 laboratories. The posterior medians are now 0.0435 and 0.0693, a difference of sixty per cent, against a REML estimate of 0.0493. With five groups the prior is doing a large part of the work, and saying so is not optional.

Figure 32.6.1: Posterior densities of the between-laboratory standard deviation σ_a under two priors, from a Gibbs sampler with 40 000 draws. The dotted line marks the REML estimate. (a) All twelve laboratories. (b) The first five, where the prior matters a great deal.

32.6.4 What the Bayesian version buys, and what it costs

Three gains. The uncertainty about $\boldsymbol{\theta}$ is carried through automatically, so intervals for fixed effects and prediction intervals for random effects are honestly wider, with no need for the corrections of [Section 32.5](#). The boundary problem disappears: the posterior of σ_a^2 is a proper distribution on $[0, \infty)$, with no point mass and no chi-bar-squared mixture to calibrate. And the same machinery handles models with no closed form, which is what [Chapter 33](#) needs for richer covariance structures and [Chapter 40](#) needs once the response is not normal.

Two costs. A prior for the variance components must be chosen, and with few groups it matters, as panel (b) shows; the only defensible practice is to state it and show the sensitivity. And the answers are not exactly the frequentist ones: the two frameworks agree on the point estimates, but they part company on the spread, and the frequentist coverage of a credible interval for a variance component is not guaranteed ([Proposition 12.6.4](#)).

32.6.5 Exercises

32.6.5.1 A. Check your understanding

Exercise A1.

Explain in two sentences why a random effect and a prior are formally the same object, and name one thing that distinguishes them in practice.

32.6.5.2 B. Practice

Exercise B1.

Show that in the one-way model the marginal posterior density of σ_a^2 under the prior $\pi(\sigma_a^2) \propto \sigma_a^{-2}$ is not integrable, by showing that $\exp\{\ell_R(\sigma_a^2)\}$ tends to a strictly positive limit as $\sigma_a^2 \downarrow 0$ with σ^2 profiled out. Contrast with the behaviour of the prior $\pi(\sigma_a) \propto 1$.

Solution. By [Eq. 32.4.8](#), $-2\ell_R$ is continuous in (λ_1, λ_2) on $\lambda_1 \geq \lambda_2 > 0$, and at $\sigma_a^2 = 0$ it equals $(n-1)\log \lambda_2 + (\text{SSB} + \text{SSE})/\lambda_2$, finite and minimized at a positive λ_2 . So $\exp\{\ell_R\} \rightarrow c > 0$ as $\sigma_a^2 \downarrow 0$, and $\int_0^\delta c \sigma_a^{-2} d\sigma_a^2 = \infty$. With $\pi(\sigma_a) \propto 1$ the Jacobian gives $\pi(\sigma_a^2) \propto \sigma_a^{-1}$, and $\int_0^\delta \sigma_a^{-1} d(\sigma_a^2) = 2 \int_0^{\sqrt{\delta}} d\sigma_a < \infty$: the posterior is proper near the origin.

Exercise B2.

In [Proposition 32.6.1\(c\)](#), suppose $\boldsymbol{\theta}$ takes only two values with posterior probabilities $1/2$ each, giving conditional posterior means $\hat{\mathbf{u}}_1, \hat{\mathbf{u}}_2$ and common conditional variance v for a coordinate. Compute the correct marginal posterior variance, and say how large the disagreement between $\hat{u}_1$ and $\hat{u}_2$ must be before the plug-in understates the standard deviation by ten per cent.

32.6.5.3 C. Going deeper

Exercise C1.

Formula [Eq. 32.6.2](#) shows REML is the posterior mode of $\boldsymbol{\theta}$ under a flat prior on $\boldsymbol{\theta}$. A mode is not invariant to reparameterization: the mode of the posterior of σ_a^2 is not the square of the mode of the posterior of σ_a . Reconcile this with [Theorem 32.4.2\(c\)](#), which says the REML estimate is well defined. What is invariant, and what is not?

Exercise C2.

Take the balanced one-way model with σ^2 known, $m = 1$ so that $\bar{y}_k = y_k$, and μ known to be zero. Show that plugging the unbiased moment estimate of σ_a^2 into [Eq. 32.3.3](#) gives a shrinkage factor of the form $1 - c\sigma^2/\sum_k y_k^2$, and compare with the James–Stein estimator of [Theorem 27.5.2](#). Which constant c does the plug-in give, and which does James–Stein use?

Solution. With $m = 1$ and $\mu = 0$ the data are $y_k \sim N(a_k, \sigma^2)$ with $a_k \sim N(0, \sigma_a^2)$, so marginally $y_k \sim N(0, \sigma^2 + \sigma_a^2)$. The moment estimate from $\sum_k y_k^2$ is $\hat{\sigma}_a^2 = \sum_k y_k^2/g - \sigma^2$, and

$$B = \frac{\hat{\sigma}_a^2}{\hat{\sigma}_a^2 + \sigma^2} = 1 - \frac{g\sigma^2}{\sum_k y_k^2},$$

so $c = g$ in the stated form. The James–Stein estimator of [Theorem 27.5.2](#) uses $1 - (g-2)\sigma^2/\sum_k y_k^2$. The difference is the same degrees-of-freedom correction that separates ML from REML: $g-2$ is the constant that makes $(g-2)\sigma^2/\sum_k y_k^2$ unbiased for $\sigma^2/(\sigma^2 + \sigma_a^2)$, and it is what makes the estimator dominate the unshrunk one for every $\boldsymbol{\alpha}$, not merely on average.

32.7 Summary and Notes

32.7.1 Summary

Idea.

1. A factor is random when its levels are a sample and the conclusion is meant for the population of levels. The one-way random effects model has covariance $\sigma^2\mathbf{I} + \sigma_a^2\mathbf{Z}\mathbf{Z}^\top$, intraclass correlation $\sigma_a^2/(\sigma_a^2 + \sigma^2)$, and unbiased moment estimates from the analysis of variance ([Definition 32.1.1](#) and [Proposition 32.1.1](#)).
2. In a balanced normal layout the between and within sums of squares are independent scaled chi-squares, so MSB/MSE has an exact F distribution for every value of the variance ratio. Inverting it gives an exact interval for σ_a^2/σ^2 and for the intraclass correlation ([Corollary 32.1.2](#)).
3. The moment estimate of a variance can be negative, with probability $\Pr\{F(g-1, n-g) < 1/(1+m\gamma)\}$, which is just over one half when $\sigma_a^2 = 0$. Reporting, truncating and re-thinking the model are all defensible responses ([Eq. 32.1.4](#)).
4. The linear mixed model $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon}$ has marginal mean $\mathbf{X}\boldsymbol{\beta}$ and covariance $\mathbf{V} = \mathbf{Z}\mathbf{G}\mathbf{Z}^\top + \mathbf{R}$, a structured member of the general Gauss–Markov family. Woodbury’s identity inverts $\mathbf{V}$ at the cost of a $q \times q$ inverse ([Definition 32.2.1](#) and [Proposition 32.2.1](#)).
5. Ordinary least squares is efficient exactly when $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, which holds for cluster-constant regressors in a balanced design and fails as soon as a regressor varies within clusters; the mixed estimate then interpolates between the within and between estimators ([Example \(Cluster-constant regressors\)](#) and [Example \(Regressors that vary within a cluster\)](#)).
6. The best linear unbiased predictor of $\boldsymbol{\lambda}^\top\boldsymbol{\beta} + \mathbf{c}^\top\mathbf{u}$ is $\boldsymbol{\lambda}^\top\hat{\boldsymbol{\beta}} + \mathbf{c}^\top\mathbf{G}\mathbf{Z}^\top\mathbf{V}^{-1}(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})$: the best linear predictor with $\boldsymbol{\beta}$ replaced by its generalized least squares estimate. Its prediction error variance has two terms, one for predicting $\mathbf{u}$ and one for estimating $\boldsymbol{\beta}$ ([Theorem 32.3.1](#), which is [Theorem 14.2.8](#) of [Section 14.2](#) written for mixed functions).
7. In the balanced one-way model the BLUP is $B(\bar{y}_k - \bar{y})$ with $B = m\gamma/(1+m\gamma)$: shrinkage towards the overall mean, of the empirical Bayes kind, with a genuine gain in mean squared error and a conditional bias that matters for ranking ([Eq. 32.3.3](#)).
8. Henderson’s mixed model equations solve for $(\hat{\boldsymbol{\beta}}, \hat{\mathbf{u}})$ in one sparse system of size $p+q$; they are the normal equations of a penalized least squares criterion with penalty $\mathbf{u}^\top\mathbf{G}^{-1}\mathbf{u}$, and the inverse of their coefficient matrix holds both $\text{Cov}(\hat{\boldsymbol{\beta}})$ and the prediction error variance ([Theorem 32.3.2](#)).
9. Restricted maximum likelihood is the likelihood of a maximal set of error contrasts. It does not depend on which contrasts are used, it equals the profile likelihood plus $-\frac{1}{2}\log\det(\mathbf{X}^\top\mathbf{V}^{-1}\mathbf{X})$ up to constants, and it reduces to $s^2 = \text{SSE}/(n-p)$ when $\mathbf{V} = \sigma^2\mathbf{I}$ ([Definition 32.4.1](#) and [Theorem 32.4.2](#)).
10. In the balanced one-way model, the interior maximum likelihood estimate underestimates σ_a^2 by exactly $\lambda_1/(gm)$, while REML reproduces the unbiased moment estimates. The two score equations differ only in $\text{tr}(\mathbf{V}^{-1}\mathbf{V}_j)$ against $\text{tr}(\mathbf{P}\mathbf{V}_j)$ ([Proposition 32.4.3](#) and [Proposition 32.4.4](#)).

11. Feasible generalized least squares is still unbiased when the variance estimate is translation invariant and even. Its Wald statistic is not normal: in a balanced cluster-randomized trial it is exactly $t(g-2)$, and treating it as normal costs real coverage. Satterthwaite and Kenward–Roger approximate the right reference distribution in general ([Proposition 32.5.1](#)).
12. Testing $\sigma_a^2 = 0$ puts the null on the boundary. In the balanced one-way model the restricted likelihood ratio is an explicit increasing function of the F ratio, zero with probability $\Pr(F \leq 1)$, and its exact null distribution follows; asymptotically it is the chi-bar-squared mixture $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$ ([Theorem 32.5.2](#), the variance-component companion of [Proposition 32.5.1](#)).
13. Restricted likelihoods may be compared only across covariance structures with the same fixed effects; comparisons of fixed effects need the ordinary likelihood ([Section 32.5](#)).
14. In the hierarchical reading, the BLUP is a posterior mean and Henderson’s coefficient matrix is a posterior precision; the restricted likelihood is the marginal posterior of the variance components under a flat prior on $\boldsymbol{\beta}$. A plug-in analysis omits the variance of the conditional mean, so its intervals are too short ([Proposition 32.6.1](#)).

32.7.2 Notes and sources

Fixed and random effects. The separation of variability into components goes back to Fisher (1918), who decomposed the correlation between relatives. Eisenhart (1947) fixed the terminology “model I” and “model II” and made explicit that the choice changes the expected mean squares and therefore which ratio is a test. [Section 32.1](#) follows the expected-mean-squares route of [Chapter 9](#), and [Eq. 32.1.1](#) is the first of Henderson’s (1953) three methods for unbalanced data. Searle, Casella and McCulloch (1992) is the standard reference for variance component estimation, including methods this chapter omits such as Rao’s (1971) MINQUE; Burdick and Graybill (1992) treats intervals for variance components at book length.

Prediction. [Theorem 32.3.1](#) is [Section 14.2](#)’s theorem with a random effect in place of the new observation’s error, which is why its proof is a substitution. Best linear unbiased prediction is due to Henderson, in a sequence of papers beginning with the abstract Henderson (1950) and developed in Henderson, Kempthorne, Searle and von Krosigk (1959) and Henderson (1975); the motivating problem was ranking dairy sires from unbalanced records, where shrinkage is the difference between a usable and an unusable ranking. Harville (1976, 1977) gave the modern treatment, including the relation to Bayesian prediction. Robinson (1991) is the best single essay on what BLUP is and why several derivations converge on it, and the warning in [Section 32.3](#) about ranking shrunk predictions is developed there. The equivalence with penalized least squares, and hence with ridge regression ([Theorem 27.2.2](#)), is the bridge to smoothing: Ruppert, Wand and Carroll (2003) build semiparametric regression on it, and [Chapter 43](#) uses it to estimate a smoothing parameter by REML ([Theorem 43.6.1](#)).

REML. Restricted maximum likelihood was introduced by Patterson and Thompson (1971) for recovering inter-block information in incomplete block designs, the problem Yates (1940) had posed; [Section 18.5](#) met it in its fixed-effects form. Harville (1974) proved the marginal-posterior characterization that [Proposition 32.6.1\(b\)](#) restates, and Harville (1977) surveyed the area; Hartley and Rao (1967) had treated maximum likelihood for the mixed model a few years earlier, and Corbeil and Searle (1976) established REML’s advantage for small designs by simulation. The determinant identity [Eq. 32.4.5](#) and the identity $\mathbf{K}(\mathbf{K}^\top \mathbf{V} \mathbf{K})^{-1} \mathbf{K}^\top = \mathbf{P}$

are standard; the proof of the latter given here, through a constrained minimization, seems the shortest route and makes [Lemma 32.4.1\(c\)](#) immediate. On algorithms, Dempster, Laird and Rubin (1977) supplied EM, Laird and Ware (1982) brought it to longitudinal data, and Gilmour, Thompson and Cullis (1995) introduced average information REML. Bates, Mächler, Bolker and Walker (2015) describe a sparse-matrix implementation in which the profiled deviance is evaluated by a single sparse Cholesky update.

Inference. The unbiasedness result [Proposition 32.5.1\(a\)](#) is the covariance analogue of the weighted least squares argument of [Section 21.3](#); Kackar and Harville (1981) proved it in this generality, and Kackar and Harville (1984) gave the approximation to the extra variance of $\hat{\beta}(\hat{\theta})$ that Kenward and Roger (1997) turned into a usable small-sample correction. The degrees-of-freedom approximation of [Eq. 32.5.2](#) is Satterthwaite (1946); Giesbrecht and Burns (1985) extended it to mixed models. For the boundary problem, Self and Liang (1987) gave the general asymptotic theory of likelihood ratios when the true parameter is on the boundary, and Stram and Lee (1994) worked out the mixed-model cases most often needed. Crainiceanu and Ruppert (2004) showed that for a single variance component the exact finite-sample null distribution of the restricted likelihood ratio can be computed, and documented how poor the chi-bar-squared approximation can be; the exact balanced calculation of [Theorem 32.5.2](#) is a special case that can be done by hand, and the proof sketch of the chi-bar-squared limit given after it is our own. One question left to the econometric literature is whether the random effects are uncorrelated with the regressors at all, as [Definition 32.2.1](#) assumes; if they are not, the mixed fit is inconsistent and the within fit of [Example \(Regressors that vary within a cluster\)](#) is not. Hausman (1978) tests this by comparing the two, using the fact that when one estimator is the BLUE the covariance of the difference is the difference of the covariances. Verbeke and Molenberghs (2000) and Pinheiro and Bates (2000) are the standard applied references, the first for the theory of inference in linear mixed models and the second for practice; McCulloch, Searle and Neuhaus (2008) covers both linear and generalized mixed models.

Bayesian mixed models. Gelman (2006) changed practice on priors for variance parameters, showing that the inverse gamma with small parameters is not a safe default and recommending half- t priors on standard deviations; the scale-mixture representation used in our sampler is from that paper.

Sources for the chapter. The coverage checklist was built from Rencher and Schaalje (2008, chapter 17), Agresti (2015, sections 9.2–9.3), Fahrmeir, Kneib, Lang and Marx (2021, sections 7.1–7.4) and Sen and Srivastava (1990, sections 7.4–7.5). All the text, proofs, examples, data and exercises here are our own. The proficiency study is simulated from stated parameter values with a fixed seed; the investment panel is Grunfeld’s, in the public-domain reconstruction distributed with statsmodels, and continues the analysis begun in [Section 6.6](#).

Chapter 33

Clustered, Longitudinal and Split-Plot Data

Most data arrive in groups. Plots lie in fields, pupils sit in classrooms, patients return for repeated visits, firms are followed for twenty years. Two observations from the same group are more alike than two from different groups, and the error covariance is no longer $\sigma^2\mathbf{I}$. This chapter is the applied half of Part VII: it takes the general Gauss–Markov theory of [Chapter 31](#) and the mixed models of [Chapter 32](#) and puts them to work on the three structures that account for most correlated data in practice. A split-plot experiment randomizes at two levels and therefore has two error terms, so some comparisons are precise and others are not. A repeated-measures analysis needs a condition on the covariance that is weaker than equicorrelation and stronger than nothing, and there are three standard ways of dealing with its failure. A longitudinal study needs a covariance model chosen from a small catalogue, checked against the data, and hedged with a standard error that survives its being wrong. The chapter closes with growth curves, where each subject has its own trajectory and the whole point is to borrow strength across subjects.

What you need. [Chapter 6](#) (projection in a general inner product, [Definition 6.9.1](#), and when it agrees with least squares, [Theorem 6.9.3](#)), [Chapter 9](#) (expected mean squares, [Theorem 9.6.1](#)), [Chapter 16](#) (balanced layouts as Kronecker products, [Lemma 16.1.1](#), [Theorem 16.3.1](#)), [Chapter 18](#) (randomized blocks, [Theorem 18.4.1](#)), [Chapter 19](#) (the effect of a wrong covariance, [Theorem 19.2.2](#)), [Chapter 21](#) (sandwich estimators, [Theorem 21.4.2](#), autoregressive errors, [Definition 21.6.1](#)), [Chapter 29](#) ([Definition 29.2.2](#)), and the two chapters before this one: generalized least squares and its inference ([Definition 31.1.1](#), [Theorem 31.1.1](#), [Theorem 31.2.2](#)) and the mixed model with its predictors and likelihoods ([Definition 32.2.1](#), [Theorem 32.3.1](#), [Theorem 32.3.2](#), [Definition 32.4.1](#)).

Figure 33.1.1: A split-plot layout with $r = 4$ blocks, $a = 3$ irrigation regimes assigned at random within each block, and $b = 4$ varieties assigned at random within each whole plot.

33.1 Split-plot designs

Some treatments cannot be applied to small units: an irrigation rig waters a strip of field, not a square metre of it; a teaching method is delivered to a class, not to a pupil. An experiment combining such a treatment with one applied as finely as one likes gives the coarse treatment to large units and the fine treatment to subdivisions of them — a **split-plot** design, named after the field trials it came from. Two independent randomizations mean two error terms, so that an analysis ignoring the distinction gets both wrong, in opposite directions.

33.1.1 The design and its randomization

Take r blocks. Each is divided into a **whole plots**, carrying the a levels of a factor A in random order: a randomized complete block design (Definition 18.4.1). Each whole plot is then divided into b **subplots**, carrying the b levels of a factor C in random order. The two randomizations are independent, and the second is repeated separately inside every whole plot. Figure 33.1.1 shows one such layout.

Two things vary from subplot to subplot: whatever makes whole plots differ, shared by all b subplots of a whole plot, and whatever makes subplots differ within a whole plot, which is not. So the model carries two error terms.

Definition 33.1.1 — The balanced split-plot model

Index blocks by $i = 1, \dots, r$, whole-plot treatments by $j = 1, \dots, a$ and subplot treatments by $k = 1, \dots, b$, and write y_{ijk} for the response on the subplot of block i receiving whole-plot treatment j and subplot treatment k . The **split-plot model** is

$$y_{ijk} = \mu + \xi_i + \omega_j + \eta_{ij} + \tau_k + \gamma_{jk} + e_{ijk}, \quad (33.1.1)$$

where ξ_i , ω_j , τ_k and γ_{jk} are fixed effects, the η_{ij} are uncorrelated **whole-plot errors** with mean zero and variance σ_w^2 , the e_{ijk} are uncorrelated **subplot errors** with mean zero and variance σ_s^2 , and the two sets are uncorrelated with each other. The **normal split-plot model** takes both sets to be normal.

The whole plot (i, j) is a cluster of b observations that share η_{ij} . Writing $\mathbf{Z}_w$ for the $n \times ra$ matrix of whole-plot indicators, with $n = rab$, the combined error $\eta_{ij} + e_{ijk}$ has

$$\text{Cov}(\mathbf{Y}) = \mathbf{V} = \sigma_s^2 \mathbf{I} + \sigma_w^2 \mathbf{Z}_w \mathbf{Z}_w^\top = \sigma_s^2 \mathbf{I} + b \sigma_w^2 \mathbf{P}_W, \quad (33.1.2)$$

where $\mathbf{P}_W = b^{-1} \mathbf{Z}_w \mathbf{Z}_w^\top$ replaces every observation by its whole-plot mean (Example (The one-way layout)). Every pair of subplots in a whole plot has correlation $\rho = \sigma_w^2 / (\sigma_w^2 + \sigma_s^2)$, pairs in different whole plots none. The next section studies this structure in general; here balance makes everything explicit.

Where does the equicorrelation come from? In a randomized experiment, random assignment plus unit-treatment additivity *produces* the model rather than assuming it (Section 15.1), and here the argument runs twice: the second randomization is performed anew in every whole plot, making the subplots of a whole plot exchangeable — exactly the covariance Eq. 33.1.2. When the subplot factor is not randomized, as it is not when that factor is time (Section 33.3), the justification disappears and with it the equicorrelation.

33.1.2 Two strata

Order the observations with k fastest, then j , then i , and use the averaging and centring matrices $\bar{\mathbf{J}}_l$, $\mathbf{C}_l$ of Section 16.1. Define

$$\begin{aligned} \mathbf{P}_0 &= \bar{\mathbf{J}}_r \otimes \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b, & \mathbf{P}_B &= \mathbf{C}_r \otimes \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b, & \mathbf{P}_A &= \bar{\mathbf{J}}_r \otimes \mathbf{C}_a \otimes \bar{\mathbf{J}}_b, \\ \mathbf{P}_{AB} &= \mathbf{C}_r \otimes \mathbf{C}_a \otimes \bar{\mathbf{J}}_b, & \mathbf{P}_C &= \bar{\mathbf{J}}_r \otimes \bar{\mathbf{J}}_a \otimes \mathbf{C}_b, & \mathbf{P}_{AC} &= \bar{\mathbf{J}}_r \otimes \mathbf{C}_a \otimes \mathbf{C}_b, \end{aligned} \quad (33.1.3)$$

and $\mathbf{P}_E = \mathbf{C}_r \otimes \mathbf{I}_a \otimes \mathbf{C}_b$, the terms of the balanced three-way layout with one observation per cell (Theorem 16.3.1): $\mathbf{P}_{AB}$ is the block-by- A interaction, and $\mathbf{P}_E$ collects the block-by- C and three-factor interactions. The split-plot analysis rests on the fact that these seven projections fall into two groups according to how $\mathbf{V}$ acts on them.

Lemma 33.1.1 — The two error strata

Let $\mathbf{V}$ be as in Eq. 33.1.2 and put $\lambda_w = \sigma_s^2 + b \sigma_w^2$ and $\lambda_s = \sigma_s^2$. Then:

- $\mathbf{P}_W = \mathbf{I}_r \otimes \mathbf{I}_a \otimes \bar{\mathbf{J}}_b$, and $\mathbf{V} = \lambda_w \mathbf{P}_W + \lambda_s (\mathbf{I} - \mathbf{P}_W)$, so $\mathbf{V}$ has the two eigenvalues λ_w and λ_s with eigenspaces $\mathcal{C}(\mathbf{P}_W)$ and $\mathcal{C}(\mathbf{P}_W)^\perp$, of dimensions ra and $ra(b-1)$.
- The six matrices of Eq. 33.1.3 together with $\mathbf{P}_E$ are mutually orthogonal projections summing to $\mathbf{I}$, with ranks 1, $r-1$, $a-1$, $(r-1)(a-1)$, $b-1$, $(a-1)(b-1)$ and $(r-1)a(b-1)$.
- $\mathbf{P}_0, \mathbf{P}_B, \mathbf{P}_A, \mathbf{P}_{AB}$ have their ranges inside $\mathcal{C}(\mathbf{P}_W)$, and $\mathbf{P}_C, \mathbf{P}_{AC}, \mathbf{P}_E$ have their ranges inside $\mathcal{C}(\mathbf{P}_W)^\perp$. Hence $\mathbf{V}\mathbf{P} = \lambda_w \mathbf{P}$ for the first four and $\mathbf{V}\mathbf{P} = \lambda_s \mathbf{P}$ for the last three.

Proof.

- (a) The whole plot (i, j) consists of the b observations with those first two indices, so averaging within whole plots is $\mathbf{I}_r \otimes \mathbf{I}_a \otimes \bar{\mathbf{J}}_b$, which is symmetric and idempotent of rank ra by Lemma 16.1.1(b). Substituting $\mathbf{P}_W$ in Eq. 33.1.2 gives $\mathbf{V} = \sigma_s^2(\mathbf{I} - \mathbf{P}_W) + (\sigma_s^2 + b\sigma_w^2)\mathbf{P}_W$.
- (b) Ranks, symmetry and idempotence are Lemma 16.1.1(b), noting $\mathbf{P}_E = \mathbf{C}_r \otimes \bar{\mathbf{J}}_a \otimes \mathbf{C}_b + \mathbf{C}_r \otimes \mathbf{C}_a \otimes \mathbf{C}_b$. Distinct terms differ in at least one slot, so they are orthogonal by Lemma 16.1.1(c), and they are the 2^3 products of Lemma 16.1.1(d) regrouped, so they sum to $\mathbf{I}$.
- (c) A product $\mathbf{E}_1 \otimes \mathbf{E}_2 \otimes \bar{\mathbf{J}}_b$ satisfies $\mathbf{P}_W \mathbf{P} = \mathbf{P}$ by the mixed-product rule and $\bar{\mathbf{J}}_b \bar{\mathbf{J}}_b = \bar{\mathbf{J}}_b$; a product $\mathbf{E}_1 \otimes \mathbf{E}_2 \otimes \mathbf{C}_b$ satisfies $\mathbf{P}_W \mathbf{P} = \mathbf{0}$ because $\bar{\mathbf{J}}_b \mathbf{C}_b = \mathbf{0}$. The first four matrices are of the first kind and the last three of the second. Then $\mathbf{V} \mathbf{P} = \lambda_w \mathbf{P}_W \mathbf{P} + \lambda_s (\mathbf{P} - \mathbf{P}_W \mathbf{P})$ gives the two cases. ■

Part (c) is the whole idea. The **whole-plot stratum** $\mathcal{C}(\mathbf{P}_W)$ carries the whole-plot error intact, so its variance is λ_w ; in the **subplot stratum** $\mathcal{C}(\mathbf{P}_W)^\perp$ that error is differenced away and only σ_s^2 remains.

Idea. A split-plot design is two experiments sharing one field: a whole-plot experiment with ra units and error variance $\sigma_s^2 + b\sigma_w^2$, and a subplot experiment with rab units and error variance σ_s^2 . Effects constant within whole plots belong to the first and effects averaging to zero within every whole plot to the second — the interaction among them, which is why such a design studies an interaction well and the coarse main effect badly.

33.1.3 The analysis

Theorem 33.1.2 — The balanced split-plot design

Assume Eq. 33.1.1 with $r, a, b \geq 2$, and write the cell means $\mu_{ijk} = E(y_{ijk})$. Let $\mathbf{M}$ be the orthogonal projection onto the model space $\mathcal{C}(\mathbf{X}) = \mathcal{C}(\mathbf{P}_0 + \mathbf{P}_B + \mathbf{P}_A + \mathbf{P}_C + \mathbf{P}_{AC})$.

- (a) $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, so least squares is generalized least squares and every least squares estimate of an estimable function is its best linear unbiased estimator, whatever σ_w^2 and σ_s^2 are.
- (b) The sums of squares are those of the balanced three-way layout, with $\text{SS}_A = rb \sum_j (\bar{y}_{\cdot j \cdot} - \bar{y}_{\dots})^2$, $\text{SS}_C = ra \sum_k (\bar{y}_{\cdot \cdot k} - \bar{y}_{\dots})^2$, $\text{SS}_{AC} = r \sum_{j,k} (\bar{y}_{\cdot jk} - \bar{y}_{\cdot j \cdot} - \bar{y}_{\cdot \cdot k} + \bar{y}_{\dots})^2$, and the two error sums of squares $\text{SS}_{AB} = \|\mathbf{P}_{AB}\mathbf{y}\|^2$ and $\text{SSE} = \|\mathbf{P}_E\mathbf{y}\|^2$.
- (c) The expected mean squares (Theorem 9.6.1) are

$$\begin{aligned}
E MS_B &= \lambda_w + \frac{ab}{r-1} \sum_i (\xi_i - \bar{\xi})^2, & E MS_{AB} &= \lambda_w = \sigma_s^2 + b\sigma_w^2, \\
E MS_A &= \lambda_w + \frac{rb}{a-1} \sum_j (\alpha_j - \bar{\alpha})^2, & E MSE &= \lambda_s = \sigma_s^2, \\
E MS_C &= \lambda_s + \frac{ra}{b-1} \sum_k (\kappa_k - \bar{\kappa})^2, & E MS_{AC} &= \lambda_s + \frac{r}{(a-1)(b-1)} \sum_{j,k} \delta_{jk}^2,
\end{aligned} \tag{33.1.4}$$

where $\alpha_j = \omega_j + \bar{\gamma}_{j\cdot}$, $\kappa_k = \tau_k + \bar{\gamma}_{\cdot k}$ and $\delta_{jk} = \gamma_{jk} - \bar{\gamma}_{j\cdot} - \bar{\gamma}_{\cdot k} + \bar{\gamma}$ are the equal-weight effects of Definition 16.2.1 computed from $\bar{\mu}_{\cdot jk}$.

- (d) Under normality the six sums of squares are independent, $SS_{AB}/\lambda_w \sim \chi^2((r-1)(a-1))$, $SSE/\lambda_s \sim \chi^2((r-1)a(b-1))$, and

$$\frac{MS_A}{MS_{AB}} \sim F\left(a-1, (r-1)(a-1), \frac{rb}{\lambda_w} \sum_j (\alpha_j - \bar{\alpha})^2\right),$$

while MS_C/MSE and MS_{AC}/MSE have noncentral F distributions on $(b-1, (r-1)a(b-1))$ and $((a-1)(b-1), (r-1)a(b-1))$ degrees of freedom with noncentralities $ra \sum_k (\kappa_k - \bar{\kappa})^2/\lambda_s$ and $r \sum_{j,k} \delta_{jk}^2/\lambda_s$. So the whole-plot factor is tested against MS_{AB} and the subplot factor and the interaction against MSE .

- (e) A contrast $\sum_j c_j \alpha_j$ is estimated by $\sum_j c_j \bar{y}_{\cdot j}$ with variance $\lambda_w \sum_j c_j^2/(rb)$; a contrast $\sum_k d_k \kappa_k$ is estimated by $\sum_k d_k \bar{y}_{\cdot k}$ with variance $\lambda_s \sum_k d_k^2/(ra)$. Both are best linear unbiased, and the two estimators are uncorrelated.
- (f) Fix a subplot treatment k and a contrast $\sum_j c_j = 0$. The simple effect $\sum_j c_j \bar{\mu}_{\cdot jk}$ is estimated by $\sum_j c_j \bar{y}_{\cdot jk}$, best linear unbiased, with variance

$$\left(\sum_j c_j^2\right) \frac{\lambda_w + (b-1)\lambda_s}{rb} = \left(\sum_j c_j^2\right) \frac{\sigma_w^2 + \sigma_s^2}{r}, \tag{33.1.5}$$

which belongs to neither stratum: no single mean square estimates it, and the unbiased estimate is the combination $(\sum_j c_j^2)\{MS_{AB} + (b-1)MSE\}/(rb)$.

Proof.

- (a) Every $\mathbf{v} \in \mathcal{C}(\mathbf{X})$ splits as $\mathbf{v} = \mathbf{v}_1 + \mathbf{v}_2$ with $\mathbf{v}_1 \in \mathcal{C}(\mathbf{P}_0 + \mathbf{P}_B + \mathbf{P}_A)$ and $\mathbf{v}_2 \in \mathcal{C}(\mathbf{P}_C + \mathbf{P}_{AC})$, because the five projections are mutually orthogonal and sum to $\mathbf{M}$. By Lemma 33.1.1(c), $\mathbf{V}\mathbf{v} = \lambda_w \mathbf{v}_1 + \lambda_s \mathbf{v}_2$, again in $\mathcal{C}(\mathbf{X})$. So $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, and Theorem 6.9.3 says the ordinary and the $\mathbf{V}^{-1}$ projection onto $\mathcal{C}(\mathbf{X})$ coincide. The estimator is therefore both the least squares and the generalized least squares estimator, which is the best linear unbiased estimator by Corollary 7.2.3. (This is the balanced case of Theorem 31.2.2.)
- (b) Each projection averages over the slots carrying $\bar{\mathbf{J}}$ and centres in the slots carrying $\mathbf{C}$. For instance $\mathbf{P}_A = \bar{\mathbf{J}}_r \otimes \mathbf{I}_a \otimes \bar{\mathbf{J}}_b - \bar{\mathbf{J}}_r \otimes \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b$ puts $\bar{y}_{\cdot j\cdot} - \bar{y}_{\cdot\cdot\cdot}$ in position (i, j, k) , a value repeated rb times, giving SS_A ; the same expansion gives SS_C and SS_{AC} , as in Theorem 16.3.1(b). The error sums of squares are the squared lengths of the remaining components.
- (c) Each $\mathbf{P}$ in the list satisfies $\mathbf{V}\mathbf{P} = \lambda\mathbf{P}$ with λ the eigenvalue of its stratum, so $E(\mathbf{Y}^\top \mathbf{P}\mathbf{Y}) = \text{tr}(\mathbf{P}\mathbf{V}) + \boldsymbol{\mu}^\top \mathbf{P}\boldsymbol{\mu} = \lambda \text{rank}(\mathbf{P}) + \|\mathbf{P}\boldsymbol{\mu}\|^2$ by Theorem 2.3.1, where $\boldsymbol{\mu}$

is the mean vector. Dividing by the rank gives $E(\text{MS}) = \lambda + \|\mathbf{P}\boldsymbol{\mu}\|^2 / \text{rank}(\mathbf{P})$. It remains to evaluate $\mathbf{P}\boldsymbol{\mu}$. Since $\boldsymbol{\mu}$ has entries $\mu + \xi_i + \omega_j + \tau_k + \gamma_{jk}$, the projection $\mathbf{P}_A$ returns $\bar{\mu}_{\cdot j} - \bar{\mu}_{\dots} = \alpha_j - \bar{\alpha}$ on each of the rb observations with whole-plot treatment j ; likewise $\mathbf{P}_C$ returns $\kappa_k - \bar{\kappa}$ on each of ra observations, $\mathbf{P}_{AC}$ returns δ_{jk} on each of r , and $\mathbf{P}_B$ returns $\xi_i - \bar{\xi}$ on each of ab . Finally $\mathbf{P}_{AB}\boldsymbol{\mu} = \mathbf{0}$ and $\mathbf{P}_E\boldsymbol{\mu} = \mathbf{0}$, because $\boldsymbol{\mu}$ has no block-by-treatment terms.

- (d) Write $\mathbf{V}^{1/2} = \lambda_w^{1/2}\mathbf{P}_W + \lambda_s^{1/2}(\mathbf{I} - \mathbf{P}_W)$, a symmetric positive definite square root (Theorem 1.7.6), and put $\mathbf{z} = \mathbf{V}^{-1/2}\mathbf{Y} \sim N_n(\mathbf{V}^{-1/2}\boldsymbol{\mu}, \mathbf{I})$ (Proposition 2.2.4). For any $\mathbf{P}$ in the list, Lemma 33.1.1(c) gives $\mathbf{V}^{1/2}\mathbf{P}\mathbf{V}^{1/2} = \lambda\mathbf{P}$, so $\mathbf{Y}^\top\mathbf{P}\mathbf{Y} = \lambda\mathbf{z}^\top\mathbf{P}\mathbf{z}$. The projections are mutually orthogonal, so Theorem 4.4.4 applied to $\mathbf{z}$ makes the quadratic forms $\mathbf{z}^\top\mathbf{P}\mathbf{z}$ independent with noncentral chi-squared distributions on $\text{rank}(\mathbf{P})$ degrees of freedom and noncentrality $\|\mathbf{P}\mathbf{V}^{-1/2}\boldsymbol{\mu}\|^2 = \|\mathbf{P}\boldsymbol{\mu}\|^2/\lambda$, the last equality because $\mathbf{V}^{-1/2}$ acts on $\mathcal{C}(\mathbf{P})$ as multiplication by $\lambda^{-1/2}$. Forming ratios and cancelling λ between numerator and denominator *within the same stratum* gives the stated F distributions (Definition 4.1.2). Ratios across strata would not cancel, which is precisely why MS_A/MSE is not an F statistic.
- (e) The coefficient vector of $\sum_j c_j \bar{y}_{\cdot j}$ is $\boldsymbol{\rho} = (rb)^{-1}\mathbf{1}_r \otimes \mathbf{c} \otimes \mathbf{1}_b \in \mathcal{C}(\mathbf{P}_A)$, since $\mathbf{c} \perp \mathbf{1}_a$, so by Lemma 33.1.1(c) $\text{Var}(\boldsymbol{\rho}^\top\mathbf{Y}) = \lambda_w\|\boldsymbol{\rho}\|^2 = \lambda_w \sum_j c_j^2/(rb)$. The same computation with $\boldsymbol{\rho}_C = (ra)^{-1}\mathbf{1}_r \otimes \mathbf{1}_a \otimes \mathbf{d} \in \mathcal{C}(\mathbf{P}_C)$ gives the second variance, and the two are uncorrelated because $\boldsymbol{\rho}^\top\boldsymbol{\rho}_C = 0$. Both are least squares estimates of estimable functions, hence best linear unbiased by (a).
- (f) Split $\mathbf{e}_k = b^{-1}\mathbf{1}_b + (\mathbf{e}_k - b^{-1}\mathbf{1}_b)$. The coefficient vector $r^{-1}\mathbf{1}_r \otimes \mathbf{c} \otimes \mathbf{e}_k$ splits accordingly into $\boldsymbol{\rho}_1 \in \mathcal{C}(\mathbf{P}_A)$ and $\boldsymbol{\rho}_2 \in \mathcal{C}(\mathbf{P}_{AC})$, of squared lengths $\sum_j c_j^2/(rb)$ and $(b-1)\sum_j c_j^2/(rb)$. They lie in different strata and are orthogonal, so the variance is $\lambda_w\|\boldsymbol{\rho}_1\|^2 + \lambda_s\|\boldsymbol{\rho}_2\|^2$, which is Eq. 33.1.5; the estimate of it is unbiased by Eq. 33.1.4, and the estimator is best linear unbiased by (a).

■

Dropping $(\xi\omega)_{ij}$ from a full three-way model is what turns the block-by- A interaction into the error term for A , on only $(r-1)(a-1)$ degrees of freedom: the formal content of “whole plots are the experimental units for A ”. And MS_A tests a contrast in $\alpha_j = \omega_j + \bar{\gamma}_{j\cdot}$, the whole-plot effect averaged over the subplot treatments used, not in ω_j alone (Section 16.2).

Part (f) is the case most often got wrong. “The interaction is tested against MSE” tempts one to compare two whole-plot treatments *within a single subplot treatment* against MSE too; but that comparison carries the whole-plot error intact, and Eq. 33.1.5 prices it between the two strata. Its estimated variance combines two mean squares, so no exact t or F test exists, and Satterthwaite’s rule (Proposition 32.5.1) gives it

$$\nu = \frac{\{\text{MS}_{AB} + (b-1)\text{MSE}\}^2}{\text{MS}_{AB}^2/\{(r-1)(a-1)\} + (b-1)^2\text{MSE}^2/\{(r-1)a(b-1)\}} \quad (33.1.6)$$

approximate degrees of freedom, which lie between the two exact values.

Example. (An irrigation and variety trial)

Four fields are each divided into three whole plots, and the regimes flood, sprinkler and drip are assigned at random within each field; each whole plot is divided into four

subplots carrying four barley varieties in random order, giving $n = 48$ yields in tonnes per hectare, simulated from Eq. 33.1.1 with $\sigma_w = 0.35$ and $\sigma_s = 0.25$ t/ha. The analysis of variance is

Source	df	SS	MS	F	p
blocks	3	9.471	3.157		
irrigation A	2	9.215	4.608	10.637	0.0106
whole-plot error	6	2.599	0.433		
variety C	3	1.755	0.585	9.442	0.0002
irrigation $\times$ variety	6	0.958	0.160	2.577	0.0419
subplot error	27	1.673	0.062		

The two error mean squares differ by a factor of seven. Solving Eq. 33.1.4 gives $\hat{\sigma}_s = \sqrt{\text{MSE}} = 0.2489$ and $\hat{\sigma}_w = \sqrt{(\text{MS}_{AB} - \text{MSE})/b} = 0.3046$, close to the generating values.

The irrigation means are 4.8075, 5.8000 and 5.6575 t/ha; a difference of two has standard error $\sqrt{2 \text{MS}_{AB}/(rb)} = 0.2327$ on 6 degrees of freedom, so drip beats flood by 0.8500 t/ha with $t = 3.653$. The variety means are 5.134, 5.364, 5.574 and 5.614, and a difference of two has standard error $\sqrt{2 \text{MSE}/(ra)} = 0.1016$ on 27 degrees of freedom — more than twice as precise, from the same 48 observations. Comparing drip with flood for one variety is neither: by Eq. 33.1.5 its standard error is $\sqrt{\{\text{MS}_{AB} + 3 \text{MSE}\}/8} = 0.2782$, on 11.77 Satterthwaite degrees of freedom.

```
import numpy as np

r, a, b = 4, 3, 4                                # blocks, irrigation regimes,
    varieties
n = r * a * b
block_eff = np.array([-0.30, 0.10, 0.05, 0.15])  # field-to-field fertility
irrig_eff = np.array([0.00, 0.45, 0.70])         # flood, sprinkler, drip
variety_eff = np.array([-0.30, -0.10, 0.15, 0.25])
inter = np.array([[0.10, -0.05, -0.10, 0.05],   # irrigation x variety
                  [-0.05, 0.10, 0.00, -0.05],
                  [-0.05, -0.05, 0.10, 0.00]])
sigma_w, sigma_s = 0.35, 0.25                   # whole-plot and subplot errors

rng = np.random.default_rng(3301)
eta = rng.normal(0, sigma_w, (r, a))            # one error per whole plot
e = rng.normal(0, sigma_s, (r, a, b))           # one error per subplot
mean = (5.0 + block_eff[:, None, None] + irrig_eff[None, :, None]
        + variety_eff[None, None, :] + inter[None, :, :])
Y = np.round(mean + eta[:, :, None] + e, 2)     # yields, t/ha
y = Y.reshape(-1)                               # stacked block, then regime,
    then variety
```

The analysis is seven inner products, each projection a Kronecker product as in Section 16.3, with two denominators in place of one.

```
from scipy import stats

def Jbar(k):
    return np.full((k, k), 1.0 / k)

    p = stats.f.sf(F, df[name], d)
    print(f"{name:22s} F({df[name]}, {d}) = {F:7.3f}    p = {p:.4f}")

```

33.1.4 What pooling costs

Pool the two error sums of squares into one residual mean square on 33 degrees of freedom — in [Example \(An irrigation and variety trial\)](#), 0.129 — and by [Eq. 33.1.4](#) the consequences are opposite in the two strata. The whole-plot denominator falls towards λ_s , inflating the irrigation F to 35.591 on (2, 33) degrees of freedom, $p = 5.78 \times 10^{-9}$ against 0.0106, and shrinking the standard error of an irrigation difference from 0.2327 to 0.1272, a factor of 1.829 too small; the subplot denominator exceeds λ_s , and that of a variety difference rises from 0.1016 to 0.1469, a factor of 1.445 too large. Pooling manufactures significance for the treatment the design studies badly and destroys it for the one it studies well.

Warning. The two error terms are a property of the *randomization*, not of the data. A split-plot experiment analysed as a completely randomized three-factor experiment produces a plausible table with one residual line, and nothing in the numbers announces the mistake. Wherever one factor is applied to groups of units and another within them, look for two errors.

33.1.5 The same analysis as a mixed model

[Eq. 33.1.1](#) is a linear mixed model ([Definition 32.2.1](#)) with $\mathbf{Z} = \mathbf{Z}_w$, $\mathbf{G} = \sigma_w^2 \mathbf{I}_{ra}$ and $\mathbf{R} = \sigma_s^2 \mathbf{I}_n$, whose marginal covariance $\mathbf{ZGZ}^\top + \mathbf{R}$ is [Eq. 33.1.2](#). In the balanced case, fitting it by restricted maximum likelihood ([Definition 32.4.1](#)) reproduces the analysis above exactly, provided $\text{MS}_{AB} \geq \text{MSE}$: the restricted likelihood depends on the data only through the two mean squares, and is maximized at the moment estimates of [Example \(An irrigation and variety trial\)](#) ([Exercise \(B2\)](#)). Satterthwaite's rule ([Proposition 32.5.1](#)) then returns exactly $(r-1)(a-1)$ degrees of freedom for a whole-plot contrast, and [Eq. 33.1.6](#) for a simple effect.

The route earns its keep when the balance fails: a missing subplot, a whole plot lost to flooding, a covariate measured at the subplot level. The strata are then no longer orthogonal, no mean square estimates λ_w or λ_s on its own, and Henderson's equations ([Theorem 32.3.2](#)) do the computing. Two variations change nothing essential: the whole-plot design may be completely randomized or a Latin square ([Definition 18.5.1](#)), which changes only the whole-plot degrees of freedom, and splitting can be repeated, giving three strata ([Exercise \(C1\)](#)).

33.1.6 Exercises

33.1.6.1 A. Check your understanding

Exercise A1.

For the design of [Example \(An irrigation and variety trial\)](#), say which stratum each of the following belongs to, and on how many degrees of freedom its error is estimated: the difference between two block means; between two variety means; between two irrigation means; between two varieties within the drip regime; the difference in the effect of drip versus flood between two varieties; and the difference between drip and flood for the first variety alone.

Solution. The block and irrigation differences are constant within whole plots, so they lie in the whole-plot stratum and use MS_{AB} on 6 degrees of freedom. The next three are contrasts summing to zero within each whole plot, so they lie in the subplot stratum and use MSE on 27 degrees of freedom. The last lies in neither: it is [Theorem 33.1.2\(f\)](#), with estimated variance $\{MS_{AB} + 3MSE\}/8$ on about 11.8 Satterthwaite degrees of freedom.

Exercise A2.

With r , a , σ_w^2 and σ_s^2 fixed, what happens to the variance of a whole-plot contrast, and to that of a subplot contrast, as b grows? Which kind of comparison does adding subplots help?

33.1.6.2 B. Practice

Exercise B1.

Verify [Theorem 33.1.2\(a\)](#) directly from [Theorem 6.9.3](#) by computing $\mathbf{V}\mathbf{X}$ for the model matrix $\mathbf{X} = [\mathbf{1}, \mathbf{B}, \mathbf{A}, \mathbf{C}, \mathbf{AC}]$ of indicator columns. Then show that adding the block-by- A columns leaves the condition true but destroys the analysis, and say why.

Exercise B2.

Show that for the balanced split-plot model the restricted likelihood of (σ_w^2, σ_s^2) depends on the data only through SS_{AB} and SSE , and that it is maximized at $\hat{\lambda}_w = MS_{AB}$, $\hat{\lambda}_s = MSE$ provided $MS_{AB} \geq MSE$. *Hint:* the error contrasts span $\mathcal{C}(\mathbf{P}_{AB}) \oplus \mathcal{C}(\mathbf{P}_E)$, and $\mathbf{V}$ acts as a scalar on each.

Solution. The error contrasts are the $\mathbf{a}^\top \mathbf{y}$ with $\mathbf{a} \in \mathcal{C}(\mathbf{X})^\perp = \mathcal{C}(\mathbf{P}_{AB}) \oplus \mathcal{C}(\mathbf{P}_E)$. Take orthonormal bases of the two summands, of sizes $f_w = (r-1)(a-1)$ and $f_s = (r-1)a(b-1)$. By Lemma 33.1.1(c) the transformed data are independent, $N(0, \lambda_w)$ for the first basis and $N(0, \lambda_s)$ for the second. By Definition 32.4.1 the restricted log likelihood is therefore $-\frac{1}{2}\{f_w \log \lambda_w + \text{SS}_{AB}/\lambda_w + f_s \log \lambda_s + \text{SSE}/\lambda_s\}$ up to a constant, a sum of two ordinary normal-variance likelihoods maximized at the two mean squares. Since $\sigma_s^2 = \lambda_s$ and $\sigma_w^2 = (\lambda_w - \lambda_s)/b$, the constraint $\sigma_w^2 \geq 0$ is $\text{MS}_{AB} \geq \text{MSE}$.

33.1.6.3 C. Going deeper

Exercise C1.

A split-split-plot design divides each subplot into c sub-subplots and randomizes a third factor D among them, adding an error ζ_{ijk} of variance σ_u^2 shared by the sub-subplots of a subplot. Write down the covariance matrix in the style of Eq. 33.1.2, find its three eigenvalues and eigenspaces, and state which effects are tested against which of the three error mean squares.

33.2 Clustered data and compound symmetry

Whole plots are one instance of a pattern that is everywhere in applied work: observations arrive in groups — households, schools, hospitals, litters, survey clusters — and within a group resemble one another more than they resemble observations from elsewhere. The simplest description gives every pair within a group the same correlation and every pair across groups none. What that does to least squares is sharp and exactly computable: it inflates the variance of some coefficients and *deflates* that of others.

33.2.1 The equicorrelated cluster model

Definition 33.2.1 — Clustered errors with compound symmetry

The n observations fall into G **clusters**, cluster g containing m_g of them, with $n = \sum_g m_g$. The model is $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $E\boldsymbol{\varepsilon} = \mathbf{0}$ and

$$\text{Cov}(\boldsymbol{\varepsilon}) = \mathbf{V} = \text{diag}(\boldsymbol{\Sigma}_1, \dots, \boldsymbol{\Sigma}_G), \quad \boldsymbol{\Sigma}_g = \sigma^2 \{(1-\rho)\mathbf{I}_{m_g} + \rho \mathbf{1}\mathbf{1}^\top\}, \quad (33.2.1)$$

a block diagonal matrix with one block per cluster. This covariance is called **compound symmetry** or **equicorrelation**, and ρ is the **intraclass correlation**. The matrix is positive definite iff $-1/(\max_g m_g - 1) < \rho < 1$. The clusters are **balanced** if $m_g = m$ for all g .

Compound symmetry is what a single shared random effect produces: if $\varepsilon_i = u_{g(i)} + e_i$ with u_g and e_i uncorrelated, of variances σ_u^2 and σ_e^2 , then Eq. 33.2.1 holds with $\sigma^2 = \sigma_u^2 + \sigma_e^2$

and $\rho = \sigma_u^2/\sigma^2$ — the one-way random effects model of [Proposition 32.1.1](#) and [Exercise \(B1\)](#), whose power to inflate an F statistic was met at [Exercise \(C1\)](#). So read, ρ is the fraction of variance attributable to the cluster and is nonnegative; negative intraclass correlations occur — a fixed quota within a cluster, competition among littermates — but not from a random-effect representation.

The results below take the clusters balanced, $m_g = m$; the clean statements fail otherwise ([Exercise \(B2\)](#)), balance being what makes the two strata of [Lemma 33.1.1](#) eigenspaces of $\mathbf{V}$.

33.2.2 Which coefficients suffer

Call $\mathbf{v}$ **cluster-constant** if it is constant on every cluster and **cluster-centred** if its entries sum to zero within every cluster. With $\mathbf{P}_W$ the orthogonal projection replacing each entry by its cluster mean, the two conditions are $\mathbf{P}_W \mathbf{v} = \mathbf{v}$ and $\mathbf{P}_W \mathbf{v} = \mathbf{0}$, and every vector is the sum of one of each.

Proposition 33.2.1 — Compound symmetry and the design effect

Let [Eq. 33.2.1](#) hold with $m_g = m$ for all g , let $\lambda_w = \sigma^2\{1 + (m-1)\rho\}$ and $\lambda_s = \sigma^2(1 - \rho)$, and let $\text{rank}(\mathbf{X}) = p$.

- (a) $\mathbf{V} = \lambda_w \mathbf{P}_W + \lambda_s (\mathbf{I} - \mathbf{P}_W)$. Its eigenvalues are λ_w with multiplicity G and λ_s with multiplicity $n - G$, and

$$\mathbf{V}^{-1} = \frac{1}{\lambda_s} \left(\mathbf{I} - \frac{m\rho}{1 + (m-1)\rho} \mathbf{P}_W \right).$$

- (b) $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ iff $\mathcal{C}(\mathbf{P}_W \mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$. In particular, if $\mathbf{X} = [\mathbf{X}_b, \mathbf{X}_w]$ with every column of $\mathbf{X}_b$ cluster-constant and every column of $\mathbf{X}_w$ cluster-centred, then least squares is generalized least squares and every least squares estimate of an estimable function is best linear unbiased.
- (c) Let $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ be estimable and let $\mathbf{c} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-\boldsymbol{\lambda}}$, so that $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} = \mathbf{c}^\top \mathbf{y}$. If $\mathbf{c}$ is cluster-constant then

$$\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}) = \{1 + (m-1)\rho\} \cdot \sigma^2 \|\mathbf{c}\|^2,$$

and if $\mathbf{c}$ is cluster-centred then $\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}) = (1 - \rho) \sigma^2 \|\mathbf{c}\|^2$. In both cases $\sigma^2 \|\mathbf{c}\|^2$ is the variance the estimate would have under $\text{Cov}(\boldsymbol{\epsilon}) = \sigma^2 \mathbf{I}$; the multiplier is the **design effect**. In either case $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}$ is best linear unbiased even if (b) fails.

- (d) Suppose $\mathcal{C}(\mathbf{X}) = \mathcal{S}_b \oplus \mathcal{S}_w$ with $\mathcal{S}_b \subseteq \mathcal{C}(\mathbf{P}_W)$ of dimension p_b and $\mathcal{S}_w \subseteq \mathcal{C}(\mathbf{P}_W)^\perp$ of dimension $p_w = p - p_b$. Then the usual residual mean square has

$$E(s^2) = \frac{\lambda_w(G - p_b) + \lambda_s(n - G - p_w)}{n - p}, \quad (33.2.2)$$

and for any $\mathbf{c}$ as in (c) the usual variance estimate $v = s^2 \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-\boldsymbol{\lambda}}$ satisfies $E(v)/\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}) = E(s^2)/\lambda$, with $\lambda = \lambda_w$ or λ_s according to the stratum of $\mathbf{c}$.

Proof.

- (a) Within one cluster, $\mathbf{1}\mathbf{1}^\top = m\bar{\mathbf{J}}_m$, so the block is $\sigma^2\{(1 - \rho)\mathbf{I}_m + m\rho\bar{\mathbf{J}}_m\} = \lambda_s(\mathbf{I}_m -$

$\bar{\mathbf{J}}_m) + \lambda_w \bar{\mathbf{J}}_m$, using $\lambda_s + m\rho\sigma^2 = \lambda_w$. Assembling the blocks gives the stated form, since $\mathbf{P}_W$ is block diagonal with blocks $\bar{\mathbf{J}}_m$. A matrix $\lambda_w \mathbf{P} + \lambda_s(\mathbf{I} - \mathbf{P})$ with $\mathbf{P}$ an orthogonal projection of rank G has the two eigenvalues with those multiplicities and inverse $\lambda_w^{-1} \mathbf{P} + \lambda_s^{-1}(\mathbf{I} - \mathbf{P}) = \lambda_s^{-1} \{\mathbf{I} - (1 - \lambda_s/\lambda_w)\mathbf{P}\}$, and $1 - \lambda_s/\lambda_w = m\rho/\{1 + (m-1)\rho\}$.

- (b) By (a), $\mathbf{V}\mathbf{X} = \lambda_s \mathbf{X} + (\lambda_w - \lambda_s)\mathbf{P}_W \mathbf{X}$, so $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ iff $\mathcal{C}(\mathbf{P}_W \mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ (the case $\lambda_w = \lambda_s$, that is $\rho = 0$, being trivial). Under the stated partition, $\mathbf{P}_W \mathbf{X}_b = \mathbf{X}_b$ and $\mathbf{P}_W \mathbf{X}_w = \mathbf{0}$, so $\mathcal{C}(\mathbf{P}_W \mathbf{X}) = \mathcal{C}(\mathbf{X}_b) \subseteq \mathcal{C}(\mathbf{X})$. The conclusion is [Theorem 6.9.3](#) together with [Corollary 7.2.3](#), as in [Theorem 33.1.2\(a\)](#); the general statement is [Theorem 31.2.2](#).
- (c) $\text{Var}(\mathbf{c}^\top \mathbf{Y}) = \mathbf{c}^\top \mathbf{V} \mathbf{c}$. If $\mathbf{P}_W \mathbf{c} = \mathbf{c}$ then $\mathbf{V} \mathbf{c} = \lambda_w \mathbf{c}$ and the variance is $\lambda_w \|\mathbf{c}\|^2$; if $\mathbf{P}_W \mathbf{c} = \mathbf{0}$ then it is $\lambda_s \|\mathbf{c}\|^2$. Under $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$ it would be $\sigma^2 \|\mathbf{c}\|^2$, and dividing gives the two multipliers. For the last claim, write λ for λ_w or λ_s according to the stratum of $\mathbf{c}$, so that $\mathbf{V} \mathbf{c} = \lambda \mathbf{c}$ in either case, and let $\mathbf{a}^\top \mathbf{Y}$ be any linear unbiased estimate of $\lambda^\top \boldsymbol{\beta}$. Then $\mathbf{X}^\top (\mathbf{a} - \mathbf{c}) = \mathbf{0}$, so $\mathbf{a} = \mathbf{c} + \mathbf{d}$ with $\mathbf{d} \perp \mathcal{C}(\mathbf{X})$ and in particular $\mathbf{c}^\top \mathbf{d} = 0$. The cross term $\mathbf{c}^\top \mathbf{V} \mathbf{d} = \lambda \mathbf{c}^\top \mathbf{d}$ vanishes and

$$\mathbf{a}^\top \mathbf{V} \mathbf{a} = \lambda \|\mathbf{c}\|^2 + \mathbf{d}^\top \mathbf{V} \mathbf{d} \geq \lambda \|\mathbf{c}\|^2,$$

with equality iff $\mathbf{d}^\top \mathbf{V} \mathbf{d} = 0$, that is $\mathbf{d} = \mathbf{0}$, $\mathbf{V}$ being positive definite. So $\mathbf{c}^\top \mathbf{Y}$ is the unique best linear unbiased estimate. This is the criterion behind [Theorem 31.2.2](#): a linear estimate $\mathbf{c}^\top \mathbf{Y}$ of an estimable function is best as soon as $\mathbf{V} \mathbf{c} \in \mathcal{C}(\mathbf{X})$.

- (d) By [Theorem 19.2.2\(b\)](#), whose part (b) uses $\mathbf{X}$ only through $\mathbf{M}$ and $\text{rank}(\mathbf{X}) = p$ and so holds verbatim here, $E(s^2) = \text{tr}\{(\mathbf{I} - \mathbf{M})\mathbf{V}\}/(n - p)$ with $\mathbf{M}$ the projection onto $\mathcal{C}(\mathbf{X})$. Now $\text{tr}\{(\mathbf{I} - \mathbf{M})\mathbf{V}\} = \lambda_w \text{tr}\{(\mathbf{I} - \mathbf{M})\mathbf{P}_W\} + \lambda_s \text{tr}\{(\mathbf{I} - \mathbf{M})(\mathbf{I} - \mathbf{P}_W)\}$. Because $\mathbf{M} = \mathbf{P}_{S_b} + \mathbf{P}_{S_w}$ with $\mathbf{P}_{S_b} \mathbf{P}_W = \mathbf{P}_{S_b}$ and $\mathbf{P}_{S_w} \mathbf{P}_W = \mathbf{0}$,

$$\text{tr}\{(\mathbf{I} - \mathbf{M})\mathbf{P}_W\} = \text{tr}(\mathbf{P}_W) - \text{tr}(\mathbf{P}_{S_b}) = G - p_b,$$

and similarly $\text{tr}\{(\mathbf{I} - \mathbf{M})(\mathbf{I} - \mathbf{P}_W)\} = (n - G) - p_w$. This gives [Eq. 33.2.2](#). Finally $v = s^2 \|\mathbf{c}\|^2$ because $\|\mathbf{c}\|^2 = \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda} = \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda}$ for estimable $\boldsymbol{\lambda}$, so $E(v)/\text{Var}(\mathbf{c}^\top \mathbf{Y}) = E(s^2) \|\mathbf{c}\|^2 / (\lambda \|\mathbf{c}\|^2)$.

■

The design effect cuts both ways. A regressor measured at the cluster level — the school's curriculum, the village's water supply — is cluster-constant, and its variance is multiplied by $1 + (m - 1)\rho$: with $m = 50$ and $\rho = 0.05$ the factor is 3.45, so 5000 pupils in 100 schools carry the information of about 1450 independent pupils, the **effective sample size** $n/\{1 + (m - 1)\rho\}$. Since the factor grows linearly in m , extra clusters buy far more than extra members per cluster ([Exercise \(A2\)](#)). A cluster-centred regressor is in the opposite position: its design effect $1 - \rho$ is less than one, the shared component cancelling out of within-cluster comparisons — the subplot stratum again.

Idea. Clustering does not simply lose information; it moves it from between-cluster to within-cluster comparisons. A design that can ask its question within clusters gains, one that must ask it between clusters loses, in proportion to the cluster size.

Part (d) says what the usual output does with all this: s^2 averages $\mathbf{V}$ over the residual space while the variance of an estimate reads $\mathbf{V}$ along one direction, so reported and true variance stand in the ratio $E(s^2)/\lambda$, the same for every direction in a stratum.

Example. (Forty clusters of five)

Take $G = 40$ clusters of $m = 5$, with $\rho = 0.4$, $\sigma^2 = 1$, one cluster-level and one within-cluster regressor besides the intercept, so $p_b = 2$ and $p_w = 1$. Then $\lambda_w = 2.6$ and $\lambda_s = 0.6$, and the design effects are exactly 2.60 and 0.60, as the listing confirms from the full 200×200 covariance matrix. By Eq. 33.2.2, $E(s^2) = \{2.6(38) + 0.6(159)\}/197 = 0.9858$, so the reported variance of the cluster-level coefficient is 0.379 times the truth and that of the within-cluster coefficient 1.643 times the truth. A nominal 95% interval for the first is about 1.62 times too short, and the simulation below finds its coverage to be 0.759.

```
import numpy as np

m, rho, sigma2 = 5, 0.4, 1.0                                # cluster size, intraclass
                                                         # correlation

print("design effects (intercept, between, within):", deff.round(4))
print("predicted:", [1 + (m - 1) * rho, 1 + (m - 1) * rho, 1 - rho])
```

33.2.3 Standard errors that survive the model

Generalized least squares with the right $\mathbf{V}$ fixes everything, and by Proposition 33.2.1(b) is not even needed for the point estimate when the regressors split into cluster-constant and cluster-centred parts. But ρ is rarely known and compound symmetry is itself a guess. With many clusters the alternative is to keep ordinary least squares and estimate its covariance from the

clusters themselves: the sandwich idea of [Section 21.4](#) with the cluster in place of the observation. Writing $\mathbf{X}_g$ and $\hat{\boldsymbol{\varepsilon}}_g$ for the rows and least squares residuals of cluster g , the **cluster-robust** covariance estimator is, as in [Exercise \(C1\)](#),

$$\hat{\mathbf{U}}_{\text{CR}} = (\mathbf{X}^\top \mathbf{X})^{-1} \left(\sum_{g=1}^G \mathbf{X}_g^\top \hat{\boldsymbol{\varepsilon}}_g \hat{\boldsymbol{\varepsilon}}_g^\top \mathbf{X}_g \right) (\mathbf{X}^\top \mathbf{X})^{-1}. \quad (33.2.3)$$

Nothing about $\mathbf{V}$ is assumed except that different clusters are uncorrelated: within a cluster the covariance may be arbitrary, and may differ from cluster to cluster — far weaker than [Eq. 33.2.1](#).

Remark (Consistency of the cluster-robust estimator). Let the clusters be independent, cluster g contributing rows $\mathbf{X}_g$ and errors $\boldsymbol{\varepsilon}_g$ of mean zero and covariance $\boldsymbol{\Sigma}_g$, with p fixed, and assume (K1) $m_g \leq m_{\max}$ for all g , and $\mathbb{E}\|\boldsymbol{\varepsilon}_g\|^4 \leq K$; (K2) $\|\mathbf{x}_{(i)}\| \leq C$ for all i ; (K3) $n^{-1} \mathbf{X}^\top \mathbf{X} \rightarrow \mathbf{A}$, positive definite. Write $\mathbf{U} = \text{Cov}(\hat{\boldsymbol{\beta}}) = (\mathbf{X}^\top \mathbf{X})^{-1} (\sum_g \mathbf{X}_g^\top \boldsymbol{\Sigma}_g \mathbf{X}_g) (\mathbf{X}^\top \mathbf{X})^{-1}$. Then $n(\hat{\mathbf{U}}_{\text{CR}} - \mathbf{U}) \rightarrow \mathbf{0}$ in probability as $G \rightarrow \infty$; and if also $n^{-1} \sum_g \mathbf{X}_g^\top \boldsymbol{\Sigma}_g \mathbf{X}_g \rightarrow \mathbf{B}$, positive definite, then $\sqrt{n}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) \rightarrow N_p(\mathbf{0}, \mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-1})$ and the Wald statistic of a hypothesis $\mathbf{A}^\top \boldsymbol{\beta}$ of rank q , formed with $\hat{\mathbf{U}}_{\text{CR}}$, tends to $\chi^2(q)$.

The proof is that of [Theorem 21.4.2](#) with the cluster in place of the observation: the cluster score $\mathbf{s}_g = \mathbf{X}_g^\top \boldsymbol{\varepsilon}_g$ replaces $\mathbf{x}_{(i)} e_i$, every sum has G independent terms instead of n , and each bound goes through with $m_{\max} C$ in place of C ([Exercise \(C1\)](#)).

Note where the asymptotics live: $G \rightarrow \infty$, with cluster sizes bounded; the number of *observations* is irrelevant. A study of a million patients in eight hospitals has eight independent pieces of information about anything varying at the hospital level, and no covariance estimator manufactures more.

```
def cluster_sandwich(X, resid, g):
    """The cluster-robust covariance estimate: one outer product per cluster."""
    XtXinv = np.linalg.inv(X.T @ X)
    meat = np.zeros((X.shape[1], X.shape[1]))
    for k in np.unique(g):
        s = X[g == k].T @ resid[g == k]                # the cluster's score
        # contribution
        meat += np.outer(s, s)
    return XtXinv @ meat @ XtXinv

rng_one = np.random.default_rng(55)
n, p = X.shape
e_one = (np.linalg.cholesky(S) @ rng_one.standard_normal((m, G))).T.reshape(-1)
y_one = X[:, 1] + e_one                                # the between coefficient is 1
b_one = XtXinv @ X.T @ y_one
res_one = y_one - X @ b_one
s2_one = res_one @ res_one / (n - p)
se_naive_one = np.sqrt(s2_one * XtXinv[1, 1])
se_cr_one = np.sqrt(cluster_sandwich(X, res_one, g)[1, 1] * G / (G - 1))
se_true_one = np.sqrt(cov_true[1, 1])
print(f"between coefficient {b_one[1]:.4f}: naive se {se_naive_one:.4f}, "
      f"cluster-robust {se_cr_one:.4f}, true sd {se_true_one:.4f}")
```

On the data generated here the cluster-level coefficient is 1.0376 against a true value of 1, with a usual standard error of 0.0856, a cluster-robust one of 0.1600 (the listing scales the estimator by the simple factor $G/(G-1)$) and an exact standard deviation of 0.1239: the naive interval

Figure 33.2.1: (a) The design effect of Proposition 33.2.1(c): inflation $1 + (m - 1)\rho$ for a cluster-level regressor, deflation $1 - \rho$ for a within-cluster one. (b) Simulated coverage of nominal 95% intervals for a cluster-level coefficient, with $m = 5$ and $\rho = 0.4$.

is far too short, the robust one conservative on this sample.

Figure 33.2.1 shows the pattern over repeated samples, with the fuller correction $G/(G - 1) \cdot (n - 1)/(n - p)$. The naive interval covers about three quarters of the time — 0.757 to 0.781 across the six designs — whatever the number of clusters, its error being a bias rather than a variance. The cluster-robust interval is badly short with 8 clusters (coverage 0.874), still short with 20 (0.917) and acceptable by 160 (0.951); generalized least squares with the correct covariance is right throughout.

Warning. With few clusters the cluster-robust standard error is not a safe default: its bias is downward and substantial, and referring the statistic to $t(G - 1)$, the usual remedy and the one used in the figure, is not enough. Better are a bias correction of the residuals, a bootstrap over whole clusters (Exercise (C1)), or a covariance model fitted by restricted maximum likelihood, which does not need G large. Twenty clusters is a common rule of thumb; it is a floor, not a target.

33.2.4 Exercises

33.2.4.1 A. Check your understanding

Exercise A1.

Show from Proposition 33.2.1(a) that the compound symmetric matrix is positive definite iff $-1/(m - 1) < \rho < 1$, and that the random-effects representation $\varepsilon_i = u_{g(i)} + e_i$ forces $\rho \geq 0$. Give a mechanism that produces $\rho < 0$.

Exercise A2.

A trial can afford $n = 1200$ pupils and must randomize schools, not pupils, to the two

arms. The intraclass correlation of the outcome is $\rho = 0.10$. Compare the effective sample size for 12 schools of 100 pupils, 40 schools of 30, and 120 schools of 10.

Solution. The effective sample size is $n/\{1+(m-1)\rho\}$: $1200/10.9 = 110$, $1200/3.9 = 308$ and $1200/1.9 = 632$ pupils. As m grows the effective size tends to $n/(m\rho) = G/\rho$, which depends only on the number of schools. For a school-level treatment the number of schools is nearly the whole story, and pupils within a school are cheap but nearly redundant.

33.2.4.2 B. Practice

Exercise B1.

Let $\mathbf{X} = [\mathbf{X}_b, \mathbf{X}_w]$ as in Proposition 33.2.1(b), with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_b)$. Show that $\mathbf{M} = \mathbf{M}_b + \mathbf{M}_w$ with $\mathbf{M}_b$ and $\mathbf{M}_w$ the projections onto $\mathcal{C}(\mathbf{X}_b)$ and $\mathcal{C}(\mathbf{X}_w)$, that the residual sum of squares splits into a between-cluster and a within-cluster part, and that the two corresponding mean squares are unbiased for λ_w and λ_s .

Solution. Any column of $\mathbf{X}_b$ is fixed by $\mathbf{P}_W$ and any column of $\mathbf{X}_w$ is annihilated by it, so $\mathcal{C}(\mathbf{X}_b) \perp \mathcal{C}(\mathbf{X}_w)$ and Theorem 6.3.7 gives $\mathbf{M} = \mathbf{M}_b + \mathbf{M}_w$. Then $\mathbf{I} - \mathbf{M} = (\mathbf{P}_W - \mathbf{M}_b) + (\mathbf{I} - \mathbf{P}_W - \mathbf{M}_w)$, a sum of two orthogonal projections of ranks $G - p_b$ and $n - G - p_w$. By Proposition 33.2.1(a), $\mathbf{V}$ acts as λ_w on the range of the first and λ_s on the range of the second, so Theorem 2.3.1 gives the expectations $\lambda_w(G - p_b)$ and $\lambda_s(n - G - p_w)$. Dividing by the ranks gives the unbiased estimates, of which Eq. 33.2.2 is the pooled average.

Exercise B2.

Let the clusters have unequal sizes m_g . Show that $\mathbf{V}$ of Eq. 33.2.1 has eigenvalues $\sigma^2\{1 + (m_g - 1)\rho\}$, one per cluster, together with $\sigma^2(1 - \rho)$ with multiplicity $n - G$. Deduce that $\mathbf{1}$ is an eigenvector only if all clusters have the same size, so that the intercept alone breaks Proposition 33.2.1(b).

33.2.4.3 C. Going deeper

Exercise C1.

Carry out in detail the three steps of the cluster-sandwich argument above, with the constants: show that (K1)–(K3) give $\|\mathbf{X}_g\| \leq m_{\max}C$ and $E\|\mathbf{X}_g^\top \boldsymbol{\varepsilon}_g\|^2 \leq m_{\max}^2 C^2 K^{1/2}$; that $\text{Var}(\mathbf{a}^\top \mathbf{X}_g^\top (\boldsymbol{\varepsilon}_g \boldsymbol{\varepsilon}_g^\top - \boldsymbol{\Sigma}_g) \mathbf{X}_g \mathbf{a})$ is bounded uniformly in g ; and that $n^{-1} \sum_g \|\mathbf{t}_g\|^2 \leq m_{\max}^2 C^2 (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})^\top \mathbf{A}_n (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})$. Where exactly does the number of clusters, rather than of observations, enter?

Exercise C2.

Show that $E(\mathbf{X}_g^\top \hat{\boldsymbol{\varepsilon}}_g \hat{\boldsymbol{\varepsilon}}_g^\top \mathbf{X}_g) \neq \mathbf{X}_g^\top \boldsymbol{\Sigma}_g \mathbf{X}_g$ in general, by writing $\hat{\boldsymbol{\varepsilon}}_g = \boldsymbol{\varepsilon}_g - \mathbf{X}_g(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \boldsymbol{\varepsilon}$ and expanding, and show that the leading correction is of order p/G . Why is the bias downward, and what does this suggest about the factor $G/(G-1) \cdot (n-1)/(n-p)$ used

in the coverage simulation behind [Figure 33.2.1](#)?

33.3 Repeated measures

A repeated-measures study observes the same subject on several occasions: a clustered design whose cluster is the subject and whose “treatments” are the occasions, laid out like the split-plot design of [Section 33.1](#), and for many years analysed that way.

The analogy has one weak joint. What makes the split-plot covariance compound symmetric is the *randomization* of subplot treatments within the whole plot, and occasions cannot be randomized: measurements close together in time are more alike than distant ones, so compound symmetry here is usually false. What is remarkable is that the univariate F test survives a much weaker condition, and that the condition can be written down exactly.

33.3.1 The univariate analysis

Let $\mathbf{y}_1, \dots, \mathbf{y}_N$ be independent $N_m(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ vectors, one per subject, with $\boldsymbol{\Sigma}$ positive definite and unknown, and write y_{ij} for occasion j of subject i . The hypothesis of interest is

$$H : \mu_1 = \dots = \mu_m, \quad \text{that is,} \quad \boldsymbol{\mu} \in \text{span}\{\mathbf{1}\}.$$

Laid out with subjects as rows and occasions as columns the data have one observation per cell, and the classical analysis is the additive two-way analysis of variance of [Section 16.1](#), with the subject-by-occasion interaction as error. With $\bar{y}_{i\cdot}$, $\bar{y}_{\cdot j}$ and $\bar{y}$ the subject, occasion and grand means,

$$SS_T = N \sum_{j=1}^m (\bar{y}_{\cdot j} - \bar{y})^2, \quad SS_E = \sum_{i=1}^N \sum_{j=1}^m (y_{ij} - \bar{y}_{i\cdot} - \bar{y}_{\cdot j} + \bar{y})^2, \quad (33.3.1)$$

and the statistic is $F = \{SS_T/(m-1)\}/\{SS_E/((N-1)(m-1))\}$. It is the subplot stratum of a split-plot design with one whole plot per subject, and under compound symmetry it is exact ([Theorem 33.3.2\(b\)](#) below, with [Exercise \(B1\)](#)). The question is how much of that exactness survives a general $\boldsymbol{\Sigma}$.

Everything reduces to the within-subject contrasts. Let $\mathbf{U}$ be $m \times (m-1)$ with orthonormal columns orthogonal to $\mathbf{1}$, so that $\mathbf{U}\mathbf{U}^\top = \mathbf{I} - \bar{\mathbf{J}}_m$, and set $\mathbf{z}_i = \mathbf{U}^\top \mathbf{y}_i$: independent $N_{m-1}(\mathbf{U}^\top \boldsymbol{\mu}, \boldsymbol{\Psi})$ with $\boldsymbol{\Psi} = \mathbf{U}^\top \boldsymbol{\Sigma} \mathbf{U}$, with H saying exactly that $\mathbf{U}^\top \boldsymbol{\mu} = \mathbf{0}$. The subject means carry no information about H .

33.3.2 Sphericity

Definition 33.3.1 — Sphericity and Box’s measure

Let $\boldsymbol{\Sigma}$ be an $m \times m$ positive definite matrix and $\mathbf{U}$ as above. $\boldsymbol{\Sigma}$ satisfies **sphericity** if $\mathbf{U}^\top \boldsymbol{\Sigma} \mathbf{U} = \lambda \mathbf{I}_{m-1}$ for some $\lambda > 0$. **Box’s measure of sphericity** is

$$\epsilon(\Sigma) = \frac{\{\text{tr } \Psi\}^2}{(m-1) \text{tr}(\Psi^2)}, \quad \Psi = \mathbf{U}^\top \Sigma \mathbf{U}. \quad (33.3.2)$$

Neither the condition nor ϵ depends on the choice of $\mathbf{U}$: two such matrices satisfy $\tilde{\mathbf{U}} = \mathbf{U}\mathbf{Q}$ with $\mathbf{Q}$ orthogonal, so $\tilde{\Psi} = \mathbf{Q}^\top \Psi \mathbf{Q}$ has the same trace, the same trace of square, and is a multiple of the identity exactly when Ψ is.

Lemma 33.3.1 — Equivalent forms of sphericity

For a positive definite $m \times m$ matrix Σ the following are equivalent:

- (i) $\mathbf{U}^\top \Sigma \mathbf{U} = \lambda \mathbf{I}_{m-1}$;
- (ii) $\text{Var}(Y_j - Y_k) = 2\lambda$ for every $j \neq k$;
- (iii) $\sigma_{jk} = a_j + a_k + \lambda \delta_{jk}$ for some $a_1, \dots, a_m$, where δ_{jk} is one if $j = k$ and zero otherwise;
- (iv) $\Sigma = \lambda \mathbf{I} + \mathbf{1}\mathbf{a}^\top + \mathbf{a}\mathbf{1}^\top$ for some $\mathbf{a} \in \mathbb{R}^m$.

Moreover $1/(m-1) \leq \epsilon(\Sigma) \leq 1$, with $\epsilon = 1$ iff sphericity holds, and compound symmetry implies sphericity but not conversely.

Proof. Write $\mathbf{C} = \mathbf{I} - \bar{\mathbf{J}}_m = \mathbf{U}\mathbf{U}^\top$. Since $\mathbf{U}^\top \mathbf{U} = \mathbf{I}_{m-1}$, condition (i) holds iff $\mathbf{C}\Sigma\mathbf{C} = \lambda\mathbf{C}$.

- (i) $\Rightarrow$ (ii): $\mathbf{e}_j - \mathbf{e}_k$ is orthogonal to $\mathbf{1}$, hence fixed by $\mathbf{C}$, so $\text{Var}(Y_j - Y_k)$ equals $(\mathbf{e}_j - \mathbf{e}_k)^\top \mathbf{C}\Sigma\mathbf{C}(\mathbf{e}_j - \mathbf{e}_k)$, which is $\lambda\|\mathbf{e}_j - \mathbf{e}_k\|^2 = 2\lambda$.
- (ii) $\Rightarrow$ (iii): $\text{Var}(Y_j - Y_k) = \sigma_{jj} + \sigma_{kk} - 2\sigma_{jk} = 2\lambda$ gives $\sigma_{jk} = (\sigma_{jj} - \lambda)/2 + (\sigma_{kk} - \lambda)/2$ for $j \neq k$. Put $a_j = (\sigma_{jj} - \lambda)/2$; then $\sigma_{jk} = a_j + a_k$ off the diagonal and $\sigma_{jj} = 2a_j + \lambda$ on it, which is (iii).
- (iii) $\Leftrightarrow$ (iv) is the same statement in matrix form.
- (iv) $\Rightarrow$ (i): $\mathbf{C}\mathbf{1} = \mathbf{0}$, so $\mathbf{C}\Sigma\mathbf{C} = \lambda\mathbf{C}$.

For the bounds, let $\psi_1, \dots, \psi_{m-1} > 0$ be the eigenvalues of Ψ . Then $\epsilon = (\sum_l \psi_l)^2 / \{(m-1) \sum_l \psi_l^2\}$. The Cauchy–Schwarz inequality gives $(\sum_l \psi_l)^2 \leq (m-1) \sum_l \psi_l^2$ with equality iff all ψ_l are equal, so $\epsilon \leq 1$ with equality iff $\Psi = \lambda \mathbf{I}$; and $\sum_l \psi_l^2 \leq (\sum_l \psi_l)^2$ for nonnegative numbers gives $\epsilon \geq 1/(m-1)$. Compound symmetry is (iv) with all a_j equal; taking the a_j unequal gives sphericity without compound symmetry, and such a Σ is positive definite as soon as λ is large enough. ■

Condition (ii) is the form to remember and to check: *all pairwise differences of the repeated measurements have the same variance*. Compound symmetry says more than the F test needs.

Theorem 33.3.2 — Sphericity is necessary and sufficient for the exact F test

Let $\mathbf{y}_1, \dots, \mathbf{y}_N$ be independent $N_m(\boldsymbol{\mu}, \Sigma)$ with Σ positive definite, $m \geq 2$, $N \geq 2$,

and let F be the statistic built from Eq. 33.3.1. Put $\Psi = \mathbf{U}^\top \Sigma \mathbf{U}$, $\mathbf{q} = \sqrt{N} \bar{\mathbf{z}}$ and $\mathbf{W} = \sum_i (\mathbf{z}_i - \bar{\mathbf{z}})(\mathbf{z}_i - \bar{\mathbf{z}})^\top$.

- (a) $SS_T = \|\mathbf{q}\|^2$ and $SS_E = \text{tr}(\mathbf{W})$, and under H the vector $\mathbf{q} \sim N_{m-1}(\mathbf{0}, \Psi)$ is independent of $\mathbf{W} \sim W_{m-1}(N-1, \Psi)$. Hence $F = N(N-1)\|\bar{\mathbf{z}}\|^2 / \text{tr}(\mathbf{W})$.
- (b) If Σ satisfies sphericity, then under H $F \sim F(m-1, (N-1)(m-1))$ exactly, for every $N \geq 2$.
- (c) Conversely, if the null distribution of F is $F(m-1, (N-1)(m-1))$ for every $N \geq 2$, then Σ satisfies sphericity.

Proof.

- (a) Since $\mathbf{C} = \mathbf{U}\mathbf{U}^\top$ and $\mathbf{U}$ has orthonormal columns, $\sum_j (\bar{y}_{.j} - \bar{y})^2 = \|\mathbf{C}\bar{\mathbf{y}}\|^2 = \|\bar{\mathbf{z}}\|^2$, so $SS_T = N\|\bar{\mathbf{z}}\|^2 = \|\mathbf{q}\|^2$; likewise subject i 's contribution to SS_E is $\|\mathbf{z}_i - \bar{\mathbf{z}}\|^2$, summing to $\text{tr}(\mathbf{W})$. Under H the $\mathbf{z}_i$ are independent $N_{m-1}(\mathbf{0}, \Psi)$, so Lemma 14.2.3 gives the Wishart law of $\mathbf{W}$ and its independence of $\bar{\mathbf{z}}$. Finally $F = \{\|\mathbf{q}\|^2 / (m-1)\} \{(N-1)(m-1) / \text{tr} \mathbf{W}\}$.
- (b) If $\Psi = \lambda \mathbf{I}_{m-1}$, then $\mathbf{q}/\sqrt{\lambda}$ is standard normal, so $\|\mathbf{q}\|^2/\lambda \sim \chi^2(m-1)$. And $\mathbf{W}/\lambda \sim W_{m-1}(N-1, \mathbf{I})$, which is the matrix of sums of squares and cross products of $(N-1)(m-1)$ independent standard normal variables, so $\text{tr}(\mathbf{W})/\lambda \sim \chi^2((N-1)(m-1))$. The two are independent, and λ cancels from the ratio, leaving the ratio of two independent chi-squared variables each divided by its degrees of freedom (Definition 4.1.2).
- (c) Write F_N for the statistic with N subjects. By (a),

$$F_N = \|\mathbf{q}\|^2 \cdot \frac{N-1}{\text{tr}(\mathbf{W})},$$

where $\mathbf{q} \sim N_{m-1}(\mathbf{0}, \Psi)$ has the *same* distribution for every N and is independent of $\mathbf{W}$. Since $\mathbf{W}/(N-1)$ is an average of $N-1$ independent $W_{m-1}(1, \Psi)$ matrices, the weak law of large numbers gives $\text{tr}(\mathbf{W})/(N-1) \rightarrow \text{tr} \Psi$ in probability, so by Slutsky's lemma $F_N \rightarrow \|\mathbf{q}\|^2 / \text{tr} \Psi$ in distribution. On the other hand $F(m-1, \nu) \rightarrow \chi^2(m-1)/(m-1)$ in distribution as $\nu \rightarrow \infty$, because its denominator chi-squared divided by ν tends to one in probability. If the exactness holds for every N , the two limits agree:

$$\|\mathbf{q}\|^2 \stackrel{d}{=} \frac{\text{tr} \Psi}{m-1} \chi^2(m-1).$$

Now match variances. By Theorem 4.2.3, $\text{Var}(\|\mathbf{q}\|^2) = 2 \text{tr}(\Psi^2)$, while the right-hand side has variance $2\{\text{tr} \Psi\}^2/(m-1)$. Equality says $(m-1) \text{tr}(\Psi^2) = \{\text{tr} \Psi\}^2$, that is $\epsilon(\Sigma) = 1$, and Lemma 33.3.1 makes that sphericity. ■

Idea. The repeated-measures F test does not require the occasions to be exchangeable, only that the $m-1$ orthonormalized within-subject contrasts be uncorrelated with equal variances — that the contrast space look spherical, which series of measurements in time almost never do.

33.3.3 Two corrections and one alternative

When sphericity fails, $\|\mathbf{q}\|^2$ and $\text{tr}(\mathbf{W})$ are still weighted sums of chi-squared variables, and matching their first two moments to scaled chi-squared variables gives a usable approximation (Box 1954).

Proposition 33.3.3 — The moment-matched approximation

Under the assumptions of [Theorem 33.3.2](#), with H true, write $\epsilon = \epsilon(\mathbf{\Sigma})$, $d_1 = m - 1$ and $d_2 = (N - 1)(m - 1)$. Then

- (a) $E \text{SS}_T = \text{tr } \mathbf{\Psi}$, $\text{Var } \text{SS}_T = 2 \text{tr}(\mathbf{\Psi}^2)$, $E \text{SS}_E = (N - 1) \text{tr } \mathbf{\Psi}$ and $\text{Var } \text{SS}_E = 2(N - 1) \text{tr}(\mathbf{\Psi}^2)$.
- (b) The scaled chi-squared variable $g\chi^2(h)$ matching the first two moments of SS_T has $h = \epsilon d_1$ and $g = \text{tr}(\mathbf{\Psi}^2) / \text{tr } \mathbf{\Psi}$; the one matching SS_E has $h' = \epsilon d_2$ and the *same* g . Since SS_T and SS_E are independent by [Theorem 33.3.2\(a\)](#), replacing each by its matched scaled chi-squared gives the approximation $F \approx F(\epsilon d_1, \epsilon d_2)$, which is exact when $\epsilon = 1$.

Proof.

- (a) The first two are [Theorem 4.2.3](#) with $\mathbf{A} = \mathbf{I}$ and mean zero. Writing $\mathbf{W} = \sum_{l=1}^{N-1} \mathbf{w}_l \mathbf{w}_l^\top$ with $\mathbf{w}_l$ independent $N_{m-1}(\mathbf{0}, \mathbf{\Psi})$ ([Lemma 14.2.3](#)), $\text{tr } \mathbf{W} = \sum_l \|\mathbf{w}_l\|^2$ is a sum of $N - 1$ independent copies of $\|\mathbf{q}\|^2$, so its mean and variance are $N - 1$ times theirs.
- (b) Matching $gh = \text{tr } \mathbf{\Psi}$ and $2g^2h = 2 \text{tr}(\mathbf{\Psi}^2)$ gives $g = \text{tr}(\mathbf{\Psi}^2) / \text{tr } \mathbf{\Psi}$ and $h = \{\text{tr } \mathbf{\Psi}\}^2 / \text{tr}(\mathbf{\Psi}^2) = \epsilon d_1$. For SS_E both moments are multiplied by $N - 1$, so g is unchanged and $h' = (N - 1)h = \epsilon d_2$. Since $d_2/d_1 = h'/h$, the ratio $(\text{SS}_T/d_1)/(\text{SS}_E/d_2)$ becomes $\{\chi^2(h)/h\}/\{\chi^2(h')/h'\}$, an $F(h, h')$ variable, the two chi-squared variables being independent by [Theorem 33.3.2\(a\)](#); at $\epsilon = 1$ this is the exact result of [Theorem 33.3.2\(b\)](#). ■

By [Lemma 33.3.1](#), $\epsilon \geq 1/(m - 1)$, so the approximating distribution is never more dispersed than $F(d_1/(m - 1), d_2/(m - 1)) = F(1, N - 1)$, the largest that [Proposition 33.3.3\(b\)](#) can ask for. Referring F to $F(1, N - 1)$ is therefore conservative within Box's approximation, and Geisser and Greenhouse (1958) proved it exactly conservative, for every $\mathbf{\Sigma}$ and N . This is the **lower-bound** correction, turned into a recommendation by Greenhouse and Geisser (1959).

Part (b) becomes a procedure once ϵ is estimated from the sample covariance matrix $\mathbf{S}$ of the $\mathbf{y}_i$.

- The **Greenhouse–Geisser** correction refers F to $F(\hat{\epsilon}d_1, \hat{\epsilon}d_2)$ with the plug-in $\hat{\epsilon} = \epsilon(\mathbf{S})$, which is biased downward, so the test is conservative.
- The **Huynh–Feldt** correction removes the leading bias. For a single group of N subjects it uses

$$\tilde{\epsilon} = \min \left\{ 1, \frac{N(m - 1)\hat{\epsilon} - 2}{(m - 1)\{(N - 1) - (m - 1)\hat{\epsilon}\}} \right\}, \quad (33.3.3)$$

which exceeds $\hat{\epsilon}$ and gives a less conservative test; its own bias is upward when ϵ is small.

- The **lower-bound** correction takes $\epsilon = 1/(m-1)$: safe, and usually too conservative to be useful.

A third option avoids the issue. Since the $\mathbf{z}_i$ are independent $N_{m-1}(\mathbf{U}^\top \boldsymbol{\mu}, \boldsymbol{\Psi})$ with $\boldsymbol{\Psi}$ unrestricted, H says a multivariate normal mean is zero, and the classical test is Hotelling's.

Proposition 33.3.4 — The multivariate test

Under the assumptions of Theorem 33.3.2 with $N \geq m$, let $\mathbf{S}_z = \mathbf{W}/(N-1)$ and

$$T^2 = N \bar{\mathbf{z}}^\top \mathbf{S}_z^{-1} \bar{\mathbf{z}}.$$

Then T^2 does not depend on the choice of $\mathbf{U}$, nor on replacing $\mathbf{U}$ by $\mathbf{U}\mathbf{K}$ for any nonsingular $(m-1) \times (m-1)$ matrix $\mathbf{K}$; and under H ,

$$\frac{N-m+1}{(N-1)(m-1)} T^2 \sim F(m-1, N-m+1),$$

whatever $\boldsymbol{\Sigma}$ is. The distributional statement is Hotelling's and is not proved here; see Anderson (2003, §5.2).

Proof. Only the invariance is proved. Replacing $\mathbf{U}$ by $\mathbf{U}\mathbf{K}$ replaces $\bar{\mathbf{z}}$ by $\mathbf{K}^\top \bar{\mathbf{z}}$ and $\mathbf{S}_z$ by $\mathbf{K}^\top \mathbf{S}_z \mathbf{K}$, leaving T^2 unchanged; two orthonormal bases differ by an orthogonal $\mathbf{K}$. The requirement $N \geq m$ makes $\mathbf{S}_z$, a Wishart matrix on $N-1 \geq m-1$ degrees of freedom, invertible with probability one. ■

Exactness under any $\boldsymbol{\Sigma}$ sounds decisive, but it costs power: the multivariate test estimates a whole covariance matrix and has $N-m+1$ denominator degrees of freedom rather than $(N-1)(m-1)$. When sphericity nearly holds the univariate test is much more powerful, when it fails badly the two are comparable, and when $N < m$ the multivariate test does not exist.

33.3.4 An example, four ways

Example. (Grip strength over six visits)

Twenty-four patients have grip strength measured, in kilograms, at six weekly visits, simulated from $N_6(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ with $\boldsymbol{\Sigma}$ first-order autoregressive, $\sigma_{jk} = 4 \times 0.6^{|j-k|}$, and a mean drifting slowly upward; the observed occasion means are 47.818, 48.099, 49.056, 49.177, 49.561 and 49.263 kg. The true Box measure is $\epsilon = 0.700$: adjacent visits correlate 0.6 and visits five weeks apart only 0.6^5 , so adjacent differences are much less variable than distant ones. The four analyses of H give

Analysis	statistic	degrees of freedom	p
univariate, uncorrected	4.770	5, 115	0.0005

Greenhouse– Geisser, $\hat{\epsilon} = 0.645$	4.770	3.23, 74.2	0.0035
Huynh–Feldt, $\tilde{\epsilon} = 0.763$	4.770	3.81, 87.7	0.0019
multivariate	3.605	5, 19	0.0184

All four reject, but the evidence differs by a factor of nearly forty between first and last. Distrust the uncorrected test: its nominal degrees of freedom are too large by the factor ϵ .

```
import numpy as np
from scipy import stats

N, m = 24, 6
mu_true = np.array([48.0, 48.5, 48.9, 49.2, 49.4, 49.5]) # kg, a slow improvement

```

Figure 33.3.1: (a) The null distribution of the uncorrected F statistic with autoregressive errors, against the nominal $F(5, 115)$ density and the moment-matched $F(\epsilon d_1, \epsilon d_2)$ of Proposition 33.3.3, with the nominal 5% point marked. (b) Simulated level of four tests as ρ grows.

How much does the failure of sphericity cost? Figure 33.3.1 answers with a simulation under H . Panel (a) shows the null distribution of the uncorrected F : more dispersed than $F(5, 115)$, with a heavier right tail, and tracking Proposition 33.3.3 closely. Panel (b) traces the level of a nominal 5% test as the autoregressive parameter grows. At $\rho = 0$ it is 0.050, as Theorem 33.3.2(b) requires; by $\rho = 0.8$, where $\epsilon = 0.562$, it is 0.085. The Greenhouse–Geisser test is conservative throughout (0.038 to 0.049), the Huynh–Feldt test close to nominal (0.049 to 0.056), and the multivariate test exact at 0.049 for every ρ . A spherical covariance of the form Lemma 33.3.1(iv) with unequal a_j , far from compound symmetric, gives the uncorrected test a level of 0.050: sphericity, not compound symmetry, is what matters.

33.3.5 The modern treatment

The corrections above patch a fixed analysis; the mixed-model approach fits the covariance instead. Write the data as a linear mixed model (Definition 32.2.1) with a fixed effect for each occasion and a within-subject covariance $\mathbf{R}$ of chosen shape, estimate its parameters by restricted maximum likelihood (Definition 32.4.1), and test the fixed effects by a Wald statistic with estimated degrees of freedom (Proposition 32.5.1). Compound symmetric $\mathbf{R}$ reproduces the uncorrected univariate F (Exercise (B2)), unstructured $\mathbf{R}$ the multivariate test up to the degrees-of-freedom approximation, and anything between is a model the classical scheme has no room for. Unbalanced data and missing visits are handled too, whereas Eq. 33.3.1 and T^2 need a complete rectangle. The price is that the covariance must be chosen, and the choice affects the standard errors: Section 33.4.

Remark (Between-subjects factors). With a between-subjects factor the within-subject analysis is the same, applied to the pooled within-group covariance, and the univariate tests are exact iff the pooled Ψ is spherical *and* the groups share a common Σ . Mauchly’s (1940) test of sphericity itself, which most software reports, is sensitive to non-normality and, like any preliminary test, distorts the level of what follows.

33.3.6 Exercises

33.3.6.1 A. Check your understanding

Exercise A1.

Show that every 2×2 covariance matrix satisfies sphericity, so that with $m = 2$ the repeated-measures F test is exact whatever Σ is. Identify the test in that case.

Solution. With $m = 2$, $\Psi = \mathbf{U}^\top \Sigma \mathbf{U}$ is 1×1 , hence a multiple of $\mathbf{I}_1$. By [Theorem 33.3.2\(b\)](#) the test is exact. It is the paired t test: the single contrast is $(y_{i1} - y_{i2})/\sqrt{2}$, and F is the square of the paired t statistic on $N - 1$ degrees of freedom.

Exercise A2.

For $m = 3$ and an autoregressive covariance $\sigma_{jk} = \rho^{|j-k|}$ with $0 < \rho < 1$, compute Ψ for the basis $\mathbf{u}_1 = (1, -1, 0)^\top/\sqrt{2}$, $\mathbf{u}_2 = (1, 1, -2)^\top/\sqrt{6}$ and show that sphericity fails. Which pairwise difference has the largest variance?

33.3.6.2 B. Practice

Exercise B1.

Show directly that compound symmetry $\Sigma = \sigma^2\{(1 - \rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top\}$ gives $\Psi = \sigma^2(1 - \rho)\mathbf{I}_{m-1}$, and hence that the split-plot analysis of [Theorem 33.1.2](#) is the repeated-measures F test with $\epsilon = 1$. Which λ of [Lemma 33.3.1](#) does it correspond to?

Solution. $\mathbf{U}^\top \mathbf{1} = \mathbf{0}$, so $\Psi = \mathbf{U}^\top \Sigma \mathbf{U} = \sigma^2(1 - \rho)\mathbf{U}^\top \mathbf{U} = \sigma^2(1 - \rho)\mathbf{I}_{m-1}$. Hence $\epsilon = 1$ and $\lambda = \sigma^2(1 - \rho)$, which is the subplot stratum eigenvalue λ_s of [Lemma 33.1.1](#). In [Lemma 33.3.1\(iv\)](#) take $\mathbf{a} = (\sigma^2\rho/2)\mathbf{1}$.

Exercise B2.

Consider the mixed model $y_{ij} = \mu_j + u_i + e_{ij}$ with u_i and e_{ij} independent normal, of variances σ_u^2 and σ_e^2 . Show that restricted maximum likelihood gives $\hat{\sigma}_e^2 = \text{MS}_E$ and $\hat{\sigma}_u^2 = (\text{MS}_S - \text{MS}_E)/m$ when this is nonnegative, where MS_S is the between-subject mean square, and that the Wald statistic for $H: \mu_1 = \cdots = \mu_m$, divided by $m - 1$, is the uncorrected F of [Eq. 33.3.1](#).

33.3.6.3 C. Going deeper

Exercise C1.

For $m = 4$, $N = 20$ and Σ compound symmetric, compare by simulation the power of the uncorrected univariate test, the Greenhouse–Geisser test and the multivariate test of [Proposition 33.3.4](#) against a linear trend in the occasion means. Repeat with an

autoregressive Σ of the same total variance. Which would you choose if you knew the alternative were a linear trend, and why is a single contrast better still?

33.4 Covariance models for longitudinal data

A longitudinal study follows subjects over time. Its data are clustered by subject, but with a structure the previous sections have not used: observations inside a cluster are *ordered*, and the distance between two of them matters. Compound symmetry ignores the ordering; an unstructured covariance uses it but pays $m(m+1)/2$ parameters. Between the extremes lies a catalogue of models with two to four parameters, each a different story about where the correlation comes from.

33.4.1 Three sources of correlation

A longitudinal measurement is usefully read as the sum of three parts, a decomposition due to Diggle (1988):

$$y_{ij} = \mathbf{x}_{(ij)}^\top \boldsymbol{\beta} + \mathbf{z}_{(ij)}^\top \mathbf{u}_i + W_i(t_{ij}) + e_{ij}. \quad (33.4.1)$$

The vector $\mathbf{u}_i$ holds **random effects**: a subject's own level or slope, anything persisting for the whole study. The process $W_i(\cdot)$ is **serial correlation**, making nearby times alike and distant times nearly independent. And e_{ij} is **measurement error**. The three leave different fingerprints — correlation that does not decay with the gap, correlation that does, and a discontinuity at gap zero — and most models in use are [Eq. 33.4.1](#) with one or two parts dropped.

Definition 33.4.1 — Covariance models for a subject's observations

Let subject i be observed at times $t_{i1} < \dots < t_{im_i}$, and write Σ_i for the covariance matrix of its response vector, with entries σ_{jk} and time gap $d_{jk} = |t_{ij} - t_{ik}|$. The standard models are

Model	σ_{jk}	Parameters
independence	$\sigma^2 \delta_{jk}$	1
compound symmetry	$\sigma_u^2 + \sigma^2 \delta_{jk}$	2
first-order autoregressive	$\sigma^2 \rho^{ j-k }$	2
exponential (spatial power)	$\sigma^2 \rho^{d_{jk}}$	2
autoregressive plus random intercept	$\sigma_u^2 + \sigma^2 \rho^{ j-k }$	3
Toeplitz of order q	$\sigma^2 c_{ j-k }$, with $c_0 = 1$ and $c_u = 0$ for $u \geq q$	q
random intercept and slope	$(1, t_{ij}) \mathbf{D}(1, t_{ik})^\top + \sigma^2 \delta_{jk}$	4
unstructured	σ_{jk} , unrestricted	$m(m+1)/2$

Each model must also be nonnegative definite; the constraint is $\sigma_u^2, \sigma^2 \geq 0$ and $|\rho| < 1$ for the first five, $\mathbf{D}$ nonnegative definite for the random-coefficient model, and a genuine restriction on $(c_1, \dots, c_{q-1})$ for the Toeplitz model ([Exercise \(B2\)](#)).

Compound symmetry is [Definition 33.2.1](#), what a random intercept alone produces: it makes the correlation between the first and last visit equal to that between consecutive visits, which over five years it rarely is. The autoregressive model is [Definition 21.6.1](#) within a subject and needs equally spaced occasions; the exponential model is its continuous-time version. A random intercept added to either puts a floor under the decaying correlation, and that two-source version of [Eq. 33.4.1](#) fits much real longitudinal data. The Toeplitz model lets the decay take an arbitrary shape, truncated after $q - 1$ lags. Unstructured assumes nothing, and is right when the occasions are few, common and complete and the subjects comfortably outnumber $m(m + 1)/2$: the covariance implicit in [Proposition 33.3.4](#).

Warning. The covariance model is a choice with consequences. It changes the standard errors of the fixed effects, and — unlike in the balanced cases of the previous sections — the estimates themselves whenever the design is unbalanced or the regressors vary within subjects.

33.4.2 Choosing, and what goes wrong if you choose badly

Proposition 33.4.1 — Working covariances, likelihood comparisons and empirical standard errors

Let the N subjects be independent, with $E(\mathbf{Y}_i) = \mathbf{X}_i\boldsymbol{\beta}$ and true covariance $\boldsymbol{\Sigma}_i^0$. Let $\boldsymbol{\Sigma}_i(\boldsymbol{\theta})$ be a working covariance model whose eigenvalues are bounded above and away from zero uniformly in i and, for fixed $\boldsymbol{\theta}$, let

$$\tilde{\boldsymbol{\beta}}(\boldsymbol{\theta}) = \mathbf{A}(\boldsymbol{\theta})^{-1} \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i(\boldsymbol{\theta})^{-1} \mathbf{Y}_i, \quad \mathbf{A}(\boldsymbol{\theta}) = \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i(\boldsymbol{\theta})^{-1} \mathbf{X}_i,$$

assumed nonsingular.

- (a) $\tilde{\boldsymbol{\beta}}(\boldsymbol{\theta})$ is unbiased for every $\boldsymbol{\theta}$, whether or not the working model is correct, with exact covariance $\mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}$ where $\mathbf{B} = \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i^{-1} \boldsymbol{\Sigma}_i^0 \boldsymbol{\Sigma}_i^{-1} \mathbf{X}_i$. If the working model is correct, $\mathbf{B} = \mathbf{A}$ and the covariance is $\mathbf{A}^{-1}$.
- (b) The **empirical** covariance estimate $\hat{\mathbf{U}}_E$ replaces $\boldsymbol{\Sigma}_i^0$ by $\mathbf{r}_i \mathbf{r}_i^\top$, with $\mathbf{r}_i = \mathbf{Y}_i - \mathbf{X}_i \tilde{\boldsymbol{\beta}}$. Under the conditions (K1)–(K3) of [Section 33.2](#), applied with $\boldsymbol{\Sigma}_i(\boldsymbol{\theta})^{-1} \mathbf{X}_i$ in place of $\mathbf{X}_i$, it satisfies $n(\hat{\mathbf{U}}_E - \mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}) \rightarrow \mathbf{0}$ in probability as $N \rightarrow \infty$, whatever $\boldsymbol{\Sigma}_i^0$ is.
- (c) Let $\mathbf{K}$ be any $n \times (n - p)$ matrix whose columns form an orthonormal basis of $\mathcal{C}(\mathbf{X})^\perp$. The restricted log likelihood of a covariance model is the log likelihood of $\mathbf{K}^\top \mathbf{Y}$ ([Definition 32.4.1](#)) and does not depend on the choice of $\mathbf{K}$ ([Theorem 32.4.2](#)). Hence two covariance models fitted with the *same* $\mathbf{X}$ have restricted likelihoods that are densities of one and the same random vector, and their difference is a genuine log likelihood ratio. If the models differ in $\mathbf{X}$, the two are densities of different random vectors and cannot be compared.

Proof.

- (a) $\tilde{\boldsymbol{\beta}} = \mathbf{A}^{-1} \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i^{-1} \mathbf{Y}_i$ is a fixed linear function of $\mathbf{Y}$, so $E \tilde{\boldsymbol{\beta}} = \mathbf{A}^{-1} \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i^{-1} \mathbf{X}_i \boldsymbol{\beta} = \boldsymbol{\beta}$ and, by independence of the subjects, $\text{Cov}(\tilde{\boldsymbol{\beta}}) = \mathbf{A}^{-1} \{ \sum_i \mathbf{X}_i^\top \boldsymbol{\Sigma}_i^{-1} \boldsymbol{\Sigma}_i^0 \boldsymbol{\Sigma}_i^{-1} \mathbf{X}_i \} \mathbf{A}^{-1}$ by Theorem 2.2.1. If $\boldsymbol{\Sigma}_i^0 = \boldsymbol{\Sigma}_i$, the middle sum telescopes to $\mathbf{A}$.
- (b) Put $\tilde{\mathbf{X}}_i = \boldsymbol{\Sigma}_i^{-1} \mathbf{X}_i$, so that $\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta} = (\sum_i \tilde{\mathbf{X}}_i^\top \mathbf{X}_i)^{-1} \sum_i \tilde{\mathbf{X}}_i^\top \boldsymbol{\varepsilon}_i$ and the empirical estimate is the same expression with $\mathbf{r}_i \mathbf{r}_i^\top$ in the middle. The cluster-sandwich argument of Section 33.2 — that is, the proof of Theorem 21.4.2 with the cluster in place of the observation — goes through with $\tilde{\mathbf{X}}_g$ in the meat and $\mathbf{X}_g$ in the bread: the assumed bounds on the eigenvalues of $\boldsymbol{\Sigma}_i$ make $\|\tilde{\mathbf{X}}_i\|$ satisfy (K2) whenever $\|\mathbf{X}_i\|$ does, and (K1) and (K3) are unchanged.
- (c) The first two sentences are Definition 32.4.1 and Theorem 32.4.2, and $\mathbf{K}$ is determined up to an orthogonal rotation by $\mathcal{C}(\mathbf{X})$. Two models with the same $\mathbf{X}$ therefore attach densities to the same $(n - p)$ -dimensional random vector, so their ratio is a likelihood ratio; two models with different $\mathbf{X}$ attach them to different random vectors, and the ratio is not even dimensionless when the two $\mathbf{X}$ have different ranks.

■

Part (c) has a practical corollary: **fix the mean model first and compare covariance models by restricted likelihood; compare mean models by ordinary likelihood, or by a Wald or F test, holding the covariance fixed.** The criteria of Chapter 29 then apply to the restricted likelihood as to any likelihood (Definition 29.2.2):

$$\text{AIC}_R = -2\ell_R + 2q, \quad \text{BIC}_R = -2\ell_R + q \log(n - p), \quad (33.4.2)$$

with q the number of covariance parameters and $n - p$ the number of error contrasts, the dimension of the data whose likelihood ℓ_R is.

Part (a) is why all this is less dangerous than it sounds: a wrong covariance model costs efficiency, not validity, since $\boldsymbol{\beta}$ stays unbiased and part (b) supplies a standard error that is right anyway — the longitudinal version of the sandwich argument of Section 21.4, and the basis of the generalized estimating equations (Definition 40.4.1) of Chapter 40.

Warning. The empirical standard error protects against the covariance model and nothing else. If $E(\mathbf{Y}_i) \neq \mathbf{X}_i \boldsymbol{\beta}$, part (a) fails at the first line and there is nothing left to be robust about; it does not protect against missing data that depend on the unobserved responses; and it needs N large in the sense of (K1)–(K3), being worse than the model-based estimate with a dozen subjects.

33.4.3 Checking the fit of a covariance model

Two displays do most of the work, both built from residuals $\hat{r}_{ij} = y_{ij} - \mathbf{x}_{(ij)}^\top \hat{\boldsymbol{\beta}}$ after a fit of the mean model. The **empirical variogram** plots, against the time gap u , the average of $\frac{1}{2}(\hat{r}_{ij} - \hat{r}_{ik})^2$ over same-subject pairs at that gap. Its population version $\gamma(u) = \frac{1}{2} \text{Var}(r_{ij} - r_{ik})$ is, for Eq. 33.4.1, $\sigma_e^2 + \sigma_s^2 \{1 - \rho(u)\}$, rising from σ_e^2 to $\sigma_e^2 + \sigma_s^2$; the gap between that plateau and the total residual variance $\sigma_u^2 + \sigma_s^2 + \sigma_e^2$ measures σ_u^2 , the part of the correlation that

never decays. The **residual correlogram** plots the average correlation of residuals at gap u : compound symmetry predicts a horizontal line, the autoregressive model a geometric decay to zero, the combination a decay to a positive floor. Comparing empirical with fitted curves shows quickly which model does violence to the data.

Example. (Investment in eleven firms)

Grunfeld's panel records gross investment, market value and capital stock for 11 US firms in each of the 20 years from 1935 to 1954, a complete rectangle with $n = 220$. Take log investment as the response and the mean model $E(y) = \beta_0 + \beta_1 t + \beta_2 \log(\text{value})$, with t in decades from the middle of the record, so $p = 3$. An unstructured covariance would need 210 parameters from 11 subjects, which is hopeless. Fitting the alternatives by restricted maximum likelihood gives

Covariance model	q	$-2\ell_R$	AIC_R	BIC_R
independence	1	476.95	478.95	482.33
compound symmetry	2	114.83	118.83	125.59
autoregressive	2	49.89	53.89	60.65
autoregressive + random intercept	3	29.87	35.87	46.01
random intercept and slope	4	98.66	106.66	120.18
Toeplitz of order 4	4	147.97	155.97	169.49

Independence is hopeless: the firms differ enormously in size, and log investment is nearly constant within a firm relative to the spread between firms. Compound symmetry captures that and improves $-2\ell_R$ by 362, the autoregressive model on the same two parameters does better still, and the combination is best on both criteria, by 82.96 of AIC_R over compound symmetry. The random-coefficient model, which gives each firm its own trend, describes these data worse than a persistent level plus decaying serial correlation.

Figure 33.4.1 shows why. The residual correlations are 0.953 at one year, 0.918 at two, 0.884 at five and 0.839 at ten: high everywhere, because the firm's level dominates, but visibly decaying, which compound symmetry cannot reproduce. The variogram rises to a plateau of about 0.099, far below the total residual variance of 0.4839; the gap is the between-firm variance. The selected model is not innocent either: its fitted correlogram flattens onto its own floor after three or four years while the data go on decaying. That is what the diagnostic is for, and a reason to read the empirical standard error of Proposition 33.4.1(b) alongside the model-based one.

With the selected model the coefficient of $\log(\text{value})$ is 0.6295, with a model-based standard error of 0.0712 and an empirical one of 0.0608, and the coefficient of t is 0.4261 with standard errors 0.0600 and 0.0601. Ordinary least squares, treating the 220 observations as independent, reports 0.9833 and 0.3768 with standard errors 0.0351 and 0.0821. The two disagree substantially about the elasticity with respect to market value, because least squares reads it mostly from differences between firms while generalized least squares, having absorbed the firm levels into the covariance, reads it from movements within firms — the between-versus-within distinction of Section 6.6 again, and a question about the subject matter.

```
import numpy as np
import statsmodels.api as sm

df = sm.datasets.grunfeld.load_pandas().data
firms = sorted(df["firm"].unique())
years = np.sort(df["year"].unique())
N, m = len(firms), len(years)
t = (years - years.mean()) / 10

Ylist, Xlist = [], []
for f in firms:
    d = df[df["firm"] == f].sort_values("year")
    Ylist.append(np.log(d["invest"].to_numpy()))
    Xlist.append(np.column_stack([np.ones(m), t, np.log(d["value"].to_numpy())]))
p = Xlist[0].shape[1]
n = N * m
```

With a common Σ , $-2\ell_R$ is $N \log|\Sigma| + \sum_i \mathbf{r}_i^\top \Sigma^{-1} \mathbf{r}_i + \log|\sum_i \mathbf{X}_i^\top \Sigma^{-1} \mathbf{X}_i|$ plus a constant, evaluated at the generalized least squares $\hat{\beta}$, the third term being what distinguishes it from the ordinary likelihood (Theorem 32.4.2).

```

33.4.4 Missing data

Longitudinal data are rarely complete. The mixed-model machinery handles ragged data without complaint — [Proposition 33.4.1](#) never assumed a common m_i — an advantage over the classical analysis of [Section 33.3](#), which needs a complete rectangle. But “handles” means “computes”. If the probability of a missing value depends only on the covariates and the responses that *were* observed, the observed-data likelihood is the right one: the data are missing at random. If it depends on the value that would have been observed — dropout because a patient is not improving — the likelihood is wrong and no covariance model repairs it.

Warning. Software that fits a mixed model to incomplete longitudinal data makes a missing-at-random assumption on the analyst’s behalf, silently, and the empirical standard error of [Proposition 33.4.1\(b\)](#) does *not* protect against its failure. [Chapter 41](#) treats missing data properly.

33.4.5 Exercises

33.4.5.1 A. Check your understanding

Exercise A1.

A trial measures 60 patients at 8 visits. How many parameters does each model of [Definition 33.4.1](#) need? Which could not be fitted with only 10 patients, and why?

Exercise A2.

Sketch the population variogram $\gamma(u)$ for compound symmetry, for the autoregressive model and for their combination, marking the total variance on each. Which feature identifies σ_u^2 , and which identifies measurement error?

Solution. Compound symmetry gives $\gamma(u) = \sigma^2$ for every $u > 0$, flat and well below the total variance $\sigma^2 + \sigma_u^2$. The autoregressive model gives $\gamma(u) = \sigma^2(1 - \rho^u)$, rising from 0 to its total variance σ^2 . The combination rises from 0 to σ^2 and stops, leaving the gap σ_u^2 to the total. The gap between plateau and total variance is σ_u^2 ; the intercept of the variogram as $u \rightarrow 0$ is the measurement-error variance.

33.4.5.2 B. Practice

Exercise B1.

Two analysts fit the investment data of [Example \(Investment in eleven firms\)](#). The first uses the mean model of the example with an autoregressive covariance; the second adds a quadratic term in t and uses compound symmetry. They compare AIC_R . Explain what is wrong, and describe a correct sequence of comparisons.

Solution. By [Proposition 33.4.1\(c\)](#) the two restricted likelihoods are densities of different random vectors, of dimensions $n - 3$ and $n - 4$, so their difference is not a log likelihood ratio and AIC_R cannot compare them. Correct sequence: fix a rich mean model and

compare covariance models by AIC_R ; then, with the chosen covariance fixed, compare mean models by a Wald or F test, or by AIC from the *full* likelihood; then refit the covariance.

Exercise B2.

Show that the Toeplitz model of [Definition 33.4.1](#) with $q = 3$ is nonnegative definite for every m iff $(1, c_1, c_2, 0, \dots)$ is the autocorrelation sequence of a moving-average process of order two, and explain why the parameterization $c_u \propto \sum_l a_l a_{l+u}$ used in the listing above satisfies this automatically.

33.4.5.3 C. Going deeper

Exercise C1.

The autoregressive model is nested in the autoregressive-plus-random-intercept model at $\sigma_u^2 = 0$, a boundary of the parameter space. Explain why the likelihood ratio statistic comparing the two does not have a $\chi^2(1)$ null distribution, state what it does have ([Proposition 32.5.1](#)), and say what this means for reading AIC_R differences as informal evidence.

33.5 Growth curves

A growth-curve model gives each subject a *curve of its own* — a straight line, a polynomial in time — the population curve being their average. How is the average curve estimated, and how is an individual's curve recovered from its own few observations? The second answer is the best linear unbiased predictor: a matrix-weighted average of the subject's own noisy curve and the precise population curve, weighted by signal against signal-plus-noise — the shrinkage of [Chapter 27](#) by a different road.

33.5.1 Two formulations

Let each of N subjects be observed at the same m times, and collect the data in an $m \times N$ matrix $\mathbf{Y}$ whose column i is subject i 's profile. Let $\mathbf{X}$ be the $m \times p$ matrix of a chosen basis in time, say $[\mathbf{1}, \mathbf{t}]$ for a straight line.

The **Potthoff–Roy** formulation (Potthoff and Roy 1964) writes

$$\mathbf{E}(\mathbf{Y}) = \mathbf{X}\mathbf{\Xi}\mathbf{A}^\top, \quad \text{Cov}(\text{column } i) = \mathbf{\Sigma}, \text{ columns independent}, \quad (33.5.1)$$

where $\mathbf{A}$ is an $N \times k$ matrix of between-subject covariates (a column of ones if the subjects form one group, group indicators if not) and $\mathbf{\Xi}$ is the $p \times k$ matrix of curve coefficients, with $\mathbf{\Sigma}$ unstructured. It is a multivariate regression with a design on *both* sides: $\mathbf{X}$ acts on the times and $\mathbf{A}$ on the subjects.

The **random-coefficient** formulation gives each subject its own coefficient vector,

$$\mathbf{y}_i = \mathbf{X}(\boldsymbol{\beta} + \mathbf{u}_i) + \boldsymbol{\varepsilon}_i, \quad \mathbf{u}_i \sim (\mathbf{0}, \mathbf{D}) \text{ independent of } \boldsymbol{\varepsilon}_i \sim (\mathbf{0}, \sigma^2 \mathbf{I}_m), \quad (33.5.2)$$

with $\mathbf{u}_1, \dots, \mathbf{u}_N$ uncorrelated. This is the linear mixed model (Definition 32.2.1) with $\mathbf{Z}_i = \mathbf{X}$, $\mathbf{G} = \mathbf{D}$ and $\mathbf{R} = \sigma^2 \mathbf{I}$, and the implied within-subject covariance is

$$\boldsymbol{\Sigma} = \mathbf{XDX}^\top + \sigma^2 \mathbf{I}_m, \quad (33.5.3)$$

a covariance with $p(p+1)/2 + 1$ parameters instead of the $m(m+1)/2$ of Eq. 33.5.1 — four, for a straight line, whatever m is. The two describe the same *mean* structure: with one group of subjects, the random-coefficient model is Eq. 33.5.1 with $\mathbf{A} = \mathbf{1}_N$ and $\boldsymbol{\Sigma}$ restricted to Eq. 33.5.3. That restriction gives $\mathcal{C}(\boldsymbol{\Sigma}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, so the population curve is ordinary least squares and needs no covariance parameter (Proposition 33.5.1(a) below); with $\boldsymbol{\Sigma}$ unstructured the inclusion fails unless $p = m$, and the efficient estimate is a genuine generalized least squares fit.

33.5.2 Estimation

Proposition 33.5.1 — The balanced random-coefficient growth model

Assume Eq. 33.5.2 with a common $\mathbf{X}$ of full column rank $p \leq m$, and $\mathbf{D}$ positive definite. Write $\mathbf{K} = \mathbf{X}^\top \mathbf{X}$, $\mathbf{C} = \sigma^2 \mathbf{K}^{-1}$, $\mathbf{S} = \mathbf{D} + \mathbf{C}$, and let $\mathbf{b}_i = \mathbf{K}^{-1} \mathbf{X}^\top \mathbf{y}_i$ be subject i 's own least squares coefficient vector.

- (a) $\mathcal{C}(\boldsymbol{\Sigma}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, so ordinary and generalized least squares coincide, and

$$\hat{\boldsymbol{\beta}} = \mathbf{K}^{-1} \mathbf{X}^\top \bar{\mathbf{y}} = \bar{\mathbf{b}}, \quad \text{Cov}(\hat{\boldsymbol{\beta}}) = \frac{\mathbf{D} + \sigma^2 \mathbf{K}^{-1}}{N} = \frac{\mathbf{S}}{N}, \quad (33.5.4)$$

exactly, for every N . No covariance parameter is needed to estimate the population curve.

- (b) The best linear unbiased predictor of $\mathbf{u}_i$ (Theorem 32.3.1, which is Theorem 14.2.8 applied coordinatewise with $\mathbf{x}_0 = \mathbf{0}$) is

$$\hat{\mathbf{u}}_i = \mathbf{DX}^\top \boldsymbol{\Sigma}^{-1}(\mathbf{y}_i - \mathbf{X}\hat{\boldsymbol{\beta}}) = \mathbf{W}(\mathbf{b}_i - \hat{\boldsymbol{\beta}}), \quad \mathbf{W} = \mathbf{DS}^{-1}, \quad (33.5.5)$$

with $\mathbf{W} = \mathbf{D}(\mathbf{D} + \mathbf{C})^{-1}$ and $\text{Cov}(\hat{\mathbf{u}}_i - \mathbf{u}_i) = \mathbf{D} - (1 - 1/N)\mathbf{WD}$. The predicted curve of subject i is $\mathbf{X}(\hat{\boldsymbol{\beta}} + \hat{\mathbf{u}}_i)$, with

$$\text{Cov}(\hat{\boldsymbol{\beta}} + \hat{\mathbf{u}}_i - \boldsymbol{\beta} - \mathbf{u}_i) = (\mathbf{D}^{-1} + \mathbf{C}^{-1})^{-1} + (\mathbf{I} - \mathbf{W})\frac{\mathbf{C}}{N}. \quad (33.5.6)$$

- (c) The restricted maximum likelihood estimates of σ^2 and $\mathbf{D}$ are

$$\hat{\sigma}^2 = \frac{1}{N(m-p)} \sum_{i=1}^N \|\mathbf{y}_i - \mathbf{Xb}_i\|^2, \quad \hat{\mathbf{D}} = \mathbf{S}_b - \hat{\sigma}^2 \mathbf{K}^{-1}, \quad (33.5.7)$$

where $\mathbf{S}_b = (N-1)^{-1} \sum_i (\mathbf{b}_i - \bar{\mathbf{b}})(\mathbf{b}_i - \bar{\mathbf{b}})^\top$, provided $\hat{\mathbf{D}}$ is nonnegative definite.

Proof.

- (a) $\Sigma\mathbf{X} = \mathbf{XDK} + \sigma^2\mathbf{X} = \mathbf{X}(\mathbf{DK} + \sigma^2\mathbf{I})$, whose columns lie in $\mathcal{C}(\mathbf{X})$. Stacking the subjects, the model matrix is $\mathbf{1}_N \otimes \mathbf{X}$ and the covariance is $\mathbf{I}_N \otimes \Sigma$, so $(\mathbf{I}_N \otimes \Sigma)(\mathbf{1}_N \otimes \mathbf{X}) = \mathbf{1}_N \otimes \Sigma\mathbf{X}$ has columns in $\mathcal{C}(\mathbf{1}_N \otimes \mathbf{X})$, and [Theorem 6.9.3](#) gives the equality of the two fits (this is [Theorem 31.2.2](#) in the balanced case). The ordinary least squares estimate from the stacked data is $(N\mathbf{K})^{-1} \sum_i \mathbf{X}^\top \mathbf{y}_i = \mathbf{K}^{-1} \mathbf{X}^\top \bar{\mathbf{y}} = \bar{\mathbf{b}}$. Its covariance is $\mathbf{K}^{-1} \mathbf{X}^\top (\Sigma/N) \mathbf{X} \mathbf{K}^{-1}$, and $\mathbf{K}^{-1} \mathbf{X}^\top \Sigma \mathbf{X} \mathbf{K}^{-1} = \mathbf{K}^{-1} (\mathbf{KDK} + \sigma^2 \mathbf{K}) \mathbf{K}^{-1} = \mathbf{D} + \sigma^2 \mathbf{K}^{-1}$.
- (b) The first expression is [Theorem 32.3.1](#). For the second, [Theorem 1.6.5](#) gives $\Sigma^{-1} = \sigma^{-2} \{ \mathbf{I} - \mathbf{X}(\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1} \mathbf{X}^\top \}$, so $\mathbf{DX}^\top \Sigma^{-1} = \sigma^{-2} \mathbf{D} \{ \mathbf{I} - \mathbf{K}(\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1} \} \mathbf{X}^\top$. The braced matrix is $\sigma^2 \mathbf{D}^{-1} (\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1}$, so $\mathbf{DX}^\top \Sigma^{-1} = (\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1} \mathbf{X}^\top$; applying this to $\mathbf{y}_i - \mathbf{X}\hat{\boldsymbol{\beta}}$ and inserting $\mathbf{K}\mathbf{K}^{-1}$ gives $\hat{\mathbf{u}}_i = (\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1} \mathbf{K}(\mathbf{b}_i - \hat{\boldsymbol{\beta}})$, and $(\sigma^2 \mathbf{D}^{-1} + \mathbf{K})^{-1} \mathbf{K} = (\sigma^2 \mathbf{I} + \mathbf{DK})^{-1} \mathbf{DK} = \mathbf{D}(\sigma^2 \mathbf{K}^{-1} + \mathbf{D})^{-1} = \mathbf{W}$. For the prediction error covariance, [Theorem 32.3.1](#) gives $\text{Cov}(\hat{\mathbf{u}} - \mathbf{u}) = \mathbf{G} - \mathbf{GZ}^\top \mathbf{PZG}$ with $\mathbf{P} = \mathbf{V}^{-1} - \mathbf{V}^{-1} \mathbf{X}_* (\mathbf{X}_*^\top \mathbf{V}^{-1} \mathbf{X}_*)^{-1} \mathbf{X}_*^\top \mathbf{V}^{-1}$ for the stacked model. Here $\mathbf{Z} = \mathbf{I}_N \otimes \mathbf{X}$, $\mathbf{G} = \mathbf{I}_N \otimes \mathbf{D}$, $\mathbf{X}_* = \mathbf{1}_N \otimes \mathbf{X}$ and $\mathbf{V} = \mathbf{I}_N \otimes \Sigma$, so $\mathbf{Z}^\top \mathbf{PZ} = (\mathbf{I}_N - N^{-1} \mathbf{1}_N \mathbf{1}_N^\top) \otimes (\mathbf{X}^\top \Sigma^{-1} \mathbf{X})$ and the i th diagonal block of $\mathbf{G} - \mathbf{GZ}^\top \mathbf{PZG}$ is $\mathbf{D} - (1 - 1/N) \mathbf{DX}^\top \Sigma^{-1} \mathbf{XD} = \mathbf{D} - (1 - 1/N) \mathbf{WD}$, using $\mathbf{DX}^\top \Sigma^{-1} \mathbf{X} = \mathbf{W}$ from the first part. For [Eq. 33.5.6](#), write $\mathbf{b}_i = \boldsymbol{\beta} + \mathbf{u}_i + \mathbf{c}_i$ with $\mathbf{c}_i = \mathbf{K}^{-1} \mathbf{X}^\top \boldsymbol{\varepsilon}_i \sim (\mathbf{0}, \mathbf{C})$ independent of $\mathbf{u}_i$, so $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta} + \bar{\mathbf{u}} + \bar{\mathbf{c}}$ and $\hat{\mathbf{u}}_i = \mathbf{W}(\mathbf{b}_i - \hat{\boldsymbol{\beta}})$. Then $\text{Cov}(\hat{\boldsymbol{\beta}}, \hat{\mathbf{u}}_i) = \{\text{Cov}(\bar{\mathbf{b}}, \mathbf{b}_i) - \text{Cov}(\bar{\mathbf{b}}, \bar{\mathbf{b}})\} \mathbf{W}^\top = \mathbf{0}$ and $\text{Cov}(\hat{\boldsymbol{\beta}}, \mathbf{u}_i) = \mathbf{D}/N$, so

$$\text{Cov}(\hat{\boldsymbol{\beta}} + \hat{\mathbf{u}}_i - \boldsymbol{\beta} - \mathbf{u}_i) = \frac{\mathbf{S}}{N} + \mathbf{D} - \left(1 - \frac{1}{N}\right) \mathbf{WD} - \frac{2\mathbf{D}}{N}.$$

Now $\mathbf{D} - \mathbf{WD} = \mathbf{D} - \mathbf{DS}^{-1}\mathbf{D} = \mathbf{DS}^{-1}(\mathbf{S} - \mathbf{D}) = \mathbf{WC}$ and $\mathbf{I} - \mathbf{W} = (\mathbf{S} - \mathbf{D})\mathbf{S}^{-1} = \mathbf{CS}^{-1}$, so the right-hand side is $\mathbf{WC} + (\mathbf{S} - 2\mathbf{D} + \mathbf{DS}^{-1}\mathbf{D})/N = \mathbf{WC} + \mathbf{CS}^{-1}\mathbf{C}/N = \mathbf{WC} + (\mathbf{I} - \mathbf{W})\mathbf{C}/N$. Finally $\mathbf{WC} = \mathbf{DS}^{-1}\mathbf{C} = \{\mathbf{C}^{-1}\mathbf{SD}^{-1}\}^{-1} = (\mathbf{C}^{-1} + \mathbf{D}^{-1})^{-1}$, which is [Eq. 33.5.6](#).

- (c) An error contrast is a linear function of the data with mean zero for every $\boldsymbol{\beta}$ ([Definition 32.4.1](#)). Let $\mathbf{U}$ be $m \times (m - p)$ with columns an orthonormal basis of $\mathcal{C}(\mathbf{X})^\perp$, and consider the $Nm - p$ functions

$$\mathbf{w}_i = \mathbf{U}^\top \mathbf{y}_i \quad (i = 1, \dots, N), \quad \mathbf{b}_i - \bar{\mathbf{b}} \quad (i = 1, \dots, N).$$

They are error contrasts, and a maximal set: the map $\mathbf{y}_i \mapsto (\mathbf{b}_i, \mathbf{w}_i)$ is a bijection, the $\mathbf{w}_i$ contribute $N(m - p)$ independent functions and the $\mathbf{b}_i - \bar{\mathbf{b}}$ contribute $(N - 1)p$, totalling $Nm - p$. Now $\mathbf{w}_i = \mathbf{U}^\top \boldsymbol{\varepsilon}_i \sim N_{m-p}(\mathbf{0}, \sigma^2 \mathbf{I})$ independently, while $\mathbf{b}_i \sim N_p(\boldsymbol{\beta}, \mathbf{S})$ independently, and $\text{Cov}(\mathbf{b}_i, \mathbf{w}_i) = \sigma^2 \mathbf{K}^{-1} \mathbf{X}^\top \mathbf{U} = \mathbf{0}$; the two blocks are independent, so the restricted likelihood factors as

$$L_R(\sigma^2, \mathbf{D}) = L_1(\sigma^2) \cdot L_2(\mathbf{S}), \quad \mathbf{S} = \mathbf{D} + \sigma^2 \mathbf{K}^{-1},$$

with L_1 the likelihood of $N(m - p)$ independent $N(0, \sigma^2)$ variables and L_2 that of $\mathbf{S}$ from the contrasts $\mathbf{b}_i - \bar{\mathbf{b}}$. Since $(\sigma^2, \mathbf{D}) \mapsto (\sigma^2, \mathbf{S})$ is a bijection onto $\{\mathbf{S} - \sigma^2 \mathbf{K}^{-1} \succeq \mathbf{0}\}$, the unconstrained maximizers are the restricted maximum likelihood estimates whenever they satisfy the constraint. Maximizing L_1 gives $\hat{\sigma}^2 = \sum_i \|\mathbf{y}_i - \mathbf{X}\mathbf{b}_i\|^2 / \{N(m - p)\}$, and maximizing L_2 , the restricted likelihood of a multivariate normal mean model with design $\mathbf{1}_N$, gives $\hat{\mathbf{S}} = \mathbf{S}_b$ ([Theorem 32.4.2](#)). Subtracting yields $\hat{\mathbf{D}}$.

■

Part (a) is a statement about the restriction [Eq. 33.5.3](#), not about balance alone: the population curve is ordinary least squares on the *average profile*, which is also the average of the subjects' own curves, and nothing has to be estimated first. Potthoff and Roy's own proposal was not to estimate Σ at all: transforming each profile by a positive definite weight matrix reduces [Eq. 33.5.1](#) to an ordinary multivariate analysis of variance, whose tests are exact for weights chosen without looking at the data. The efficient estimate came later, with Rao (1965); estimating Σ from the residual profiles and weighting by it is feasible generalized least squares ([Definition 31.4.1](#)).

Idea. $\mathbf{W} = \mathbf{D}(\mathbf{D} + \mathbf{C})^{-1}$ compares two covariances: $\mathbf{D}$, how much subjects really differ, and $\mathbf{C} = \sigma^2(\mathbf{X}^\top \mathbf{X})^{-1}$, how noisily each subject's own curve is measured. When subjects differ a lot relative to the noise each keeps its own curve, $\mathbf{W} \approx \mathbf{I}$; when they hardly differ every subject is given the population curve, $\mathbf{W} \approx \mathbf{0}$. Between those the predictor borrows strength across subjects, coordinate by coordinate: an intercept may be barely shrunk while a slope is shrunk by a quarter.

Part (c) says that restricted maximum likelihood here is the obvious moment estimator: pool the within-subject residual sums of squares for σ^2 , and from the spread of the subjects' own coefficient vectors subtract the part that is estimation noise. The subtraction can produce a matrix that is not nonnegative definite — the growth-curve version of the negative variance component of [Proposition 32.1.1](#) — and the estimate then sits on the boundary, where the closed form no longer applies.

33.5.3 Whose curve

Two prediction problems must be kept apart. For a subject **in the data** the predicted curve is $\mathbf{X}(\hat{\beta} + \hat{u}_i)$, with error covariance [Eq. 33.5.6](#): the first term is what remains even with β known, the second the price of estimating it. For a subject **not in the data** nothing is known but its membership of the population, so the best predictor is $\mathbf{X}\hat{\beta}$ with error covariance $\mathbf{D} + \mathbf{S}/N$ — far larger, as it should be.

33.5.4 An example

Example. (The investment trajectories of eleven firms)

The panel of [Example \(Investment in eleven firms\)](#), seen a third time — after the random firm effect of [Chapter 32](#) and the covariance models of [Section 33.4](#) — now with a straight line in t (decades from the middle of the record) whose intercept *and slope* vary by firm. The within-firm residual standard deviation is $\hat{\sigma} = 0.2797$, and

$$\hat{\mathbf{D}} = \begin{pmatrix} 2.3635 & 0.0455 \\ 0.0455 & 0.0361 \end{pmatrix},$$

so firms' log-investment levels have standard deviation 1.5374 — enormous, the difference between General Motors and Diamond Match — and their slopes 0.1899 per decade, correlated 0.156 with the level. Maximizing the restricted likelihood numerically returns the same three values to four decimals, as [Proposition 33.5.1\(c\)](#) predicts.

The population curve has intercept 3.9109 and slope 0.5577 per decade, with standard

errors 0.4639 and 0.0659 from Eq. 33.5.4; the slope is 8.46 standard errors from zero. The shrinkage matrix is

$$\mathbf{W} = \begin{pmatrix} 0.9983 & 0.0016 \\ 0.0048 & 0.7496 \end{pmatrix},$$

so intercepts are left alone — with twenty observations per firm a firm's own level is known almost exactly — while slopes are pulled a quarter of the way towards the population slope. The firms' own slopes span 0.158 to 0.943, the predicted slopes 0.248 to 0.846, a standard deviation 0.755 times that of the raw slopes; the largest adjustment is IBM's, from 0.943 to 0.846. Figure 33.5.1 shows the eleven firms with all three lines.

For the last year of the record, $t = 0.95$, the predicted value on a firm's own curve has standard error 0.1102, against 1.6461 for a firm outside the data — fifteen times larger, and simulation from the fitted model confirms both, at 0.1103 and 1.6603. The interval for a new firm, 1.214 to 7.667 on the log scale, is nearly useless, and rightly so: without knowing a firm's size, its investment cannot be predicted within three orders of magnitude.

```
import numpy as np
import statsmodels.api as sm

df = sm.datasets.grunfeld.load_pandas().data
firms = sorted(df["firm"].unique())
years = np.sort(df["year"].unique())
N, m = len(firms), len(years)
t = (years - years.mean()) / 10                                # decades from the middle of
                                                                # the record
X = np.column_stack([np.ones(m), t])                          # the same design for every
                                                                # firm

se_curve_new = np.sqrt(x_end @ V_new @ x_end)
pred_new = x_end @ beta_hat
print(f"1954 curve: se for a firm in the data {se_curve_known:.4f}, "
      f"for a new firm {se_curve_new:.4f}")

```

Remark (Beyond the balanced straight line). Three extensions matter in practice and none changes the ideas. Subjects observed at different times, or a different number of times: Eq. 33.5.4 fails, the fit becomes genuine generalized least squares with $\boldsymbol{\Sigma}_i = \mathbf{X}_i \mathbf{D} \mathbf{X}_i^\top + \sigma^2 \mathbf{I}$, and Henderson's equations (Theorem 32.3.2) do the computing. Between-subject covariates: replace $\boldsymbol{\beta}$ by $\boldsymbol{\Xi} \mathbf{a}_i$ as in the formulation Eq. 33.5.1. Serial correlation on top of the random coefficients: take $\mathbf{R}$ autoregressive, as in Section 33.4. Beyond all of these lies the question whether a polynomial in time is the right shape at all: Chapter 42 and Chapter 43.

33.5.5 Exercises

33.5.5.1 A. Check your understanding

Exercise A1.

Take $p = 1$, so $\mathbf{X} = \mathbf{1}_m$ and each subject has a single random level. Show that $\mathbf{W}$ reduces to $\sigma_u^2/(\sigma_u^2 + \sigma^2/m)$ and that the predictor is the shrunk mean $\hat{\boldsymbol{\beta}} + \mathbf{W}(\bar{y}_i - \hat{\boldsymbol{\beta}})$. What happens as $m \rightarrow \infty$, and as $\sigma_u^2 \rightarrow 0$?

Solution. With $\mathbf{X} = \mathbf{1}_m$, $\mathbf{K} = m$, $\mathbf{C} = \sigma^2/m$ and $\mathbf{D} = \sigma_u^2$, so $\mathbf{W} = \sigma_u^2/(\sigma_u^2 + \sigma^2/m)$ and $\mathbf{b}_i = \bar{y}_i$. As $m \rightarrow \infty$ the noise in $\bar{y}_i$ vanishes, $\mathbf{W} \rightarrow 1$ and no shrinkage occurs; as $\sigma_u^2 \rightarrow 0$, $\mathbf{W} \rightarrow 0$ and every subject is given the common mean, correctly, since the subjects are then identical.

Exercise A2.

The predicted curves are less spread out than the true ones. Is this a bias? Compute $E(\hat{\mathbf{u}}_i)$ and $\text{Cov}(\hat{\mathbf{u}}_i)$ and compare the latter with $\mathbf{D}$.

33.5.5.2 B. Practice

Exercise B1.

Suppose the fixed effects use a quadratic in time, $\mathbf{X} = [\mathbf{1}, \mathbf{t}, \mathbf{t}^2]$, but the random effects only a line, $\mathbf{Z} = [\mathbf{1}, \mathbf{t}]$. Show that $\mathcal{C}(\boldsymbol{\Sigma}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$ still holds, and identify what changes in $\text{Cov}(\hat{\boldsymbol{\beta}})$. What if instead the random effects used the quadratic and the fixed effects only the line?

Exercise B2.

Let subject i be observed at its own times, giving $\mathbf{X}_i$ of full column rank p , and let $\mathbf{b}_i = (\mathbf{X}_i^\top \mathbf{X}_i)^{-1} \mathbf{X}_i^\top \mathbf{y}_i$. Show that $\mathbf{b}_i \sim (\boldsymbol{\beta}, \mathbf{D} + \sigma^2(\mathbf{X}_i^\top \mathbf{X}_i)^{-1})$ independently over i , and deduce that the generalized least squares estimate from the $\mathbf{b}_i$ is $\hat{\boldsymbol{\beta}} = (\sum_i \mathbf{W}_i)^{-1} \sum_i \mathbf{W}_i \mathbf{b}_i$ with $\mathbf{W}_i = \{\mathbf{D} + \sigma^2(\mathbf{X}_i^\top \mathbf{X}_i)^{-1}\}^{-1}$, a precision-weighted average of the subjects' own curves. Recover [Eq. 33.5.4](#) as the balanced case.

Solution. $\mathbf{b}_i = \boldsymbol{\beta} + \mathbf{u}_i + (\mathbf{X}_i^\top \mathbf{X}_i)^{-1} \mathbf{X}_i^\top \boldsymbol{\varepsilon}_i$ is a sum of independent terms with covariances $\mathbf{D}$ and $\sigma^2(\mathbf{X}_i^\top \mathbf{X}_i)^{-1}$, and different subjects are independent. The $\mathbf{b}_i$ are therefore independent with common mean $\boldsymbol{\beta}$ and covariances $\mathbf{W}_i^{-1}$, so [Corollary 7.2.3](#) applied to the stacked $\mathbf{b}_i$ with design $\mathbf{1}_N \otimes \mathbf{I}_p$ gives the weighted average. When every $\mathbf{X}_i = \mathbf{X}$ the weights cancel, leaving $\hat{\boldsymbol{\beta}} = \bar{\mathbf{b}}$ with covariance $\mathbf{W}_1^{-1}/N$, which is [Eq. 33.5.4](#).

33.5.5.3 C. Going deeper

Exercise C1.

Simulate data for which $\hat{\mathbf{D}}$ of Eq. 33.5.7 is not nonnegative definite. Describe what the restricted maximum likelihood estimate does instead, relate it to the boundary problem of Proposition 32.5.1, and explain why the two-stage estimate is nevertheless unbiased for $\mathbf{D}$.

33.6 Summary and Notes

33.6.1 Summary

Idea.

1. A split-plot design randomizes twice and has two error terms: the response space splits into a whole-plot stratum with error variance $\sigma_s^2 + b\sigma_w^2$ and a subplot stratum with error variance σ_s^2 (Lemma 33.1.1).
2. In the balanced design ordinary least squares is still best, because $\mathcal{C}(\mathbf{VX}) \subseteq \mathcal{C}(\mathbf{X})$. The whole-plot factor is tested against the block-by-treatment mean square on $(r-1)(a-1)$ degrees of freedom, the subplot factor and the interaction against the residual; a comparison of whole-plot treatments at one subplot level belongs to neither stratum and needs both mean squares (Theorem 33.1.2). Pooling inflates the whole-plot F and deflates the subplot one.
3. With compound symmetry inside clusters of size m , a cluster-level coefficient has its variance multiplied by the design effect $1 + (m-1)\rho$ and a within-cluster coefficient by $1 - \rho$; the usual standard error is wrong by $\{E(s^2)/\lambda\}^{1/2}$, with $E(s^2)$ given exactly (Proposition 33.2.1). Clustering moves information from between-cluster to within-cluster comparisons.
4. The cluster-robust covariance estimator assumes only that clusters are independent, and is consistent as the number of clusters grows, not the number of observations. With few clusters it is badly biased downward.
5. The repeated-measures F test is exact if and only if the covariance satisfies sphericity: all pairwise differences of the repeated measurements have the same variance (Lemma 33.3.1, Theorem 33.3.2). Compound symmetry implies sphericity; the converse is false.
6. When sphericity fails, the moment-matched approximation multiplies both degrees of freedom by Box's ϵ (Proposition 33.3.3); the Greenhouse–Geisser and Huynh–Feldt corrections estimate ϵ , and Hotelling's T^2 avoids the issue at a cost in power (Proposition 33.3.4).
7. Longitudinal covariance is built from random effects, serial correlation and measurement error, and the standard models keep one or two of the three (Definition 33.4.1). A wrong covariance model leaves the fixed effects unbiased and is repaired by the empirical standard error; restricted likelihoods compare only models with the same mean structure (Proposition 33.4.1).
8. In the balanced random-coefficient growth model the population curve is the average of the subjects' own curves, needing no covariance parameter; the predicted subject curve shrinks the subject's own curve towards it by $\mathbf{D}(\mathbf{D} + \sigma^2(\mathbf{X}^\top \mathbf{X})^{-1})^{-1}$; and restricted maximum likelihood has the closed form of the two-stage moment estimator (Proposition 33.5.1).

33.6.2 Notes and sources

Split plots. The design and its two-stratum analysis are due to Yates (1935); Fisher (1935) had already made the choice of error term the central issue of experimental design. The route taken here is [Lemma 33.1.1](#), which reduces everything to [Theorem 16.3.1](#) plus Kruskal's condition ([Theorem 6.9.3](#)); Christensen (2020, chapter 11) develops split-plot models from a cluster sampling model in the same coordinate-free spirit. The cross-stratum simple effect of [Theorem 33.1.2\(f\)](#) is standard practical advice given a derivation here.

Clusters and the design effect. The design effect $1 + (m - 1)\rho$ is Kish's (1965), from survey sampling; its damage to standard errors for aggregate regressors was pressed on econometricians by Moulton (1990). The cluster-robust estimator [Eq. 33.2.3](#) is the clustered form of the sandwich estimators of [Section 21.4](#), whose proof also gives its consistency, cluster by cluster in place of observation by observation; its small-sample failings and their remedies are surveyed by Cameron and Miller (2015).

Sphericity. Box (1954) computed the effect of an arbitrary covariance on the two-way analysis of variance and introduced ϵ and the approximation of [Proposition 33.3.3](#). Huynh and Feldt (1970) isolated the necessary and sufficient condition of [Lemma 33.3.1](#), which is named after them, and the fixed- N form of [Theorem 33.3.2\(c\)](#) is theirs; the proof here takes the easier route through the large-sample limit. Geisser and Greenhouse (1958) showed the lower-bound reference distribution to be exactly conservative, not merely so within Box's approximation; Greenhouse and Geisser (1959) made the plug-in and lower-bound corrections a recommendation, Huynh and Feldt (1976) gave the bias-corrected [Eq. 33.3.3](#), and Mauchly (1940) the likelihood ratio test of sphericity itself. The multivariate alternative is Hotelling's T^2 (Hotelling 1931), whose distribution theory we quote from Anderson (2003).

Longitudinal covariance. The three-source decomposition [Eq. 33.4.1](#) and the empirical variogram are due to Diggle (1988); Diggle, Heagerty, Liang and Zeger (2002) is the standard account. That a working covariance can be wrong without invalidating the estimate, provided the standard error is computed empirically, is from Liang and Zeger (1986), whose generalized estimating equations are the subject of [Chapter 40](#). The rule of [Proposition 33.4.1\(c\)](#) follows from [Definition 32.4.1](#) and is a common source of error in practice. Degrees of freedom under an estimated covariance belong to Satterthwaite (1946) and Kenward and Roger (1997); missing data to [Chapter 41](#), the missing-at-random condition being Rubin's (1976).

Growth curves. Potthoff and Roy (1964) introduced [Eq. 33.5.1](#) and reduced it to an ordinary multivariate analysis of variance by a weight matrix fixed in advance; Rao (1965) gave the efficient estimate and recast growth curves in terms of random coefficients, [Eq. 33.5.2](#); Laird and Ware (1982) put the two together in the form that became standard software. The shrinkage [Eq. 33.5.5](#) is the multivariate signal-to-noise weighting of [Chapter 27](#); the closed form [Eq. 33.5.7](#) appears to be folklore, proved here by factorizing the error-contrast likelihood into within- and between-subject pieces.

The data. The investment panel of [Example \(Investment in eleven firms\)](#) and [Example \(The investment trajectories of eleven firms\)](#) is Grunfeld's (1958), in the eleven-firm version reconstructed by Kleibers and Zeileis (2010) and distributed with statsmodels — the panel already fitted with a random firm effect in [Chapter 32](#), seen here from two more angles. The split-plot and repeated-measures examples are simulated.

Chapter 34

Exponential Families and the Generalized Linear Model

Every chapter so far has modelled a response whose scatter about a linear mean is, if not normal, at least additive and of constant shape. Counts, proportions, waiting times and insurance claims are none of these: their means are confined to an interval, their spread grows with their mean, their distributions are skewed by construction. This chapter builds the framework that handles them — a response from an **exponential dispersion family**, a **linear predictor** $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, and a **link** joining the two. Least squares gives way to maximum likelihood, the normal equations to the likelihood equations, and the closed-form estimate to an iteration that turns out to be weighted least squares, run until it stops changing. Exact distribution theory gives way to asymptotics, so every claim here comes with conditions attached.

What you need. Chapter 5 and Chapter 6 (the linear model, projection, leverage), Section 7.3 and Section 7.4 (maximum likelihood Theorem 7.3.1, the score and information Proposition 7.4.7, exponential families Lemma 7.4.2), Chapter 11 (the likelihood ratio test Theorem 11.4.1 and the trinity Proposition 11.4.2), Section 21.3 (weighted least squares Theorem 21.3.1). Chapter 20 (residuals and influence, and iteratively reweighted least squares Proposition 20.6.1) and Chapter 29 (AIC) are used in the last section.

34.0.1 Roadmap

- Exponential dispersion families
- Link functions
- The likelihood equations
- Iteratively reweighted least squares
- Deviance and asymptotic inference
- Summary and notes

34.1 Exponential dispersion families

The normal linear model makes two assumptions usually stated together but logically independent: that $E(Y_i)$ is linear in the regressors, and that Y_i is normal with a variance not depending

on that mean. This section replaces the second by the least it can, a one-parameter family whose log-density is linear in the data with a single extra scale. [Section 7.4](#) already wrote the normal linear model in that form ([Eq. 7.4.1](#)); what follows names the ingredients, because in a generalized linear model each does a separate job.

34.1.1 The family

Definition 34.1.1 — Exponential dispersion family

Let ν be a σ -finite measure on $\mathbb{R}$. A random variable Y belongs to the **exponential dispersion family** generated by ν if, for a dispersion $\phi > 0$ and a known **prior weight** $w > 0$, its density with respect to ν is

$$f(y; \theta, \phi) = \exp \left\{ \frac{w \{y\theta - b(\theta)\}}{\phi} + c(y, \phi, w) \right\}, \quad (34.1.1)$$

where θ lies in the **natural parameter space**

$$\Theta = \left\{ \theta \in \mathbb{R} : \kappa(\theta) = \int e^{wy\theta/\phi} e^{c(y, \phi, w)} d\nu(y) < \infty \right\}$$

and $b(\theta) = (\phi/w) \log \kappa(\theta)$ is the **cumulant function**, required to be the *same* function of θ for every admissible pair (ϕ, w) . The normalizing constant $\kappa(\theta)$ is this chapter's only use of that letter with an argument; elsewhere $\kappa(\cdot)$ is the condition number of [Definition 1.8.1](#). The parameter θ is the **natural** (or canonical) parameter.

Four ingredients, four jobs. The measure ν fixes what kind of thing the response is: Lebesgue measure on $\mathbb{R}$ for the normal, on $(0, \infty)$ for the gamma, counting measure on $\{0, 1, \dots\}$ for the Poisson. The cumulant function b determines every moment, as this section shows. The dispersion ϕ is a nuisance scale, unknown for the normal and the gamma, fixed at 1 for the Poisson and the binomial. The prior weight w is known and records how much data each observation summarizes: 1 for a single observation, m when y is an average of m of them. Only ϕ/w appears, so w never needs estimating; and that one formalism covers $w = 1$ and $w = m$ at once is what the common- b requirement buys, since it forces c to absorb the whole dependence on (ϕ, w) . That is what makes the family a *dispersion* family (Jorgensen 1987).

The function c does no statistical work: it absorbs whatever is left once the term linear in $y\theta$ has been extracted, and never depends on θ . That is the point, because in the log-likelihood

$$\log f(y; \theta, \phi) = \frac{w \{y\theta - b(\theta)\}}{\phi} + c(y, \phi, w), \quad (34.1.2)$$

the data and the parameter of interest meet only in the product $y\theta$. By [Lemma 7.4.1](#), y itself is sufficient for θ .

The normalization $b = (\phi/w) \log \kappa$ is forced, because a density must integrate to one. The next lemma records the two properties of b that everything else rests on.

Lemma 34.1.1 — The natural parameter space and the cumulant function

Θ is a convex subset of $\mathbb{R}$, and b is convex on Θ . If Y is not degenerate under some $\theta_0 \in \Theta$, then b is strictly convex on Θ .

Proof. Write $h(y) = e^{c(y, \phi, w)}$ and $s = w/\phi > 0$, so that $\kappa(\theta) = \int e^{sy\theta} h(y) d\nu(y)$. Let $\theta_1, \theta_2 \in \Theta$ and $\alpha \in (0, 1)$. Hölder's inequality with exponents $1/\alpha$ and $1/(1-\alpha)$ applied to the factors $(e^{sy\theta_1} h)^\alpha$ and $(e^{sy\theta_2} h)^{1-\alpha}$ gives

$$\kappa(\alpha\theta_1 + (1-\alpha)\theta_2) \leq \kappa(\theta_1)^\alpha \kappa(\theta_2)^{1-\alpha} < \infty.$$

So $\alpha\theta_1 + (1-\alpha)\theta_2 \in \Theta$, which makes Θ convex, and taking logarithms shows $\log \kappa$, hence b , is convex. Equality in Hölder's inequality requires $e^{sy\theta_1} h$ and $e^{sy\theta_2} h$ to be proportional ν -almost everywhere, that is, $e^{sy(\theta_1 - \theta_2)}$ constant on the set where $h > 0$. For $\theta_1 \neq \theta_2$ this forces that set to be a single point, so Y is degenerate. ■

Throughout the chapter Θ is assumed to have nonempty interior and θ to lie in it — the same regularity Lemma 7.4.2 needs, and what makes the differentiations below legal.

34.1.2 Moments from the cumulant function

Proposition 34.1.2 — Mean, variance and cumulants

Let Y have density Eq. 34.1.1 with θ in the interior of Θ . Then Y has moments of all orders, and

- (a) $\mu := E(Y) = b'(\theta)$ and $\text{Var}(Y) = \frac{\phi}{w} b''(\theta)$;
- (b) the map $\theta \mapsto b'(\theta)$ is strictly increasing, hence a bijection from the interior of Θ onto an open interval $\mathcal{M}$, the **mean space**;
- (c) the cumulant generating function of Y is $K(t) = \log E e^{tY} = \frac{w}{\phi} \{b(\theta + t\phi/w) - b(\theta)\}$ for small $|t|$, so the r th cumulant of Y is $(\phi/w)^{r-1} b^{(r)}(\theta)$.

Proof. With h and $s = w/\phi$ as in the proof of Lemma 34.1.1, the density is $\kappa(\theta)^{-1} e^{sy\theta} h(y)$. The function κ is a two-sided Laplace transform of the measure $h d\nu$ evaluated at $-s\theta$; such a transform is analytic in the interior of its domain of convergence, and may be differentiated under the integral sign there, together with the finiteness of all moments (Widder 1941, chapter II; Brown 1986, chapter 2). Hence

$$\kappa'(\theta) = s \int y e^{sy\theta} h d\nu = s E(Y) \kappa(\theta), \quad \kappa''(\theta) = s^2 E(Y^2) \kappa(\theta).$$

Since $b = s^{-1} \log \kappa$, we have $b' = \kappa'/(s\kappa) = E(Y)$, which is (a) for the mean. Differentiating $\kappa' = s b' \kappa$ once more gives $\kappa'' = s b'' \kappa + s^2 (b')^2 \kappa$, so $E(Y^2) = b''/s + (b')^2$ and $\text{Var}(Y) = b''(\theta)/s = \phi b''(\theta)/w$.

- (b) By Lemma 34.1.1, b is strictly convex, so $b' = E(Y)$ is strictly increasing; it is continuous, so its range on an open interval is an open interval.
- (c) For t small enough that $\theta + t/s \in \Theta$, $E e^{tY} = \kappa(\theta)^{-1} \int e^{(s\theta+t)y} h d\nu = \kappa(\theta + t/s)/\kappa(\theta)$; taking logarithms gives $K(t) = s^{-1}\{b(\theta + t/s) - b(\theta)\}$ with $s^{-1} = \phi/w$, and the coefficient of $t^r/r!$ in its expansion is $s^{-(r-1)}b^{(r)}(\theta)$.

■

Part (a) is the engine of the chapter: the variance is not free but determined by the mean, up to the single scalar ϕ/w . Part (b) lets us reparameterize by the mean, which is the parameter a modeller wants.

Definition 34.1.2 — Variance function

For $\mu \in \mathcal{M}$ let $\theta(\mu)$ be the inverse of b' from Proposition 34.1.2(b). The **variance function** of the family is $V(\mu) = b''(\theta(\mu))$, so that

$$\text{Var}(Y) = \frac{\phi}{w} V(\mu), \quad \frac{d\theta}{d\mu} = \frac{1}{V(\mu)}.$$

The last identity is the derivative of an inverse function, $d\mu/d\theta = b'' = V$, and is used constantly below. The pair $(\mathcal{M}, V)$ determines the family: integrating V gives $\theta(\mu)$, hence b , hence the density.

Idea. A generalized linear model is specified by three separate choices: the **variance function** V , which fixes the family; the **link**; and the **linear predictor** $\mathbf{X}\beta$. Chapter 38 keeps the first two and throws the density away, which is possible because the estimating equations of Section 34.3 involve nothing else.

34.1.3 The standard families

The five classical families, plus the negative binomial with a known shape k , come from choosing ν and reading off b . The gamma row is written for shape a , so that $\phi = 1/a$. The measure ν is Lebesgue on $\mathbb{R}$ for the normal and on $(0, \infty)$ for the gamma and inverse Gaussian, counting measure on $\{0, 1, 2, \dots\}$ for the Poisson and negative binomial, and counting measure on $\{0, 1/m, \dots, 1\}$ for the binomial, whose response is a proportion out of m .

Family	$\theta(\mu)$	$b(\theta)$	ϕ	$V(\mu)$	$\mathcal{M}$
normal	μ	$\theta^2/2$	σ^2	1	$\mathbb{R}$
binomial	$\log \frac{\mu}{1-\mu}$	$\log(1 + e^\theta)$	1	$\mu(1 - \mu)$	$(0, 1)$
Poisson	$\log \mu$	e^θ	1	μ	$(0, \infty)$
gamma	$-1/\mu$	$-\log(-\theta)$	$1/a$	μ^2	$(0, \infty)$
inverse Gaussian	$-1/(2\mu^2)$	$-\sqrt{-2\theta}$	σ^2	μ^3	$(0, \infty)$
neg. binomial	$\log \frac{\mu}{\mu + k}$	$-k \log(1 - e^\theta)$	1	$\mu(1 + \mu/k)$	$(0, \infty)$

Two entries deserve a full derivation, because they show the two ways the prior weight and the dispersion enter.

Example. (The binomial as a family of proportions)

Let $S \sim \text{Binomial}(m, \mu)$ and let $Y = S/m$ be the observed proportion. Its probability mass function at $y = s/m$ is

$$\begin{aligned} \binom{m}{my} \mu^{my} (1 - \mu)^{m(1-y)} \\ = \exp \left\{ m \left(y \log \frac{\mu}{1 - \mu} + \log(1 - \mu) \right) + \log \binom{m}{my} \right\}. \end{aligned}$$

This is [Eq. 34.1.1](#) with $w = m$, $\phi = 1$, $\theta = \log\{\mu/(1 - \mu)\}$ and $b(\theta) = -\log(1 - \mu) = \log(1 + e^\theta)$. Then $b'(\theta) = e^\theta/(1 + e^\theta) = \mu$ and $b''(\theta) = \mu(1 - \mu)$, so [Proposition 34.1.2](#) gives $E(Y) = \mu$ and $\text{Var}(Y) = \mu(1 - \mu)/m$: the number of trials acts entirely through the prior weight. The dispersion is fixed at 1, so a proportion more variable than $\mu(1 - \mu)/m$ needs the different treatment of [Chapter 38](#).

Example. (The gamma and its constant coefficient of variation)

Let Y have the gamma density with shape $a > 0$ and mean μ ,

$$f(y) = \frac{(a/\mu)^a}{\Gamma(a)} y^{a-1} e^{-ay/\mu} \quad \text{on } (0, \infty).$$

Its logarithm is

$$a \left\{ y \left(-\frac{1}{\mu} \right) - \log \mu \right\} + (a - 1) \log y + a \log a - \log \Gamma(a),$$

which is [Eq. 34.1.1](#) with $w = 1$, $\phi = 1/a$, $\theta = -1/\mu$ and $b(\theta) = \log \mu = -\log(-\theta)$. Then $b'(\theta) = -1/\theta = \mu$ and $b''(\theta) = 1/\theta^2 = \mu^2$, so $\text{Var}(Y) = \phi\mu^2$ and the coefficient of variation $\sqrt{\text{Var}(Y)}/\mu = \sqrt{\phi}$ is free of the mean: the spread is *proportional* to the level, the defining feature of the gamma family as a regression model. With $\mu = 4$ and $\phi = 0.4$ the formula gives $\text{Var}(Y) = 6.400$, and by [Proposition 34.1.2\(c\)](#) the third cumulant is $\phi^2 b'''(\theta) = 2\phi^2 \mu^3 = 20.480$; both agree with the exact gamma moments in the listing below.

Figure 34.1.1: Variance functions. (a) The power family $V(\mu) = \mu^\xi$ on logarithmic axes: normal, Poisson, gamma and inverse Gaussian are $\xi = 0, 1, 2, 3$. (b) Two variance functions that are not powers. The binomial variance vanishes at both ends; the negative binomial variance $\mu(1 + \mu/k)$ lies above the Poisson line for every finite k .

The variance functions are drawn in Figure 34.1.1. The normal, Poisson, gamma and inverse Gaussian are powers, $V(\mu) = \mu^\xi$ with $\xi = 0, 1, 2, 3$; interpolating between them gives a continuum of families (Jorgensen 1987) that includes a useful model for a response with a point mass at zero and a continuous positive part. The remaining two are not powers: the binomial variance vanishes at both ends of $(0, 1)$, because a proportion pinned near 0 or 1 cannot vary, and the negative binomial variance exceeds the Poisson variance by an amount set by k .

Example. (The negative binomial with known shape)

Let $\Pr(Y = y) = \frac{\Gamma(y+k)}{\Gamma(k)y!} \pi^y (1 - \pi)^k$, $y = 0, 1, 2, \dots$, for a fixed $k > 0$. Writing $\theta = \log \pi$ puts this in the form Eq. 34.1.1 with $w = 1$, $\phi = 1$ and $b(\theta) = -k \log(1 - e^\theta)$, so that

$$\mu = b'(\theta) = \frac{k\pi}{1 - \pi}, \quad b''(\theta) = \frac{k\pi}{(1 - \pi)^2} = \mu \left(1 + \frac{\mu}{k}\right)$$

after substituting $\pi = \mu/(\mu + k)$. With $k = 2$ and $\mu = 3$ this gives $\text{Var}(Y) = 7.500$, against 3 for a Poisson variable with the same mean.

The caveat is essential: this is an exponential dispersion family **only for fixed k** . The shape enters the variance function, not the dispersion, so it cannot be divided out, and letting k vary leaves the form Eq. 34.1.1. Estimating k is outside this chapter's machinery; Chapter 37 takes it up.

34.1.4 Sufficiency, and what the natural parameter buys

Suppose $Y_1, \dots, Y_n$ are independent, each with density Eq. 34.1.1, with a common b and ϕ , known weights w_i , and natural parameters θ_i . The joint log-likelihood is

$$\ell = \frac{1}{\phi} \sum_{i=1}^n w_i \{y_i \theta_i - b(\theta_i)\} + \sum_{i=1}^n c(y_i, \phi, w_i). \quad (34.1.3)$$

Nothing has been assumed yet about how the θ_i depend on regressors — that is the next section's business — but Eq. 34.1.3 already shows what to expect. If the θ_i are constrained to a p -dimensional linear family $\theta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, then $\sum_i w_i y_i \theta_i = \boldsymbol{\beta}^\top \mathbf{X}^\top \text{diag}(\mathbf{w}) \mathbf{y}$ and the data enter the likelihood only through the p numbers $\mathbf{X}^\top \text{diag}(\mathbf{w}) \mathbf{y}$. With ϕ known the remaining term $\sum_i c(y_i, \phi, w_i)$ is a function of the data alone, so Lemma 7.4.1 makes this vector sufficient for $\boldsymbol{\beta}$, and if the attainable $\boldsymbol{\beta}$ contain an open subset of $\mathbb{R}^p$, Lemma 7.4.2 makes it complete. With ϕ unknown that term depends on a parameter, both arguments fail, and a second statistic is needed — as in the normal linear model, the case $b(\theta) = \theta^2/2$, $w_i = 1$, where $\mathbf{X}^\top \mathbf{y}$ is accompanied by $\mathbf{y}^\top \mathbf{y}$ for σ^2 (Proposition 7.4.3).

That is a genuine reduction, and it is why the natural parameter deserves its name. What it does not give is any analogue of the Gauss–Markov theorem: the maximum likelihood estimate is a nonlinear function of $\mathbf{y}$, generally biased, with an exact distribution unknown outside the normal case. Everything finite-sample that Parts II and III delivered is gone, and Section 34.5 replaces it with asymptotics.

Warning. The reduction needs θ_i — not μ_i , and not some other function of it — to be linear in $\boldsymbol{\beta}$. That is the *canonical link*, one modelling choice among several. With any other link the reduction fails and the data enter the likelihood through the whole vector $\mathbf{y}$; Section 34.2 explains why one might accept that.

34.1.5 Exercises

34.1.5.1 A. Check your understanding

Exercise A1.

Write the Poisson probability mass function in the form Eq. 34.1.1, identify θ , b , ϕ , w and c , and verify $E(Y) = \text{Var}(Y) = \mu$ using Proposition 34.1.2. What is Θ ?

Solution. $\Pr(Y = y) = e^{-\mu} \mu^y / y! = \exp\{y \log \mu - \mu - \log y!\}$, so $\theta = \log \mu$, $b(\theta) = e^\theta$, $\phi = w = 1$ and $c(y) = -\log y!$. Then $b' = b'' = e^\theta = \mu$, and Proposition 34.1.2 gives $E(Y) = \text{Var}(Y) = \mu$. The sum $\sum_y e^{y\theta} / y! = e^{e^\theta}$ converges for every real θ , so $\Theta = \mathbb{R}$ and $\mathcal{M} = (0, \infty)$.

34.1.5.2 B. Practice

Exercise B1.

Verify the inverse Gaussian row of the table: starting from

$$f(y) = (2\pi\sigma^2 y^3)^{-1/2} \exp\left\{-\frac{(y - \mu)^2}{2\sigma^2 \mu^2 y}\right\} \quad \text{on } (0, \infty),$$

put it in the form [Eq. 34.1.1](#) and confirm $V(\mu) = \mu^3$. What is Θ , and what happens at $\theta = 0$?

Solution. Expanding the square, $-(y-\mu)^2/(2\sigma^2\mu^2y) = -y/(2\sigma^2\mu^2) + 1/(\sigma^2\mu) - 1/(2\sigma^2y)$. So the exponent is $\sigma^{-2}\{y\theta - b(\theta)\}$ with $\theta = -1/(2\mu^2)$ and $b(\theta) = -1/\mu = -\sqrt{-2\theta}$, while the remaining terms $-\frac{1}{2}\log(2\pi\sigma^2y^3) - 1/(2\sigma^2y)$ make up $c(y, \phi, w)$ with $\phi = \sigma^2$, $w = 1$. Then $b'(\theta) = (-2\theta)^{-1/2} = \mu$ and $b''(\theta) = (-2\theta)^{-3/2} = \mu^3$. Here $\Theta = (-\infty, 0]$ and $\theta = 0$ is a boundary point: the integral still converges there, but b' blows up, so $\mathcal{M} = (0, \infty)$ is the image of the *interior* only.

Exercise B2.

Show that the variance function determines the family: if V is given on an interval $\mathcal{M}$, then $\theta(\mu) = \int^\mu dt/V(t)$ and $b(\theta(\mu)) = \int^\mu t dt/V(t)$, each up to constants that only relocate the density. Carry this out for $V(\mu) = \mu(1-\mu)$ on $(0, 1)$ and recover the binomial row.

Solution. By [Definition 34.1.2](#), $d\theta/d\mu = 1/V(\mu)$, which integrates to the stated $\theta(\mu)$. Also $db/d\mu = (db/d\theta)(d\theta/d\mu) = \mu/V(\mu)$, giving the second integral. For $V(\mu) = \mu(1-\mu)$, partial fractions give $\int d\mu/\{\mu(1-\mu)\} = \log\{\mu/(1-\mu)\} = \theta$, and $\int \mu d\mu/\{\mu(1-\mu)\} = -\log(1-\mu) = \log(1+e^\theta) = b(\theta)$, which is the binomial row.

Exercise B3.

Use [Proposition 34.1.2\(c\)](#) to show that the skewness of Y is $\gamma_1 = \sqrt{\phi/w} V'(\mu)/\sqrt{V(\mu)}$. Evaluate it for the Poisson, the gamma and the binomial, and say in each case how the skewness behaves as the mean moves.

Solution. The third cumulant is $(\phi/w)^2 b'''(\theta)$, and $b'''(\theta) = dV/d\theta = V'(\mu) d\mu/d\theta = V'(\mu)V(\mu)$. Dividing by $\text{Var}(Y)^{3/2} = \{(\phi/w)V\}^{3/2}$ gives $\gamma_1 = \sqrt{\phi/w} V'(\mu)/\sqrt{V(\mu)}$. For the Poisson ($\phi = w = 1$, $V = \mu$), $\gamma_1 = \mu^{-1/2}$: small counts are strongly skewed and large ones nearly symmetric. For the gamma, $V = \mu^2$ gives $\gamma_1 = 2\sqrt{\phi}$, free of the mean. For the binomial with $w = m$, $\gamma_1 = (1-2\mu)/\sqrt{m\mu(1-\mu)}$, which changes sign at $\mu = \frac{1}{2}$.

34.1.5.3 C. Going deeper

Exercise C1.

Show that the uniform family on $(0, \vartheta)$ is not an exponential dispersion family for any choice of ν , and that the Cauchy family with median ϑ is not either. Which hypothesis of [Definition 34.1.1](#) fails in each case?

Exercise C2.

Suppose $V(\mu) = \mu^\xi$ on $(0, \infty)$ for some $\xi \notin \{1, 2\}$. Carry out [Exercise \(B2\)](#) to find $\theta(\mu)$ and $b(\theta)$, and check that $\xi = 0$ and $\xi = 3$ reproduce the normal and inverse Gaussian rows. For $1 < \xi < 2$ the family is the distribution of a Poisson number of independent gamma variables, with positive probability at 0 and a continuous part on

$(0, \infty)$ (Jorgensen 1987); confirm from the general formula that its mean space is $(0, \infty)$.

34.2 Link functions

The linear model says $E(Y_i) = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. For a count that must be nonnegative, or a probability that must lie in $(0, 1)$, that equation is a promise the right-hand side cannot keep: a linear function of unbounded regressors takes every real value. The resolution is to put a monotone function between the mean and the linear predictor.

34.2.1 The model

Definition 34.2.1 — Generalized linear model

Let $\mathbf{X}$ be an $n \times p$ model matrix with rows $\mathbf{x}_{(i)}^\top$, and let $w_1, \dots, w_n > 0$ be known prior weights. A **generalized linear model** consists of

- (a) a **random component**: $Y_1, \dots, Y_n$ are independent, and Y_i has the density [Eq. 34.1.1](#) with natural parameter θ_i , weight w_i and a dispersion ϕ that is the same for all i ;
- (b) a **linear predictor** $\eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, with $\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} \in \mathbb{R}^n$;
- (c) a **link function** $g : \mathcal{M} \rightarrow \mathbb{R}$, strictly monotone and twice continuously differentiable, with

$$g(\mu_i) = \eta_i, \quad \mu_i = E(Y_i) = b'(\theta_i).$$

The inverse $h = g^{-1}$ is the **response function**, so $\mu_i = h(\eta_i)$. The **admissible set** of the model is $\mathcal{B} = \{\boldsymbol{\beta} \in \mathbb{R}^p : \mathbf{x}_{(i)}^\top \boldsymbol{\beta} \in g(\mathcal{M}) \text{ for all } i\}$.

The linear model of [Chapter 5](#) is the case: normal random component, identity link, $w_i = 1$, $\phi = \sigma^2$, $\mathcal{B} = \mathbb{R}^p$. Every classical result of Parts II and III is about that one cell of a large table.

Three remarks. The dispersion is common to all observations: the regressors move the mean, the variance follows through V , and nothing else may vary (modelling ϕ too is the subject of [Chapter 45](#), [Definition 45.5.1](#)). The weights w_i are known, not estimated, and usually record group sizes. And g transforms the mean, not the data: [Chapter 22](#) transformed Y itself, whereas here the response is left alone and the link acts inside the expectation.

Definition 34.2.2 — Canonical link

The **canonical link** of a family is $g = (b')^{-1}$, so that $\theta_i = \eta_i$: the natural parameter is the linear predictor. Equivalently, $g'(\mu) = 1/V(\mu)$.

Family	canonical link	$g(\mu)$	range of η	other links in use
normal	identity	μ	$\mathbb{R}$	log, inverse

Family	canonical link	$g(\mu)$	range of η	other links in use
binomial	logit	$\log\{\mu/(1-\mu)\}$	$\mathbb{R}$	probit, complementary log-log, identity
Poisson	log	$\log \mu$	$\mathbb{R}$	identity, square root
gamma	inverse	$-1/\mu$	$(-\infty, 0)$	log, identity
inverse Gaussian	inverse square	$-1/(2\mu^2)$	$(-\infty, 0)$	log
negative binomial	$\log\{\mu/(\mu+k)\}$	as shown	$(-\infty, 0)$	log

The sign conventions for the gamma and inverse Gaussian are cosmetic: $1/\mu$ and $-1/\mu$ give the same fitted values with $\boldsymbol{\beta}$ negated. The column headed “range of η ” is not. For the normal, binomial and Poisson the canonical link maps $\mathcal{M}$ onto all of $\mathbb{R}$, so $\mathcal{B} = \mathbb{R}^p$ and no constraint is ever active. For the gamma and inverse Gaussian it maps onto a half-line, and $\mathcal{B}$ is the polyhedron $\{\boldsymbol{\beta} : \mathbf{x}_{(i)}^\top \boldsymbol{\beta} < 0 \text{ for all } i\}$ — an open convex set with a boundary a fitting algorithm can walk into.

34.2.2 What a link choice costs and buys

Idea. The canonical link is a mathematical convenience, not a scientific claim. It makes the likelihood concave (Theorem 34.3.3), makes observed and expected information agree (Theorem 34.3.1), reduces the data to p sufficient statistics (Section 34.1), and forces the fitted values to reproduce the observed weighted column totals of $\mathbf{X}$ exactly (Corollary 34.3.2). None of that is a reason to believe the mean depends on the regressors in that particular way.

Four considerations decide a link in practice.

Range. A link whose range is all of $\mathbb{R}$ removes constraints from the fitting problem. The log link for a Poisson response guarantees $\hat{\mu}_i > 0$ for every $\boldsymbol{\beta} \in \mathbb{R}^p$, and the logit link for a binomial response guarantees $\hat{\mu}_i \in (0, 1)$. An identity link for either does not.

Example. (An identity link close to its boundary)

Eight counts were simulated from a Poisson model with mean $12 - 1.2x$ at $x = 1, \dots, 8$. An identity-link Poisson fit recovers the declining mean, and every fitted value is positive — but the fitted line reaches zero at $x = 9.89$, barely outside the range of the data. Predicting at $x = 10$ would return a negative mean, and a slightly different sample would push the boundary inside the observed range, where the likelihood is $-\infty$. The log link has no such boundary.

Interpretation. A log link makes the regressors act multiplicatively, $\mu = e^{\beta_0} \prod_j e^{\beta_j x_j}$, so β_j is a log rate ratio and e^{β_j} the factor multiplying the mean per unit of x_j . A logit link makes β_j a log odds ratio, the subject of Chapter 35 (Definition 35.1.1). An identity link keeps β_j a difference of means, often what a policy question asks about. These are different scientific statements, and the choice belongs on the scale where effects are plausibly additive, not on convenience.

Fit and stability. Different links give genuinely different mean curves, and a badly chosen one

shows up in the residuals like any other misspecification. Non-canonical links can also produce a log-likelihood with several stationary points, and links with a restricted range need the fitting algorithm to be protected; [Section 34.4](#) returns to this.

Example. (Food expenditure: three models, two decisions)

Engel's classic budget survey records annual income and food expenditure for 235 working-class households. Food expenditure is positive, right-skewed, and visibly more variable at high incomes. Write $u = \log(\text{income})$ and fit three models with the same linear predictor $\beta_0 + \beta_1 u$: a normal random component with the identity link (ordinary least squares), a gamma random component with the identity link, and a gamma random component with the log link. The first two differ only in the variance function, the last two only in the link.

The identity-link fits give $\hat{\beta}_1 = 571.02$ (normal) and 474.54 (gamma) francs per unit of log income. The gamma/log fit gives $\hat{\beta}_1 = 0.8629$, an elasticity: a one per cent rise in income is associated with a 0.86 per cent rise in expected food expenditure. Its estimated dispersion is $\hat{\phi} = 0.0177$, so by [Example \(The gamma and its constant coefficient of variation\)](#) the fitted coefficient of variation is $\sqrt{\hat{\phi}} = 0.133$, the same at every income.

[Figure 34.2.1](#) separates the two decisions. In panel (a) the identity-link mean curve is concave in income and flattens, while the log-link curve is a power law that keeps climbing; at the largest income in the sample the two fitted means differ by a factor of 1.786. Panel (b) holds the link at the identity and changes the variance function, so its bands come from the identity-link fits, the gamma one using $\hat{\phi} = 0.0240$ and a coefficient of variation of 0.155. The normal band has constant width and at low incomes dips below zero; the gamma band widens in proportion to the mean, as the data do.

```
import numpy as np
import statsmodels.api as sm

engel = sm.datasets.engel.load_pandas().data
y = engel["foodexp"].to_numpy()           # food expenditure
X = np.column_stack([np.ones(len(y)), np.log(engel["income"].to_numpy())])

gauss = sm.GLM(y, X, family=sm.families.Gaussian()).fit()           # identity link
gam_id = sm.GLM(y, X, family=sm.families.Gamma(sm.families.links.Identity())).fit()
gam_log = sm.GLM(y, X, family=sm.families.Gamma(sm.families.links.Log())).fit()

for name, fit in [("normal/identity", gauss), ("gamma/identity", gam_id), ("gamma/
log", gam_log)]:
    print(f"{name:16s} coefficients {fit.params[0]:9.3f} {fit.params[1]:8.3f}"
          f"    dispersion {fit.scale:8.4f}")
```

34.2.3 Links and transformations are not the same thing

Transforming the response and choosing a link both replace μ by $g(\mu)$, but in different places. Modelling $E\{g(Y)\} = \mathbf{x}^\top \boldsymbol{\beta}$ changes the quantity modelled: by Jensen's inequality $E\{g(Y)\} \neq$

Figure 34.2.1: Engel's household budget data, $n = 235$. (a) Two links with the same gamma random component and the same regressors: the identity link (solid) and the log link (dashed). (b) Two variance functions with the same identity link: the normal band $\hat{\mu} \pm 2\hat{\sigma}$ has constant width and dips below zero, while the gamma band $\hat{\mu}(1 \pm 2\sqrt{\hat{\phi}})$, with $\hat{\phi}$ from the identity-link gamma fit, widens with the mean.

$g\{E(Y)\}$ unless g is affine, so the fitted curve estimates the mean of a transformed variable, and returning to the mean of Y needs the retransformation correction of [Proposition 22.5.1](#). Modelling $g\{E(Y)\} = \mathbf{x}^\top \boldsymbol{\beta}$ leaves the response alone, and $\hat{\mu}_i = h(\mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}})$ estimates the mean of Y directly.

The transformation also had a second job the link does not do: stabilizing the variance ([Theorem 22.4.1](#)). A generalized linear model does not need that, because the variance function is already specified, and splitting one overloaded decision into two independent ones is the framework's main practical advantage. The weighted regression on empirical logits of [Exercise \(B2\)](#) is the historical compromise: the right link, but one weighted least squares step in place of the likelihood.

34.2.4 Exercises

34.2.4.1 A. Check your understanding

Exercise A1.

Describe the admissible set $\mathcal{B}$ of [Definition 34.2.1](#) for (a) a Poisson model with the identity link, (b) a binomial model with the identity link, (c) a gamma model with the log link. Which of the three is all of $\mathbb{R}^p$?

34.2.4.2 B. Practice

Exercise B1.

Let Y be positive with $E(Y) = \mu$ and $\text{Var}(Y) = \phi\mu^2$, as in the gamma family. Using a second-order Taylor expansion of $\log Y$ about μ , show that $E(\log Y) \approx \log \mu - \phi/2$.

Deduce that a least squares regression of $\log y_i$ on $\mathbf{X}$ and a gamma/log generalized linear model estimate intercepts that differ by approximately $\phi/2$, while their slopes agree to this order. For the fit of [Example \(Food expenditure: three models, two decisions\)](#), how large is the discrepancy?

Solution. With $g(y) = \log y$, $g(Y) \approx g(\mu) + (Y - \mu)/\mu - (Y - \mu)^2/(2\mu^2)$; taking expectations gives $E(\log Y) \approx \log \mu - \text{Var}(Y)/(2\mu^2) = \log \mu - \phi/2$. Since the correction is the same constant for every observation, it is absorbed by the intercept when the model has one, and the slopes are unaffected to this order. For Engel's data $\hat{\phi} = 0.0177$, so the two intercepts differ by about $\hat{\phi}/2 = 0.0177/2 = 0.009$, less than one per cent on the expenditure scale. (For the gamma, $E(\log Y)$ can be computed exactly with the digamma function; the approximation is good when ϕ is small.)

Exercise B2.

A Poisson model is sometimes fitted with the square-root link $g(\mu) = \sqrt{\mu}$, because [Theorem 22.4.1](#) makes $\sqrt{Y}$ approximately variance-stabilized. Find $\mathcal{B}$ for this link, find $d\mu/d\eta$, and explain why the link being variance-stabilizing for Y is irrelevant to whether it is a good link.

Solution. $g(\mathcal{M}) = (0, \infty)$, so $\mathcal{B} = \{\boldsymbol{\beta} : \mathbf{x}_{(i)}^\top \boldsymbol{\beta} > 0 \ \forall i\}$, and $\mu = \eta^2$ gives $d\mu/d\eta = 2\eta = 2\sqrt{\mu}$. Variance stabilization matters when the model is fitted by *least squares on the transformed data*, because least squares wants constant variance. A generalized linear model already knows $V(\mu) = \mu$ and weights each observation accordingly ([Theorem 34.3.1](#)), so the only question left about the link is whether $\sqrt{EY}$ is plausibly linear in the regressors.

Exercise B3.

The complementary log-log link for a binomial response is $g(\mu) = \log\{-\log(1 - \mu)\}$. Show that it is a bijection from $(0, 1)$ onto $\mathbb{R}$, compute $d\mu/d\eta$, and show that it is *not* symmetric: $g(\mu) \neq -g(1 - \mu)$, unlike the logit and probit links. Which tail does it approach more slowly?

Solution. $\mu \mapsto -\log(1 - \mu)$ maps $(0, 1)$ onto $(0, \infty)$ increasingly, and $\log$ maps $(0, \infty)$ onto $\mathbb{R}$, so g is an increasing bijection with inverse $h(\eta) = 1 - \exp(-e^\eta)$ and $d\mu/d\eta = e^\eta \exp(-e^\eta) = (1 - \mu)\{-\log(1 - \mu)\}$. Symmetry would require $h(-\eta) = 1 - h(\eta)$, which fails, for example at $\eta = 0$, where $h(0) = 1 - e^{-1} = 0.632 \neq \frac{1}{2}$. As $\eta \rightarrow -\infty$, $\mu \approx e^\eta \rightarrow 0$ exponentially, while as $\eta \rightarrow +\infty$, $1 - \mu = \exp(-e^\eta) \rightarrow 0$ doubly exponentially: the approach to 1 is far faster than the approach to 0. [Chapter 35](#) derives the link from a proportional-hazards argument ([Proposition 35.2.1](#)).

34.3 The likelihood equations

In the normal linear model the maximum likelihood estimate was available in closed form, because the log-likelihood was a quadratic in $\boldsymbol{\beta}$ ([Theorem 7.3.1](#)). Outside that case there is no

closed form, and everything has to be read off the derivatives of the log-likelihood. This section computes them. The answer has the same shape as the normal equations $\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) = \mathbf{0}$, with two modifications: each observation is weighted according to its variance, and the residual $y_i - \mu_i$ is converted from the mean scale to the linear-predictor scale.

Throughout, the model is [Definition 34.2.1](#), $\text{rank}(\mathbf{X}) = p$, and $\boldsymbol{\beta}$ lies in the interior of the admissible set $\mathcal{B}$. Write

$$\mu_i = h(\eta_i), \quad \eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \quad \frac{d\mu_i}{d\eta_i} = h'(\eta_i),$$

and note that $h' > 0$ everywhere, because g is strictly monotone (take g increasing; a decreasing link only flips signs).

34.3.1 The score

Theorem 34.3.1 — The likelihood equations and the information

Define the diagonal matrices

$$\mathbf{W} = \text{diag}\left\{\frac{w_i h'(\eta_i)^2}{V(\mu_i)}\right\}, \quad \mathbf{D} = \text{diag}\{h'(\eta_i)\}.$$

Then, with $\ell(\boldsymbol{\beta})$ the log-likelihood of [Eq. 34.1.3](#):

(a) the score is

$$\mathbf{U}(\boldsymbol{\beta}) = \frac{\partial \ell}{\partial \boldsymbol{\beta}} = \frac{1}{\phi} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}), \quad (34.3.1)$$

so the likelihood equations are $\sum_i x_{ij} w_i h'(\eta_i) \{y_i - \mu_i\} / V(\mu_i) = 0$ for $j = 1, \dots, p$, and they do not involve ϕ ;

(b) $\mathbf{E} \mathbf{U} = \mathbf{0}$ and the **expected (Fisher) information** is

$$\mathcal{I}(\boldsymbol{\beta}) = \text{Cov}\{\mathbf{U}(\boldsymbol{\beta})\} = \frac{1}{\phi} \mathbf{X}^\top \mathbf{W} \mathbf{X}; \quad (34.3.2)$$

(c) writing $a(\eta) = h'(\eta) / V\{h(\eta)\}$, the **observed information** is

$$-\frac{\partial^2 \ell}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}^\top} = \frac{1}{\phi} \mathbf{X}^\top (\mathbf{W} - \mathbf{D}_r) \mathbf{X},$$

where $\mathbf{D}_r = \text{diag}\{w_i (y_i - \mu_i) a'(\eta_i)\}$;

(d) under the canonical link $\mathbf{D}_r = \mathbf{0}$, so the observed and expected information coincide, $\mathbf{W} = \text{diag}\{w_i V(\mu_i)\}$, and [Eq. 34.3.1](#) becomes

$$\mathbf{U}(\boldsymbol{\beta}) = \frac{1}{\phi} \mathbf{X}^\top \text{diag}(\mathbf{w}) (\mathbf{y} - \boldsymbol{\mu}). \quad (34.3.3)$$

Proof. By [Eq. 34.1.3](#), $\ell = \phi^{-1} \sum_i w_i \{y_i \theta_i - b(\theta_i)\}$ plus a term free of $\boldsymbol{\beta}$. The chain rule gives

$$\frac{\partial \theta_i}{\partial \beta_j} = \frac{d\theta_i}{d\mu_i} \frac{d\mu_i}{d\eta_i} \frac{\partial \eta_i}{\partial \beta_j} = \frac{h'(\eta_i)}{V(\mu_i)} x_{ij},$$

using $d\theta/d\mu = 1/V(\mu)$ from [Definition 34.1.2](#). Since $b'(\theta_i) = \mu_i$,

$$\frac{\partial \ell}{\partial \beta_j} = \frac{1}{\phi} \sum_i w_i \{y_i - b'(\theta_i)\} \frac{\partial \theta_i}{\partial \beta_j} = \frac{1}{\phi} \sum_i x_{ij} \frac{w_i h'(\eta_i)}{V(\mu_i)} (y_i - \mu_i),$$

which is (a), since $\mathbf{W}\mathbf{D}^{-1} = \text{diag}\{w_i h'(\eta_i)/V(\mu_i)\}$. The dispersion appears only as the overall factor ϕ^{-1} , so setting the score to zero gives equations free of ϕ .

- (b) $E(Y_i - \mu_i) = 0$ gives $E\mathbf{U} = \mathbf{0}$. The Y_i are independent with $\text{Var}(Y_i) = \phi V(\mu_i)/w_i$ by [Proposition 34.1.2](#), so with the scalars $a_i = w_i h'(\eta_i)/V(\mu_i)$,

$$\text{Cov}(\mathbf{U}) = \frac{1}{\phi^2} \sum_i a_i^2 \text{Var}(Y_i) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top = \frac{1}{\phi} \sum_i \frac{w_i h'(\eta_i)^2}{V(\mu_i)} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top,$$

which is [Eq. 34.3.2](#).

- (c) With $a(\eta) = h'(\eta)/V\{h(\eta)\}$ we have $\partial \ell / \partial \beta_j = \phi^{-1} \sum_i x_{ij} w_i (y_i - \mu_i) a(\eta_i)$. Differentiating again, and using $\partial \mu_i / \partial \beta_k = h'(\eta_i) x_{ik}$,

$$\frac{\partial^2 \ell}{\partial \beta_j \partial \beta_k} = \frac{1}{\phi} \sum_i x_{ij} x_{ik} w_i \{-h'(\eta_i) a(\eta_i) + (y_i - \mu_i) a'(\eta_i)\}.$$

Now $w_i h'(\eta_i) a(\eta_i) = w_i h'(\eta_i)^2 / V(\mu_i)$ is the i th working weight, which gives the stated form. Taking expectations kills the second term and recovers (b), a second proof of [Eq. 34.3.2](#).

- (d) Under the canonical link $\theta_i = \eta_i$, so $h = b'$ and $h'(\eta) = b''(\theta) = V(\mu)$. Hence $a(\eta) \equiv 1$, $a' \equiv 0$, $\mathbf{D}_r = \mathbf{0}$, and $\mathbf{W} = \text{diag}\{w_i V(\mu_i)^2 / V(\mu_i)\} = \text{diag}\{w_i V(\mu_i)\}$. Also $\mathbf{W}\mathbf{D}^{-1} = \text{diag}\{w_i V(\mu_i) / V(\mu_i)\} = \text{diag}(\mathbf{w})$, which is [Eq. 34.3.3](#). ■

For the normal family with the identity link and $w_i = 1$, $h' \equiv 1$ and $V \equiv 1$, so [Eq. 34.3.1](#) reads $\mathbf{X}^\top (\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) / \sigma^2$ and [Eq. 34.3.2](#) reads $\mathbf{X}^\top \mathbf{X} / \sigma^2$: the score is the normal equations divided by the variance, and [Proposition 7.4.7](#) is recovered.

Three features of [Eq. 34.3.1](#) are worth naming. The equations are **weighted** by $w_i h'(\eta_i) / V(\mu_i)$, so a more variable observation counts for less — the logic of weighted least squares ([Theorem 21.3.1\(a\)](#)), with weights dictated by the family rather than assumed. They are **free of** ϕ , which multiplies the whole score, so ϕ can be estimated afterwards without disturbing $\hat{\boldsymbol{\beta}}$ ([Section 34.5](#)), just as least squares does not need σ^2 . And they involve the family **only through** V : two densities with the same variance function give the same $\hat{\boldsymbol{\beta}}$, the seed of the quasi-likelihood of [Chapter 38](#) ([Definition 38.2.1](#)).

34.3.2 The fitted marginals

Corollary 34.3.2 — Canonical links reproduce weighted column totals

$$\sum_{i=1}^n w_i x_{ij} \hat{\mu}_i = \sum_{i=1}^n w_i x_{ij} y_i, \quad j = 1, \dots, p.$$

Proof. Immediate from Eq. 34.3.3: the likelihood equations are $\mathbf{X}^\top \text{diag}(\mathbf{w})(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \mathbf{0}$, which is the statement column by column.

Example. (Fitted votes by party identification)

By [Corollary 34.3.2](#) the fitted probabilities must add up, within each of the seven party-identification groups, to the observed number of Dole voters — though age is in the model and varies within every group. Among the 200 strong Democrats, 3 reported voting for Dole and the fitted probabilities sum to 3 exactly; among the 175 strong Republicans observed and fitted totals are both 167. The eighth column gives $\sum_i \text{age}_i y_i = \sum_i \text{age}_i \hat{\mu}_i = 121.3000$.

A probit refit destroys the identity: the group totals are then wrong by up to 0.0966 and the age total by 0.6245. The discrepancies are small, because the fits are similar, but nothing forces them to be zero. The same contrast holds for the information, which under the logit link agrees with the expected information to machine precision and under the probit link differs by a relative 0.0056.

```
import numpy as np
import statsmodels.api as sm

anes = sm.datasets.anes96.load_pandas().data
y = anes["vote"].to_numpy(float)           # 1 if the respondent voted
    for Dole
pid = anes["PID"].to_numpy(int)           # party identification, 0 (
    Dem) to 6 (Rep)
D = np.eye(7)[pid]                       # one indicator column per
    level
age = (anes["age"].to_numpy(float) - 45.0) / 10.0
X = np.column_stack([D, age])             # no separate intercept: D
    already sums to 1
```

```

logit = sm.GLM(y, X, family=sm.families.Binomial()).fit()
mu = logit.fittedvalues

print("level    n    observed Dole votes    fitted")
for k in range(7):
    inside = pid == k
    print(f"    {k}    {inside.sum():4d}    {y[inside].sum():8.0f}    {mu[inside].sum():12.6f}")
print(f"age column: X^T y = {age @ y:.6f},    X^T mu = {age @ mu:.6f}")

```

Remark (Where the marginal property is used). [Chapter 37](#) turns [Corollary 34.3.2](#) into a tool: for a log-linear model of a contingency table the canonical link forces the fitted counts to match the observed margins of the terms in the model, which is what makes log-linear and multinomial fits agree ([Theorem 37.3.1](#)). In the binary case it means those totals carry no information about goodness of fit — a point [Proposition 35.4.1](#) takes up.

34.3.3 Concavity, existence and uniqueness

Theorem 34.3.3 — The canonical-link log-likelihood is concave

Under the canonical link, $\ell(\boldsymbol{\beta})$ is concave on the convex set $\mathcal{B}$. If in addition $\text{rank}(\mathbf{X}) = p$ and $V(\mu_i) > 0$ for all i , then ℓ is strictly concave, so it has at most one stationary point, and any stationary point is the unique global maximizer.

Proof. Under the canonical link $\theta_i = \eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, so by [Eq. 34.1.3](#)

$$\ell(\boldsymbol{\beta}) = \frac{1}{\phi} \sum_{i=1}^n w_i \{y_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta} - b(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\} + \text{const.}$$

The first term is linear in $\boldsymbol{\beta}$. In the second, b is convex by [Lemma 34.1.1](#) and $\boldsymbol{\beta} \mapsto \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ is linear, so $\boldsymbol{\beta} \mapsto b(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ is convex; multiplying by $w_i/\phi > 0$ and summing preserves convexity, and the minus sign makes ℓ concave. The set $\mathcal{B}$ is convex, being an intersection of the preimages of the interval $g(\mathcal{M})$ under linear maps.

For strictness, [Theorem 34.3.1\(d\)](#) gives the Hessian $-\phi^{-1} \mathbf{X}^\top \text{diag}\{w_i V(\mu_i)\} \mathbf{X}$, which for $\mathbf{v} \neq \mathbf{0}$ satisfies

$$\mathbf{v}^\top \left(\frac{1}{\phi} \mathbf{X}^\top \text{diag}\{w_i V(\mu_i)\} \mathbf{X} \right) \mathbf{v} = \frac{1}{\phi} \sum_i w_i V(\mu_i) (\mathbf{x}_{(i)}^\top \mathbf{v})^2 > 0,$$

because $\text{rank}(\mathbf{X}) = p$ forces $\mathbf{X}\mathbf{v} \neq \mathbf{0}$. So the Hessian is negative definite everywhere on $\mathcal{B}$ and ℓ is strictly concave there. ■

Concavity settles uniqueness but not existence: a strictly concave function on an open set need not attain its supremum. Both failures happen in practice.

Example. (Two ways the maximum fails to exist)

All counts zero. For a Poisson log-linear model with an intercept, if every $y_i = 0$ then $\ell(\boldsymbol{\beta}) = -\sum_i e^{\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}$, which increases to its supremum 0 as $\beta_0 \rightarrow -\infty$ and is never attained.

Separated binary data. If there is a vector $\mathbf{v}$ with $\mathbf{x}_{(i)}^\top \mathbf{v} > 0$ whenever $y_i = 1$ and $\mathbf{x}_{(i)}^\top \mathbf{v} < 0$ whenever $y_i = 0$, then along the ray $t\mathbf{v}$ every fitted probability moves towards the observed response, so ℓ increases without reaching a maximum. Chapter 35 proves that this is the only way the binary maximum likelihood estimate can fail to exist (Theorem 35.3.1).

The general statement belongs to exponential-family theory. Under a canonical link $\mathbf{T} = \mathbf{X}^\top \text{diag}(\mathbf{w})\mathbf{y}$ is the sufficient statistic of Section 34.1, and by Corollary 34.3.2 the likelihood equations say $\mathbf{X}^\top \text{diag}(\mathbf{w})\hat{\boldsymbol{\mu}} = \mathbf{T}$. The attainable mean-value vectors $\{\mathbf{X}^\top \text{diag}(\mathbf{w})\boldsymbol{\mu} : \boldsymbol{\mu} \in \mathcal{M}^n\}$ form an open convex set, and the maximum likelihood estimate exists precisely when $\mathbf{T}$ lies inside it rather than on its boundary (Barndorff-Nielsen 1978, chapter 9; not reproduced here). Both examples above are boundary cases: all-zero counts put $\mathbf{T}$ at the corner $\mathbf{0}$, separation puts it on a face. For non-canonical links even uniqueness can fail.

Warning. Concavity is a property of the canonical link, not of generalized linear models. Take the gamma family with the identity link, where $\ell = \phi^{-1} \sum_i \{-y_i/\mu_i - \log \mu_i\}$ with $\mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. The second derivative of one term with respect to μ_i is $(\mu_i - 2y_i)/\mu_i^3$, positive whenever $\mu_i > 2y_i$, so the Hessian is a difference of nonnegative definite matrices and can be indefinite: an iteration can stop at a local maximum. Wedderburn (1976) settles existence and uniqueness link by link, cleanly for the binomial and Poisson with the standard links and not for the gamma with the identity link.

34.3.4 Exercises

34.3.4.1 A. Check your understanding

Exercise A1.

Write the likelihood equations for a Poisson log-linear model with an intercept. Show that they are $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$, that $\sum_i \hat{\mu}_i = \sum_i y_i$, and that for the intercept-only model $\hat{\mu}_i = \bar{y}$. (This is Exercise (B2), now a special case of Corollary 34.3.2.)

34.3.4.2 B. Practice

Exercise B1.

For grouped binomial data with $y_i = s_i/m_i$, the logit link and $w_i = m_i$, write the likelihood equations in terms of the observed successes s_i . Show that the working weight is $\mathbf{W}_{ii} = m_i \mu_i (1 - \mu_i)$ and that the information is $\mathbf{X}^\top \text{diag}\{m_i \mu_i (1 - \mu_i)\} \mathbf{X}$. Where have you seen that matrix before?

Solution. The canonical form Eq. 34.3.3 with $w_i = m_i$ and $\phi = 1$ gives $\sum_i x_{ij} m_i (s_i/m_i - \mu_i) = \sum_i x_{ij} (s_i - m_i \mu_i) = 0$: fitted and observed successes agree in every column of $\mathbf{X}$. By Theorem 34.3.1(d), $\mathbf{W} = \text{diag}\{w_i V(\mu_i)\}$ with $V(\mu) = \mu(1-\mu)$, giving $\mathbf{W}_{ii} = m_i \mu_i (1-\mu_i)$ and the stated information. It is the weight matrix of the empirical-logit weighted least squares fit in Exercise (B2), with μ_i in place of $\hat{p}_i$: that procedure is one step of the iteration of Section 34.4 started from the data.

Exercise B2.

Show that the observed information equals the expected information *identically in $\mathbf{y}$* if and only if the link is canonical (up to an affine change of η). Assume that no row of $\mathbf{X}$ is zero, an observation with $\mathbf{x}_{(i)} = \mathbf{0}$ carrying no information about $\boldsymbol{\beta}$. Use Theorem 34.3.1(c).

Solution. By Theorem 34.3.1(c) the two agree for all $\mathbf{y}$ iff $\mathbf{X}^\top \mathbf{D}_r \mathbf{X} = \mathbf{0}$ for all $\mathbf{y}$, where $(\mathbf{D}_r)_{ii} = w_i (y_i - \mu_i) a'(\eta_i)$. Vary y_i over two admissible values with the other responses held fixed: subtracting the two identities leaves $\delta_i a'(\eta_i) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top = \mathbf{0}$ with $\delta_i = w_i (y_i - y'_i) \neq 0$, and since $\mathbf{x}_{(i)} \neq \mathbf{0}$ this forces $a'(\eta_i) = 0$ for every i . (Two admissible values always exist: the y_i range over an interval for the normal and gamma families, and over $\{0, 1/m, \dots, 1\}$ or $\{0, 1, 2, \dots\}$ for the binomial and Poisson.) So a is constant, say $a \equiv 1/\lambda$, that is $d\mu/d\eta = V(\mu)/\lambda$. Comparing with the canonical link, for which $d\mu/d\theta = V(\mu)$, gives $\eta = \lambda\theta + \text{const.}$

34.3.4.3 C. Going deeper

Exercise C1.

For a binary response, $\ell(\boldsymbol{\beta}) = \sum_i \{y_i \log h(\eta_i) + (1 - y_i) \log(1 - h(\eta_i))\}$. Show that ℓ is concave for every design and every data set if and only if $\log h$ and $\log(1 - h)$ are both concave functions of η . Verify that the logit link satisfies this, and that $h(\eta) = \Phi(\eta)$ does too, using the fact that the standard normal density is log-concave.

Exercise C2.

An **offset** is a known column added to the linear predictor with coefficient fixed at 1: $\eta_i = o_i + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. Show that Theorem 34.3.1 holds verbatim with η_i redefined this way, that Corollary 34.3.2 is unchanged, and that the offset does *not* appear among the columns whose totals are reproduced. Where would such a term come from in a Poisson model for rates? (Chapter 37 answers this with Proposition 37.2.1.)

34.4 Iteratively reweighted least squares

The likelihood equations Eq. 34.3.1 have no closed-form solution. Any general-purpose optimizer will solve them, but there is a better way, and it is why generalized linear models became practical: the natural Newton-type iteration is a *weighted least squares fit*, repeated. The apparatus of Chapter 6 and Section 21.3 is therefore reusable, including the stable routines

of [Chapter 10](#).

34.4.1 Fisher scoring is weighted least squares

Newton's method for maximizing ℓ replaces the observed information by its inverse: $\boldsymbol{\beta}^{(t+1)} = \boldsymbol{\beta}^{(t)} + \{-\nabla^2 \ell\}^{-1} \mathbf{U}$. **Fisher scoring** replaces the observed information by the expected information $\mathcal{I}$ instead. By [Theorem 34.3.1\(d\)](#) the two are the same under the canonical link; in general they differ, and the expected version is both simpler and guaranteed nonnegative definite.

Theorem 34.4.1 — Fisher scoring is iteratively reweighted least squares

Let $\boldsymbol{\beta}^{(t)}$ be in the interior of $\mathcal{B}$ with $\mathbf{X}^\top \mathbf{W}^{(t)} \mathbf{X}$ nonsingular, where $\mathbf{W}^{(t)}$ is the working-weight matrix of [Theorem 34.3.1](#) evaluated at $\boldsymbol{\beta}^{(t)}$. Define the **working response**

$$z_i^{(t)} = \eta_i^{(t)} + \frac{y_i - \mu_i^{(t)}}{h'(\eta_i^{(t)})} = \eta_i^{(t)} + (y_i - \mu_i^{(t)}) g'(\mu_i^{(t)}). \quad (34.4.1)$$

Then the Fisher scoring step $\boldsymbol{\beta}^{(t+1)} = \boldsymbol{\beta}^{(t)} + \mathcal{I}(\boldsymbol{\beta}^{(t)})^{-1} \mathbf{U}(\boldsymbol{\beta}^{(t)})$ is exactly the weighted least squares estimate

$$\boldsymbol{\beta}^{(t+1)} = (\mathbf{X}^\top \mathbf{W}^{(t)} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}^{(t)} \mathbf{z}^{(t)}, \quad (34.4.2)$$

that is, the regression of the working response $\mathbf{z}^{(t)}$ on $\mathbf{X}$ with weights $\mathbf{W}^{(t)}$. The dispersion ϕ cancels and never enters the iteration.

Proof. By [Eq. 34.3.2](#) and [Eq. 34.3.1](#), with everything evaluated at $\boldsymbol{\beta}^{(t)}$,

$$\begin{aligned} \mathcal{I}^{-1} \mathbf{U} &= \phi (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \cdot \frac{1}{\phi} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}) \\ &= (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}), \end{aligned}$$

so ϕ has already cancelled. Adding $\boldsymbol{\beta}^{(t)} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X} \boldsymbol{\beta}^{(t)}$ and using $\mathbf{X} \boldsymbol{\beta}^{(t)} = \boldsymbol{\eta}^{(t)}$,

$$\boldsymbol{\beta}^{(t+1)} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \{ \boldsymbol{\eta}^{(t)} + \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}) \},$$

and the braced vector is $\mathbf{z}^{(t)}$ by [Eq. 34.4.1](#), since $\mathbf{D}^{-1} = \text{diag}\{1/h'(\eta_i)\}$ and $g'(\mu) = 1/h'(\eta)$. ■

Idea. The working response is a first-order Taylor expansion of the link applied to the data: $g(y_i) \approx g(\mu_i) + (y_i - \mu_i) g'(\mu_i) = z_i$. So each step regresses “the data, mapped to the linear-predictor scale” on $\mathbf{X}$. The working weight is the reciprocal of that quantity's approximate variance, because

$$\text{Var}(z_i) \approx g'(\mu_i)^2 \text{Var}(Y_i) = \frac{\phi}{w_i} \frac{V(\mu_i)}{h'(\eta_i)^2} = \frac{\phi}{\mathbf{W}_{ii}}.$$

Both the response and the weights depend on the current fit, which is why the regression has to be iterated.

Written out, the algorithm is short.

Iteratively reweighted least squares.

1. Choose starting fitted means $\mu_i^{(0)}$ and set $\eta_i^{(0)} = g(\mu_i^{(0)})$.
2. For $t = 0, 1, 2, \dots$: compute $\mathbf{W}_{ii} = w_i h'(\eta_i^{(t)})^2 / V(\mu_i^{(t)})$ and $z_i^{(t)}$ from [Eq. 34.4.1](#); solve the weighted least squares problem [Eq. 34.4.2](#) for $\boldsymbol{\beta}^{(t+1)}$; set $\boldsymbol{\eta}^{(t+1)} = \mathbf{X}\boldsymbol{\beta}^{(t+1)}$ and $\mu_i^{(t+1)} = h(\eta_i^{(t+1)})$.
3. Stop when $\boldsymbol{\beta}$ (or the deviance of [Section 34.5](#)) stops changing; report $\hat{\boldsymbol{\beta}} = \boldsymbol{\beta}^{(t+1)}$ and $(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$, with $\hat{\mathbf{W}}$ the weights at the solution.

Because the map is a fixed-point iteration whose fixed points solve [Eq. 34.3.1](#), any limit is a solution of the likelihood equations; under the canonical link with $\text{rank}(\mathbf{X}) = p$, [Theorem 34.3.3](#) then makes it *the* maximum likelihood estimate.

Starting values. The usual device is to start from the data themselves: set $\mu_i^{(0)} = y_i$, adjusted if necessary to keep it inside $\mathcal{M}$. For a Poisson response take $\mu_i^{(0)} = y_i + 0.1$; for a binomial proportion, $\mu_i^{(0)} = (w_i y_i + \frac{1}{2}) / (w_i + 1)$, the empirical-logit correction of [Exercise \(B2\)](#); for a gamma response, $\mu_i^{(0)} = y_i$. The first step is then the one-step weighted least squares fit that preceded generalized linear models historically, and the iteration refines it.

Relation to the least squares chapters. Each step of [Eq. 34.4.2](#) is the weighted least squares problem of [Theorem 21.3.1](#) with *known* weights, so its convergence theory is numerical, not statistical: the final $(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$ is the inverse expected information of the likelihood, not the covariance of a fixed-weight estimate, and the two coincide asymptotically for a different reason ([Theorem 34.5.1](#)). Compute the step by the QR or Cholesky routines of [Section 6.10](#) applied to $\mathbf{W}^{1/2} \mathbf{X}$ and $\mathbf{W}^{1/2} \mathbf{z}$, never by inverting $\mathbf{X}^\top \mathbf{W} \mathbf{X}$.

Warning. The name “iteratively reweighted least squares” is also used for the robust M-estimation algorithm of [Proposition 20.6.1](#), and the two are different. There the weights come from a ρ function chosen to resist outliers, and the iteration provably decreases the objective at every step. Here the weights come from the variance function, the iteration is Fisher scoring, and there is no monotonicity guarantee unless the link is canonical.

34.4.2 The algorithm in practice

The listing below implements [Eq. 34.4.2](#) in a dozen lines. A family is nothing but (V, g, h) together with h' and a starting rule; the solver never needs to know which distribution it is fitting, which is the computational content of the whole chapter.

```
import numpy as np
from scipy import stats

# A family is the variance function V, the link g, its inverse h, the derivative
# h' = d(mu)/d(eta), and a rule for the starting fitted means.
def poisson_log():
    return dict(name="Poisson/log", V=lambda mu: mu, g=np.log, h=np.exp,
                dmu=lambda eta: np.exp(eta), start=lambda y, w: y + 0.1)
```

```

def binomial_logit():
    return dict(name="binomial/logit", V=lambda mu: mu * (1 - mu),
                g=lambda mu: np.log(mu / (1 - mu)), h=lambda eta: 1 / (1 + np.exp(-
eta))),
                dmu=lambda eta: 1 / (2 + np.exp(eta) + np.exp(-eta)),
                start=lambda y, w: (w * y + 0.5) / (w + 1.0))

def binomial_probit():
    return dict(name="binomial/probit", V=lambda mu: mu * (1 - mu),
                g=stats.norm.ppf, h=stats.norm.cdf, dmu=stats.norm.pdf,
                start=lambda y, w: (w * y + 0.5) / (w + 1.0))

def gamma_log():
    return dict(name="gamma/log", V=lambda mu: mu ** 2, g=np.log, h=np.exp,
                dmu=lambda eta: np.exp(eta), start=lambda y, w: y)

def irls(X, y, family, w=None, tol=1e-12, max_iter=60, trace=False):
    """Fisher scoring for a generalized linear model, as weighted least squares.

    At each step the working response is  $z = \eta + (y - \mu)/h'(\eta)$  and the working
    weight is  $W = w h'(\eta)^2 / V(\mu)$ ;  $\beta$  is the weighted least squares
    coefficient
    of  $z$  on  $X$ . The dispersion  $\phi$  never enters, because it cancels.
    """
    w = np.ones(len(y)) if w is None else np.asarray(w, float)
    mu = family["start"](y, w)

```

```

import statsmodels.api as sm

rng = np.random.default_rng(3401)
n = 300
Xs = np.column_stack([np.ones(n), rng.normal(size=n), rng.binomial(1, 0.4, n)])
beta_true = np.array([0.7, 0.5, -0.4])
counts = rng.poisson(np.exp(Xs @ beta_true))

beta_hat, cov = irls(Xs, counts.astype(float), poisson_log())
sm_fit = sm.GLM(counts, Xs, family=sm.families.Poisson()).fit()
print("from scratch:", np.round(beta_hat, 6))
print("statsmodels :", np.round(sm_fit.params, 6))

```

Figure 34.4.1: Convergence of iteratively reweighted least squares for four models. Solid curves are canonical links, dashed curves are not. On a logarithmic scale a quadratic rate bends downwards and a linear rate is straight.

```
print("standard errors:", np.round(np.sqrt(np.diag(cov)), 6), np.round(sm_fit.bse,
6))
```

The script behind this section runs the same solver on four models — Poisson/log, binomial/logit, binomial/probit and gamma/log — and checks the coefficients and standard errors against `statsmodels` to at least eight decimal places in every case. Two details matter. For the binomial fits the response passed to the solver is the *proportion* s_i/m_i with prior weight $w_i = m_i$, which is [Example \(The binomial as a family of proportions\)](#) in code. For the gamma fit the solver returns $(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$, so the standard errors need the extra factor $\hat{\phi}$, estimated separately; on Engel’s data that gives $\hat{\boldsymbol{\beta}} = (0.5068, 0.8629)$ with $\hat{\phi} = 0.0177$ and a standard error of 0.0198 for the elasticity.

34.4.3 Convergence and its failures

Example. (Two convergence rates)

[Figure 34.4.1](#) records $\max_j |\beta_j^{(t)} - \hat{\beta}_j|$ against the iteration count for the four models. The canonical-link fits reach full double precision in 5 and 4 steps, with error curves that bend downwards on the logarithmic scale: the correct digits roughly double at each step. The non-canonical fits take 5 and 7 steps, along straight lines, so their correct digits grow by a fixed amount per step.

This is what the theory predicts. Under the canonical link Fisher scoring *is* Newton’s method ([Theorem 34.3.1\(d\)](#)), quadratically convergent near a nondegenerate maximum. Under any other link the two information matrices differ by $\phi^{-1} \mathbf{X}^\top \mathbf{D}_r \mathbf{X}$, which vanishes only in expectation, so the iteration is Newton’s method with a perturbed Hessian and converges linearly — in practice, one or two extra iterations.

Four things go wrong often enough to be worth recognizing.

The estimate does not exist. When the maximum of [Example \(Two ways the maximum fails to exist\)](#) is not attained the iteration cannot converge, and its behaviour is characteristic: the coefficients grow without limit, the deviance falls towards its infimum, the working weights collapse to zero. Software that stops on a small change in the deviance then reports a large but finite estimate with a large standard error and no warning.

Example. (What separation looks like from inside the algorithm)

Ten binary responses were generated with $y_i = 1$ exactly when $x_i > 0$, so the data are completely separated. Running the solver on them gives

step	$\hat{\beta}_1$	deviance	largest working weight
1	1.36	4.589	0.245
4	5.74	0.931	0.159
7	16.95	0.0574	0.0142
8	—	—	—

At the eighth step every fitted probability has reached 0 or 1 in double precision, so $V(\hat{\mu}_i) = 0$, the working weights are 0/0, and the iteration returns nothing. The slope was never going to settle: the supremum of the likelihood is approached only as $\beta_1 \rightarrow \infty$. [Chapter 35](#) characterizes exactly when this happens and what to do about it ([Theorem 35.3.1](#)).

```
x_sep = np.array([-2.4, -1.7, -1.1, -0.6, -0.2, 0.3, 0.8, 1.4, 1.9, 2.6])
y_sep = (x_sep > 0).astype(float) # the two groups do not
                                overlap
X_sep = np.column_stack([np.ones(10), x_sep])

for iters in range(1, 9):
    with np.errstate(divide="ignore", invalid="ignore"):
        b, _ = irls(X_sep, y_sep, binomial_logit(), tol=0.0, max_iter=iters)
        mu = 1 / (1 + np.exp(-(X_sep @ b)))
        dev = -2 * np.sum(np.where(y_sep == 1, np.log(mu), np.log(1 - mu)))
    print(f"{iters} steps: slope {b[1]:9.4f}    deviance {dev:.3e}"
          f"    largest working weight {np.max(mu * (1 - mu)):.3e}")
```

The step leaves the admissible set. With a link whose range is not all of $\mathbb{R}$, a full step can produce $\eta_i^{(t+1)} \notin g(\mathcal{M})$ — a negative fitted mean for an identity-link Poisson model, where the variance function is then negative and the “weights” meaningless. The repair is **step halving**: if the proposed $\beta^{(t+1)}$ is inadmissible, or the deviance increases, halve the step and retry. A few halvings almost always suffice, and software applies them automatically.

The information matrix is nearly singular. The matrix inverted at each step is $\mathbf{X}^\top \mathbf{W} \mathbf{X}$, not $\mathbf{X}^\top \mathbf{X}$, so full column rank is no longer enough: if the weights are tiny wherever a regressor varies, the weighted matrix can be numerically singular even for a well-conditioned $\mathbf{X}$. The diagnostics of [Chapter 26](#) apply to $\mathbf{W}^{1/2} \mathbf{X}$, not $\mathbf{X}$.

The iteration converges to the wrong stationary point. For non-canonical links the log-likelihood need not be concave, and Fisher scoring from a bad start can settle at a local maximum; the defence is several starting values compared by maximized log-likelihood.

34.4.4 Exercises

34.4.4.1 A. Check your understanding

Exercise A1.

Verify the approximation $\text{Var}(z_i) \approx \phi/\mathbf{W}_{ii}$ stated in the key-idea box, and explain which two approximations are being made.

34.4.4.2 B. Practice

Exercise B1.

Take grouped binomial data with all $0 < s_i < m_i$ and start the iteration at $\mu_i^{(0)} = s_i/m_i$. Show that the first working response is the empirical logit $\log\{s_i/(m_i - s_i)\}$ and the first working weight is $s_i(m_i - s_i)/m_i$. Compare with [Exercise \(B2\)](#).

Solution. With $\mu_i^{(0)} = s_i/m_i$ the starting linear predictor is already $\eta_i^{(0)} = \log\{\mu_i^{(0)}/(1 - \mu_i^{(0)})\} = \log\{s_i/(m_i - s_i)\}$, and $y_i - \mu_i^{(0)} = 0$, so $z_i^{(0)} = \eta_i^{(0)}$ is the empirical logit. The working weight is $\mathbf{W}_{ii} = m_i\mu_i^{(0)}(1 - \mu_i^{(0)}) = s_i(m_i - s_i)/m_i$, which is the weight of [Exercise \(B2\)](#) with $\hat{p}_i = s_i/m_i$. The first iterate is therefore exactly the empirical-logit weighted least squares estimate; later iterates are not, which is why the two methods give different answers in small samples.

Exercise B2.

Modify [Eq. 34.4.2](#) for a model with an offset $\eta_i = o_i + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, as in [Exercise \(C2\)](#). Show that the working response becomes $z_i = \eta_i - o_i + (y_i - \mu_i)g'(\mu_i)$ and nothing else changes.

34.4.4.3 C. Going deeper

Exercise C1.

Show that under the canonical link, Fisher scoring is Newton's method applied to a strictly concave function, and deduce that when the maximum exists, the iteration converges to it from any starting point at which the step is well defined *provided the step is damped*: for each t there is $s_t \in (0, 1]$ with $\ell(\boldsymbol{\beta}^{(t)} + s_t \mathbf{d}^{(t)}) > \ell(\boldsymbol{\beta}^{(t)})$, where $\mathbf{d}^{(t)}$ is the Newton direction. Why does the undamped step not carry the same guarantee? (Compare [Proposition 20.6.1](#), where the undamped step *is* monotone, because the argument there is majorization rather than Newton.)

Solution. By [Theorem 34.3.3](#) the Hessian $-\mathcal{I}$ is negative definite, so the Newton direction $\mathbf{d} = \mathcal{I}^{-1}\mathbf{U}$ satisfies $\mathbf{U}^\top \mathbf{d} = \mathbf{U}^\top \mathcal{I}^{-1}\mathbf{U} > 0$ whenever $\mathbf{U} \neq \mathbf{0}$: it is an ascent direction, so the directional derivative of ℓ at $\boldsymbol{\beta}^{(t)}$ along $\mathbf{d}$ is positive and some small enough step increases ℓ . The undamped step has length fixed by the local quadratic approximation, which can overshoot badly when ℓ is far from quadratic, so it may decrease ℓ or leave $\mathcal{B}$ altogether.

34.5 Deviance and asymptotic inference

Parts II and III rested on exact distribution theory: $\hat{\boldsymbol{\beta}}$ was normal because $\mathbf{Y}$ was, and sums of squares were chi-squared because they were quadratic forms in a normal vector ([Theorem 4.3.2](#)). None of that survives. This section states what replaces it in the limit, under which conditions, and — just as important — where the approximations fail.

34.5.1 Asymptotic normality

The conditions below are stated for the canonical link, where the argument can be given in full. Throughout $\boldsymbol{\beta}^0$ is the true parameter, $\theta_i^0 = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}^0$, and

$$\mathbf{A}_n = \mathcal{I}_n(\boldsymbol{\beta}^0) = \frac{1}{\phi} \mathbf{X}^\top \text{diag}\{w_i b''(\theta_i^0)\} \mathbf{X}$$

is the expected information from [Eq. 34.3.2](#). Because the canonical-link Hessian does not involve $\mathbf{y}$ ([Theorem 34.3.1\(d\)](#)), $\mathbf{A}_n$ is a fixed matrix, not a random one. Define the scalars

$$q_{ni} = \frac{w_i b''(\theta_i^0)}{\phi} \mathbf{x}_{(i)}^\top \mathbf{A}_n^{-1} \mathbf{x}_{(i)}, \quad i = 1, \dots, n. \quad (34.5.1)$$

These are the exact analogue of leverages: nonnegative, summing to $\text{tr}(\mathbf{A}_n^{-1} \mathbf{A}_n) = p$, so they average p/n as in [Proposition 6.8.1\(b\)](#). The conditions are

- **(G1)** the responses are independent, the model is that of [Definition 34.2.1](#) with the canonical link, $\text{rank}(\mathbf{X}) = p$ with p fixed, and ϕ and the w_i are known;
- **(G2)** $\boldsymbol{\beta}^0$ is interior to $\mathcal{B}$, the natural parameters θ_i^0 lie in a fixed compact subset K of the interior of Θ , and $0 < w_{\min} \leq w_i \leq w_{\max} < \infty$;
- **(G3)** $\max_{i \leq n} q_{ni} \rightarrow 0$: no single observation carries a fixed share of the information;
- **(G4)** $\lambda_{\min}(\mathbf{A}_n) \rightarrow \infty$: information accumulates in every direction.

Theorem 34.5.1 — Consistency and asymptotic normality of the estimate

Under (G1)–(G4), with probability tending to one the likelihood equations have a solution $\hat{\boldsymbol{\beta}}_n$; it is the unique maximizer of ℓ , it is consistent for $\boldsymbol{\beta}^0$, and

$$\mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}}_n - \boldsymbol{\beta}^0) \xrightarrow{d} N_p(\mathbf{0}, \mathbf{I}). \quad (34.5.2)$$

The same holds with $\mathbf{A}_n$ replaced by $\hat{\mathbf{A}}_n = \mathcal{I}_n(\hat{\boldsymbol{\beta}}_n)$. Consequently, for a fixed $\boldsymbol{\lambda} \neq \mathbf{0}$,

$$\frac{\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_n - \boldsymbol{\lambda}^\top \boldsymbol{\beta}^0}{(\boldsymbol{\lambda}^\top \hat{\mathbf{A}}_n^{-1} \boldsymbol{\lambda})^{1/2}} \xrightarrow{d} N(0, 1),$$

and $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_n \pm z_{1-\alpha/2}(\boldsymbol{\lambda}^\top \hat{\mathbf{A}}_n^{-1} \boldsymbol{\lambda})^{1/2}$ is an interval with asymptotic coverage $1 - \alpha$.

One result is imported, not proved: the standard corollary of **the convexity lemma** of Pollard (1991, section 6), that pointwise convergence of concave random functions is automatically uniform on compact sets. Let Λ_n be random concave functions on $\mathbb{R}^p$, allowed the value $-\infty$ outside a convex set, of the form $\Lambda_n(\mathbf{s}) = \mathbf{s}^\top \mathbf{z}_n - \frac{1}{2} \|\mathbf{s}\|^2 + r_n(\mathbf{s})$ with $\mathbf{z}_n = O_p(1)$ and $\sup_{\|\mathbf{s}\| \leq M} |r_n(\mathbf{s})| \rightarrow 0$ in probability for every M . Then a maximizer $\hat{\mathbf{s}}_n$ exists with probability tending to one and $\hat{\mathbf{s}}_n - \mathbf{z}_n \rightarrow \mathbf{0}$ in probability. Concavity does the work that compactness conditions do in the usual theory, and [Theorem 34.3.3](#) supplies it free.

Proof. Step 1: the score is asymptotically normal. By [Eq. 34.3.3](#), $\mathbf{U}_n = \phi^{-1} \sum_i w_i (Y_i - \mu_i^0) \mathbf{x}_{(i)}$ is a sum of independent mean-zero vectors with $\text{Cov}(\mathbf{U}_n) = \mathbf{A}_n$. Put $\mathbf{z}_n = \mathbf{A}_n^{-1/2} \mathbf{U}_n$. For a fixed unit vector $\mathbf{v}$ write $\mathbf{v}^\top \mathbf{z}_n = \sum_i c_{ni} \xi_i$ with $\xi_i = Y_i - \mu_i^0$ and the weights $c_{ni} = \phi^{-1} w_i \mathbf{v}^\top \mathbf{A}_n^{-1/2} \mathbf{x}_{(i)}$. This is the weighted sum of [Lemma 21.2.1](#), and its case (b) applies. Moments: by (G2) the cumulants of Y_i are continuous functions of θ_i^0 on a compact set ([Proposition 34.1.2\(c\)](#)) and the w_i are bounded away from 0 and ∞ , so $E \xi_i^4$ is bounded — case (b) with $\delta = 2$ — and $\tau_{\min}^2 \leq \text{Var} \xi_i = \phi b''(\theta_i^0)/w_i \leq \tau_{\max}^2$ for constants free of i and n . Weights: by construction $\sum_i c_{ni}^2 \text{Var} \xi_i = \mathbf{v}^\top \mathbf{A}_n^{-1/2} \mathbf{A}_n \mathbf{A}_n^{-1/2} \mathbf{v} = 1$, so the sum is already normalized and $\|\mathbf{c}_n\|^2 \geq \tau_{\max}^{-2}$; while $c_{ni}^2 \leq \phi^{-2} w_{\max}^2 \|\mathbf{A}_n^{-1/2} \mathbf{x}_{(i)}\|^2$ and $\|\mathbf{A}_n^{-1/2} \mathbf{x}_{(i)}\|^2 = \mathbf{x}_{(i)}^\top \mathbf{A}_n^{-1} \mathbf{x}_{(i)} = \phi q_{ni} / \{w_i b''(\theta_i^0)\} \leq C' q_{ni}$ by [Eq. 34.5.1](#) and (G2) again. Hence $\max_i c_{ni}^2 / \|\mathbf{c}_n\|^2 \leq C'' \max_i q_{ni} \rightarrow 0$ by (G3), which is [Eq. 21.2.2](#). So $\mathbf{v}^\top \mathbf{z}_n \rightarrow N(0, 1)$ for every unit $\mathbf{v}$, and the Cramér–Wold device gives $\mathbf{z}_n \rightarrow N_p(\mathbf{0}, \mathbf{I})$.

Step 2: the log-likelihood is asymptotically quadratic. Put $\Lambda_n(\mathbf{s}) = \ell(\boldsymbol{\beta}^0 + \mathbf{A}_n^{-1/2} \mathbf{s}) - \ell(\boldsymbol{\beta}^0)$. Taylor’s theorem with integral remainder, applied to the smooth function ℓ , gives

$$\Lambda_n(\mathbf{s}) = \mathbf{s}^\top \mathbf{z}_n - \int_0^1 (1-t) \mathbf{s}^\top \mathbf{A}_n^{-1/2} \mathcal{J}_n(\boldsymbol{\beta}_t) \mathbf{A}_n^{-1/2} \mathbf{s} dt,$$

where $\boldsymbol{\beta}_t = \boldsymbol{\beta}^0 + t \mathbf{A}_n^{-1/2} \mathbf{s}$ and $\mathcal{J}_n(\boldsymbol{\beta}) = \phi^{-1} \mathbf{X}^\top \text{diag}\{w_i b''(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\} \mathbf{X}$ is the *nonrandom* observed information. Fix $M > 0$ and let $\|\mathbf{s}\| \leq M$. Then $|\mathbf{x}_{(i)}^\top \mathbf{A}_n^{-1/2} \mathbf{s}| \leq M \|\mathbf{A}_n^{-1/2} \mathbf{x}_{(i)}\| \leq M(C' q_{ni})^{1/2}$, which by (G3) tends to 0 uniformly in i . So for large n every perturbed natural parameter $\theta_i^0 + t \mathbf{x}_{(i)}^\top \mathbf{A}_n^{-1/2} \mathbf{s}$ lies in a fixed compact neighbourhood of K inside Θ , on which b'' is uniformly continuous and bounded away from 0 and ∞ ; hence $b''(\theta_i^0 + \delta_i) = b''(\theta_i^0) \{1 + \epsilon_{ni}\}$ with $\sup_i |\epsilon_{ni}| \rightarrow 0$ uniformly in $t \in [0, 1]$ and $\|\mathbf{s}\| \leq M$, and $\mathbf{A}_n^{-1/2} \mathcal{J}_n(\cdot) \mathbf{A}_n^{-1/2} = \mathbf{I} + \mathbf{R}_n$ with $\|\mathbf{R}_n\| \rightarrow 0$, and

$$\Lambda_n(\mathbf{s}) = \mathbf{s}^\top \mathbf{z}_n - \frac{1}{2} \|\mathbf{s}\|^2 + r_n(\mathbf{s}), \quad \sup_{\|\mathbf{s}\| \leq M} |r_n(\mathbf{s})| \rightarrow 0. \quad (34.5.3)$$

Step 3: the maximizer. By [Theorem 34.3.3](#) each Λ_n is concave. It is defined only on the convex set $\mathbf{A}_n^{1/2}(\mathcal{B} - \boldsymbol{\beta}^0)$, a half-space for the canonical links of the gamma and inverse Gaussian; extend it by $-\infty$ outside, which preserves concavity, and note that Step 2 put every ball $\|\mathbf{s}\| \leq M$ inside that set for large n , so the expansion holds where the lemma needs it. Then [Eq. 34.5.3](#) is exactly the form the lemma requires, with $\mathbf{z}_n = O_p(1)$ by Step 1 and a nonrandom remainder bound, so a maximizer $\hat{\mathbf{s}}_n$ exists with probability tending to one and $\hat{\mathbf{s}}_n - \mathbf{z}_n \rightarrow \mathbf{0}$ in probability. Since $\hat{\mathbf{s}}_n = \mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}}_n - \boldsymbol{\beta}^0)$, Slutsky’s theorem and Step 1 give [Eq. 34.5.2](#), and [Theorem 34.3.3](#) makes the maximizer unique.

Consistency. $\|\hat{\boldsymbol{\beta}}_n - \boldsymbol{\beta}^0\| \leq \lambda_{\min}(\mathbf{A}_n)^{-1/2} \|\hat{\mathbf{s}}_n\|$, and $\|\hat{\mathbf{s}}_n\| = O_p(1)$, so (G4) gives $\hat{\boldsymbol{\beta}}_n \rightarrow \boldsymbol{\beta}^0$ in probability.

Plug-in. Consistency and the uniform continuity of b'' used in Step 2 give

$$\mathbf{A}_n^{-1/2} \hat{\mathbf{A}}_n \mathbf{A}_n^{-1/2} \rightarrow \mathbf{I}$$

in probability, whence $\hat{\mathbf{A}}_n^{1/2}(\hat{\boldsymbol{\beta}}_n - \boldsymbol{\beta}^0) \rightarrow N_p(\mathbf{0}, \mathbf{I})$. The last two displays follow by taking the $\boldsymbol{\lambda}$ component. ■

Remark (What the conditions mean, and the non-canonical case). Condition (G3) is the honest content of “large sample”. It is the generalized-linear-model version of the requirement $\max_i h_{ii} \rightarrow 0$ that Chapter 21 needed, and Step 1 used it in exactly that role, to supply Eq. 21.2.2. It fails when it should: a group with a single observation, a regressor that indicates one case, a binary design with a nearly empty cell. The canonical link is used twice, for the concavity and for the nonrandom Hessian, and the next proposition records what survives without it.

Warning. Nothing here is a finite-sample statement: $\hat{\boldsymbol{\beta}}$ is biased, by $O(n^{-1})$ against a standard error of $O(n^{-1/2})$ — asymptotically negligible, not zero. Nor does p fixed cover many parameters: a model with a parameter per group and bounded group sizes violates (G3), and Example (Many means, one variance) showed what goes wrong.

Intervals for a fitted mean. For fixed $\mathbf{x}_0$ the theorem with $\boldsymbol{\lambda} = \mathbf{x}_0$ gives $\hat{\eta}_0 \pm z_{1-\alpha/2}(\mathbf{x}_0^\top \hat{\mathbf{A}}_n^{-1} \mathbf{x}_0)^{1/2}$ for $\eta_0 = \mathbf{x}_0^\top \boldsymbol{\beta}^0$, the counterpart of Theorem 12.1.1 with a normal quantile for a t one; applying the monotone h to both endpoints makes it an interval for $\mu_0 = h(\eta_0)$ of the same asymptotic coverage. The *interval* transforms, not the endpoint formula, so it is not symmetric about $\hat{\mu}_0$ — a feature, since a log link then keeps it positive and a logit link inside $(0, 1)$. The delta-method alternative $\hat{\mu}_0 \pm z_{1-\alpha/2} h'(\hat{\eta}_0)(\mathbf{x}_0^\top \hat{\mathbf{A}}_n^{-1} \mathbf{x}_0)^{1/2}$ agrees to first order and is the worse wherever h curves sharply. Neither is a prediction interval: Theorem 12.3.1 has no clean analogue here.

Proposition 34.5.2 — Non-canonical links

Let the link be any twice continuously differentiable g with $g' \neq 0$ on $\mathcal{M}$, and put $\mathbf{A}_n = \phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{W}$ the working weights of Theorem 34.3.1 evaluated at $\boldsymbol{\beta}^0$. Then every conclusion of Theorem 34.5.1 — existence with probability tending to one, consistency, the limit Eq. 34.5.2, the plug-in version and the Wald intervals — continues to hold, as do Proposition 34.5.3 and Theorem 34.5.5(a),(b) below, which use the theorem only through the quadratic expansion Eq. 34.5.3. The conditions are those of Fahrmeir and Kaufmann (1985): the divergence condition $\lambda_{\min}(\mathbf{A}_n) \rightarrow \infty$, and a continuity condition asking that $\mathbf{A}_n(\boldsymbol{\beta}^0)^{-1/2} \mathbf{A}_n(\boldsymbol{\beta}) \mathbf{A}_n(\boldsymbol{\beta}^0)^{-1/2} \rightarrow \mathbf{I}$ uniformly over $\boldsymbol{\beta}$ in neighbourhoods of $\boldsymbol{\beta}^0$ that shrink in the information metric. The two together play the part of (G2)–(G4).

Remark. This proposition is quoted, not proved: without concavity and a nonrandom Hessian the argument above collapses, and the replacement is the content of Fahrmeir and Kaufmann (1985). It is recorded because most models in the chapters that follow use a non-canonical link somewhere — the complementary log–log and probit links of Chapter 35, the gamma/log fit of Example (Food expenditure: three models, two decisions), the negative binomial with a log link in Chapter 37.

34.5.2 Wald, score and likelihood ratio

Consider a reduced model $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\text{rank}(\mathbf{X}_0) = p - q$, and let $\tilde{\boldsymbol{\beta}}$ be the maximum likelihood estimate under it, written as a vector in $\mathbb{R}^p$. Since $\mathbf{X}$ has full column rank, $\{\boldsymbol{\beta} : \mathbf{X}\boldsymbol{\beta} \in \mathcal{C}(\mathbf{X}_0)\}$ is a subspace of dimension $p - q$, so it is $\{\boldsymbol{\beta} : \boldsymbol{\Lambda}^\top \boldsymbol{\beta} = \mathbf{0}\}$ for some $p \times q$ matrix $\boldsymbol{\Lambda}$ of rank q , in the notation of [Definition 11.3.1](#).

Proposition 34.5.3 — The three statistics

Define

$$\text{Wald} = (\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}})^\top (\boldsymbol{\Lambda}^\top \hat{\mathbf{A}}_n^{-1} \boldsymbol{\Lambda})^{-1} \boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}},$$

$$\text{Score} = \mathbf{U}(\tilde{\boldsymbol{\beta}})^\top \mathcal{I}_n(\tilde{\boldsymbol{\beta}})^{-1} \mathbf{U}(\tilde{\boldsymbol{\beta}}),$$

$$\text{LR} = 2\{\ell(\hat{\boldsymbol{\beta}}) - \ell(\tilde{\boldsymbol{\beta}})\}.$$

Under (G1)–(G4) and the reduced model, each of the three converges in distribution to $\chi^2(q)$, and any two of them differ by $o_p(1)$. For a single coefficient ($q = 1$, $\boldsymbol{\Lambda} = \mathbf{e}_j$) the Wald statistic is $\hat{\beta}_j^2 / [\hat{\mathbf{A}}_n^{-1}]_{jj}$, the square of the “estimate over standard error” ratio that every program prints.

Proof. Work in the coordinates $\mathbf{s} = \mathbf{A}_n^{1/2}(\boldsymbol{\beta} - \boldsymbol{\beta}^0)$ of the proof of [Theorem 34.5.1](#), where $\boldsymbol{\beta}^0$ is the true parameter, which lies in the reduced model, so $\boldsymbol{\Lambda}^\top \boldsymbol{\beta}^0 = \mathbf{0}$. The reduced model is the linear subspace $\mathcal{S}_n = \mathbf{A}_n^{1/2} \mathcal{N}(\boldsymbol{\Lambda}^\top) = \mathcal{N}(\mathbf{B}_n)$ of $\mathbb{R}^p$, where $\mathbf{B}_n = \boldsymbol{\Lambda}^\top \mathbf{A}_n^{-1/2}$ has rank q ; let $\mathbf{P}_n$ be the orthogonal projection onto it, so that $\mathbf{I} - \mathbf{P}_n = \mathbf{B}_n^\top (\mathbf{B}_n \mathbf{B}_n^\top)^{-1} \mathbf{B}_n$.

For the likelihood ratio, [Eq. 34.5.3](#) gives $\Lambda_n(\mathbf{s}) = \mathbf{s}^\top \mathbf{z}_n - \frac{1}{2} \|\mathbf{s}\|^2 + r_n(\mathbf{s})$ uniformly on compacts. Maximizing $\mathbf{s}^\top \mathbf{z}_n - \frac{1}{2} \|\mathbf{s}\|^2$ over $\mathbb{R}^p$ gives $\frac{1}{2} \|\mathbf{z}_n\|^2$ at $\mathbf{s} = \mathbf{z}_n$; over $\mathcal{S}_n$ it gives $\frac{1}{2} \|\mathbf{P}_n \mathbf{z}_n\|^2$ at $\mathbf{s} = \mathbf{P}_n \mathbf{z}_n$. Both maximizers are $O_p(1)$, so the remainder is negligible at both, and

$$\text{LR} = 2\left\{ \max_{\mathbb{R}^p} \Lambda_n - \max_{\mathcal{S}_n} \Lambda_n \right\} = \|(\mathbf{I} - \mathbf{P}_n) \mathbf{z}_n\|^2 + o_p(1).$$

If $\mathbf{z} \sim N_p(\mathbf{0}, \mathbf{I})$ then $\|(\mathbf{I} - \mathbf{P}) \mathbf{z}\|^2 \sim \chi^2(q)$ for *every* projection $\mathbf{P}$ of rank $p - q$ ([Theorem 4.3.2](#)). Projections of a fixed rank form a compact set, so along any subsequence $\mathbf{P}_n \rightarrow \mathbf{P}$, and the continuous mapping theorem gives $\|(\mathbf{I} - \mathbf{P}_n) \mathbf{z}_n\|^2 \rightarrow \chi^2(q)$; the limit is the same for every subsequence, so the whole sequence converges.

For the Wald statistic, write $\hat{\mathbf{s}}_n = \mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0)$. Then $\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}} = \boldsymbol{\Lambda}^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0) = \mathbf{B}_n \hat{\mathbf{s}}_n$ and $\boldsymbol{\Lambda}^\top \hat{\mathbf{A}}_n^{-1} \boldsymbol{\Lambda} = \mathbf{B}_n \mathbf{B}_n^\top$, so with $\mathbf{A}_n$ in place of $\hat{\mathbf{A}}_n$ the statistic is exactly $\|(\mathbf{I} - \mathbf{P}_n) \hat{\mathbf{s}}_n\|^2$. The proof of [Theorem 34.5.1](#) gives $\hat{\mathbf{s}}_n = \mathbf{z}_n + o_p(1)$, and $\mathbf{A}_n^{-1/2} \hat{\mathbf{A}}_n \mathbf{A}_n^{-1/2} \rightarrow \mathbf{I}$ in probability makes the substitution of $\hat{\mathbf{A}}_n$ cost $o_p(1)$; hence $\text{Wald} = \|(\mathbf{I} - \mathbf{P}_n) \mathbf{z}_n\|^2 + o_p(1)$. The same argument inside the reduced model gives $\mathbf{A}_n^{1/2}(\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}^0) = \mathbf{P}_n \mathbf{z}_n + o_p(1)$, which is used next.

For the score statistic, differentiating [Eq. 34.5.3](#) — legitimate because pointwise convergence of differentiable concave functions forces convergence of their gradients (Rockafellar 1970, section 25) — gives $\mathbf{A}_n^{-1/2} \mathbf{U}(\boldsymbol{\beta}^0 + \mathbf{A}_n^{-1/2} \mathbf{s}) = \mathbf{z}_n - \mathbf{s} + o_p(1)$ uniformly on compacts; at $\mathbf{s} = \mathbf{P}_n \mathbf{z}_n + o_p(1)$ this is $(\mathbf{I} - \mathbf{P}_n) \mathbf{z}_n + o_p(1)$. ■

In the normal linear model the three are *exact* monotone functions of one another and of the

Figure 34.5.1: The Hauck–Donner effect. Two groups of 40 trials, with 20 successes in group A. As the successes in group B increase, the likelihood ratio statistic rises monotonically, while the Wald statistic turns over and falls. The horizontal line is the upper 5% point of $\chi^2(1)$.

F statistic, with $\text{Wald} > \text{LR} > \text{Score}$ in every sample (Proposition 11.4.2). Outside it that ordering is not guaranteed, and the three agree only to first order.

The Wald statistic is not invariant. Testing $\beta_j = 0$ and testing $e^{\beta_j} = 1$ are the same hypothesis with different Wald statistics, because the delta-method standard error of $e^{\hat{\beta}_j}$ is not the transform of that of $\hat{\beta}_j$; the likelihood ratio statistic, which compares maximized likelihoods, is invariant under every reparameterization.

The Wald statistic can move the wrong way. This failure has a name.

Example. (The Hauck–Donner effect)

Two groups of 40 trials, with 20 successes in group A and s_B in group B, fitted by a logistic model with an intercept and a group indicator. The coefficient is the log odds ratio $\hat{\beta}_1 = \log\{s_B/(40-s_B)\}$, with standard error $\{1/20+1/20+1/s_B+1/(40-s_B)\}^{1/2}$. As s_B rises from 21 to 39 the evidence against equality strengthens monotonically and the likelihood ratio statistic records it, climbing to 27.301. The Wald statistic does not: it rises to 13.842 at $s_B = 38$ and then *falls* to 11.924 at $s_B = 39$, though the fitted log odds ratio has grown to 3.664. The standard error grows faster than the coefficient.

At complete separation, $s_B = 40$, coefficient and standard error are both infinite and the Wald statistic is 0: the test accepts the null precisely where the data support it most strongly (Figure 34.5.1). The effect occurs whenever the log-likelihood is far from quadratic over the range where the estimate lies.

```
import numpy as np

m_hd, s_a = 40, 20                                     # group A: 20 successes out of
40                                                     # group B: from 21 to 39
s_b = np.arange(21, 40)
odds_ratio = (s_b / (m_hd - s_b)) / (s_a / (m_hd - s_a))
beta1 = np.log(odds_ratio)                             # the fitted log odds ratio
se1 = np.sqrt(1 / s_a + 1 / (m_hd - s_a) + 1 / s_b + 1 / (m_hd - s_b))
wald = (beta1 / se1) ** 2
```

```

def binom_ll(s, m, p):
    return s * np.log(p) + (m - s) * np.log(1 - p)

p_pool = (s_a + s_b) / (2 * m_hd)
lr = 2 * (binom_ll(s_a, m_hd, s_a / m_hd) + binom_ll(s_b, m_hd, s_b / m_hd)
          - binom_ll(s_a, m_hd, p_pool) - binom_ll(s_b, m_hd, p_pool))

for k in (0, 10, 15, 17, 18):
    print(f"successes in B = {s_b[k]:2d}: log odds ratio {beta1[k]:6.3f}"
          f"    Wald {wald[k]:7.3f}    likelihood ratio {lr[k]:7.3f}")

```

When the log-likelihood *is* close to quadratic, the three agree closely. For the age coefficient of [Example \(Fitted votes by party identification\)](#) the script obtains the single-coefficient Wald = 2.046, Score = 2.054 and LR = 2.066, all far from the 5% point 3.84 of $\chi^2(1)$, so the three lead to the same conclusion.

The score statistic needs only the null fit, so it can test a term from the model without it; but it evaluates the information at $\tilde{\beta}$, the wrong place when the alternative is far away. The recommendation is simple: report likelihood ratio tests, and where an interval is wanted invert them, $\{\beta_j : \text{LR}(\beta_j) \leq \chi^2_{1-\alpha}(1)\}$, rather than using the Wald interval.

34.5.3 The deviance

Definition 34.5.1 — Deviance and scaled deviance

Let $\hat{\mu}$ be the fitted means of a model and let $\theta(\cdot)$ be as in [Definition 34.1.2](#). Assuming every $y_i \in \mathcal{M}$, the **saturated model** is the one that sets $\mu_i = y_i$. The **deviance** of the fit is

$$D(\mathbf{y}, \hat{\mu}) = \sum_{i=1}^n d_i, \quad (34.5.4)$$

$$d_i = 2w_i \left[y_i \{ \theta(y_i) - \theta(\hat{\mu}_i) \} - b \{ \theta(y_i) \} + b \{ \theta(\hat{\mu}_i) \} \right],$$

and the **scaled deviance** is $D^* = D/\phi = 2\{\ell_{\text{sat}} - \ell(\hat{\mu})\}$.

The deviance does not involve ϕ ; the scaled deviance does. For the normal family, $\theta = \mu$ and $b(\theta) = \theta^2/2$ give $d_i = w_i(y_i - \hat{\mu}_i)^2$: the deviance is the weighted residual sum of squares, the scaled deviance SSE/σ^2 .

Family	d_i/w_i
normal	$(y - \hat{\mu})^2$
binomial (y a proportion)	$2 \left[y \log \frac{y}{\hat{\mu}} + (1 - y) \log \frac{1 - y}{1 - \hat{\mu}} \right]$
Poisson	$2 \left[y \log \frac{y}{\hat{\mu}} - (y - \hat{\mu}) \right]$
gamma	$2 \left[-\log \frac{y}{\hat{\mu}} + \frac{y - \hat{\mu}}{\hat{\mu}} \right]$

Family	d_i/w_i
inverse Gaussian	$\frac{(y - \hat{\mu})^2}{y \hat{\mu}^2}$

with the convention $0 \log 0 = 0$.

Proposition 34.5.4 — The deviance is nonnegative

Every $d_i \geq 0$, with $d_i = 0$ if and only if $\hat{\mu}_i = y_i$. Consequently $D \geq 0$, with equality only for the saturated fit, and D decreases when a model is enlarged.

Proof. Write $\tilde{\theta} = \theta(y_i)$, $\hat{\theta} = \theta(\hat{\mu}_i)$, so $b'(\tilde{\theta}) = y_i$. Then

$$\frac{d_i}{2w_i} = y_i(\tilde{\theta} - \hat{\theta}) - b(\tilde{\theta}) + b(\hat{\theta}) = b(\hat{\theta}) - b(\tilde{\theta}) - b'(\tilde{\theta})(\hat{\theta} - \tilde{\theta}) \geq 0$$

by convexity of b (Lemma 34.1.1): the right-hand side is the Bregman divergence of b , the amount by which b lies above its tangent at $\tilde{\theta}$. Strict convexity makes it strict unless $\hat{\theta} = \tilde{\theta}$, that is $\hat{\mu}_i = y_i$. Enlarging the model can only raise the maximized likelihood, and $D = 2\phi\{\ell_{\text{sat}} - \ell(\hat{\mu})\}$. ■

The other standard discrepancy is the **Pearson statistic**,

$$X^2 = \sum_{i=1}^n \frac{w_i(y_i - \hat{\mu}_i)^2}{V(\hat{\mu}_i)}, \quad (34.5.5)$$

which is $\sum_i (y_i - \hat{\mu}_i)^2 / \widehat{\text{Var}}(Y_i)$ up to the factor ϕ . It equals the deviance for the normal family and approximates it elsewhere, since a second-order expansion of d_i about $\hat{\mu}_i = y_i$ gives $w_i(y_i - \hat{\mu}_i)^2 / V(\hat{\mu}_i)$.

34.5.4 Analysis of deviance

Theorem 34.5.5 — Distribution theory for the deviance

Assume (G1)–(G4).

- (a) (*Nested models.*) Let $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\text{rank}(\mathbf{X}) - \text{rank}(\mathbf{X}_0) = q$. Under the reduced model,

$$\frac{D_0 - D}{\phi} \xrightarrow{d} \chi^2(q),$$

where D_0 and D are the deviances of the two fits. When ϕ is unknown it is replaced by an estimate, and the ratio $\{(D_0 - D)/q\}/\hat{\phi}$ is referred to $F(q, n - p)$, by analogy with Theorem 11.1.1.

- (b) (*Grouped data.*) Suppose the data consist of G groups, G and p fixed, with y_i

an average of $w_i = m_i$ observations and $m_i \rightarrow \infty$ for every i . Then under the fitted model $D/\phi \rightarrow \chi^2(G-p)$ and $X^2/\phi \rightarrow \chi^2(G-p)$, so both are goodness-of-fit statistics.

- (c) (*Ungrouped data.*) If the number of groups grows with the sample size, (b) does not apply and the limit is generally not $\chi^2(n-p)$. For binary responses with the canonical link the failure is total: D is a function of $\hat{\beta}$ alone, so it carries no information about fit beyond what $\hat{\beta}$ already contains.

Proof.

- (a) By [Definition 34.5.1](#) the saturated log-likelihood cancels in the difference, so $(D_0 - D)/\phi = 2\{\ell(\hat{\beta}) - \ell(\tilde{\beta})\}$, which is the likelihood ratio statistic of [Proposition 34.5.3](#).
- (b) Regard the data as the $\sum_i m_i$ individual observations rather than the G averages, and take the saturated model to be the one with a separate parameter per group, so that its model matrix is the group indicators and it has G parameters, fixed as $m_i \rightarrow \infty$. For that model the quantities [Eq. 34.5.1](#) evaluated at the individual observations are $q_i = 1/m_{g(i)}$, with $g(i)$ the group of observation i , so (G3) holds; and the information in group g is $m_g b''(\theta_g)/\phi \rightarrow \infty$, so (G4) holds. Part (a) applied to the fitted model against the saturated one, with $q = G - p$, gives $D/\phi \rightarrow \chi^2(G-p)$. For X^2 , a third-order expansion of d_i about $\hat{\mu}_i = y_i$ gives $w_i(y_i - \hat{\mu}_i)^2/V(\hat{\mu}_i) + O(w_i|y_i - \hat{\mu}_i|^3)$; with $w_i = m_i$ and $y_i - \hat{\mu}_i = O_p(m_i^{-1/2})$ the remainder summed over the G groups is $O_p(\max_i m_i^{-1/2})$, so $X^2 - D \rightarrow 0$ in probability.
- (c) For a binary response with the logit link, $\mathcal{M} = (0, 1)$ and $y_i \in \{0, 1\}$ is not in $\mathcal{M}$; taking limits in [Eq. 34.5.4](#) with $0 \log 0 = 0$ gives the saturated log-likelihood 0 and $D = -2 \sum_i \{y_i \log \hat{\mu}_i + (1 - y_i) \log(1 - \hat{\mu}_i)\} = -2\ell(\hat{\beta})$. Writing $\hat{\eta}_i = \mathbf{x}_{(i)}^\top \hat{\beta}$ and using $\log(1 - \hat{\mu}_i) = -\log(1 + e^{\hat{\eta}_i})$,

$$\ell(\hat{\beta}) = \sum_i \{y_i \hat{\eta}_i - \log(1 + e^{\hat{\eta}_i})\} = \hat{\beta}^\top \mathbf{X}^\top \mathbf{y} - \sum_i \log(1 + e^{\mathbf{x}_{(i)}^\top \hat{\beta}}).$$

By [Corollary 34.3.2](#), $\mathbf{X}^\top \mathbf{y} = \mathbf{X}^\top \hat{\mu}$, so $\ell(\hat{\beta}) = \hat{\beta}^\top \mathbf{X}^\top \hat{\mu} - \sum_i \log(1 + e^{\mathbf{x}_{(i)}^\top \hat{\beta}})$ depends on the data only through $\hat{\beta}$, and two data sets with the same $\hat{\beta}$ have the same deviance.

■

Example. (Grouped and ungrouped, simulated)

A logistic model with two parameters was fitted to 2000 data sets simulated from it, in two formats with the same number of Bernoulli trials over the same range of x : as 40 groups of 20 trials, and as 800 single trials. (The listing below repeats the experiment with 200 replicates, so that it runs in a few seconds.)

For the grouped data $G - p = 38$, and the simulated deviances have mean 39.74 and standard deviation 9.43, against the $\chi^2(38)$ values 38 and $\sqrt{76} = 8.72$: usable. For the ungrouped data $n - p = 798$, and the simulated deviances have mean 987.95 and standard deviation 20.62, against the $\chi^2(798)$ values 798 and 39.95 — the mean off by nearly 200, the spread by a factor of two ([Figure 34.5.2](#)). Referring that deviance to

Figure 34.5.2: Simulated null distributions of the residual deviance, with the χ^2 density that the naive degrees-of-freedom count suggests. (a) Grouped data: the approximation works. (b) The same information as ungrouped binary responses: it does not.

$\chi^2(n - p)$ would reject a correct model with overwhelming confidence.

Nothing is wrong with the sample size. The two designs carry very nearly the same Fisher information — the script checks that the standard errors of $\hat{\beta}$ agree to within 2% — so the estimates behave alike. What fails is the reference distribution, because the saturated model in the second format has 800 parameters and grows with the data.

```

print(f"ungrouped  : mean {Du.mean():8.2f} (df {N - 2}), sd {Du.std():6.2f}"
      f" (sqrt(2 df) {np.sqrt(2 * (N - 2)):.2f})")

```

Idea. Differences of deviances between nested models are reliable, and are what the analysis-of-deviance table uses. The deviance *itself* is a goodness-of-fit statistic only for grouped data with large groups. The two claims are constantly confused because software prints them in the same table.

The analysis-of-deviance table is built like the sequential analysis-of-variance table of [Definition 9.3.1](#): add terms in a chosen order, recording the drop in deviance at each step with its degrees of freedom. The reference distribution is chi-squared when ϕ is known and F when it is estimated.

Example. (Analysis of deviance for Engel's data)

Continue the gamma/log model of [Example \(Food expenditure: three models, two decisions\)](#), with u the centred logarithm of income and $n = 235$. Fitting the three nested models gives

model	residual df	deviance	change	F	p
1	234	39.01			
1 + u	233	4.27	34.73	1975.2	$< 10^{-4}$
1 + $u + u^2$	232	4.18	0.0918	5.22	0.023

Here ϕ is unknown, so each change is divided by $\hat{\phi} = 0.01758$ and referred to $F(1, 232)$, following [Theorem 34.5.5\(a\)](#). One qualification: the log link is not the gamma's canonical link, so (G1) does not hold and the calibration rests not on the proof given but on [Proposition 34.5.2](#), which extends the limit to this case without proving it. Income matters overwhelmingly; the quadratic term is borderline. The residual deviance 4.18 is *not* to be compared with $\chi^2(232)$: the data are ungrouped, so [Theorem 34.5.5\(b\)](#) does not apply, and the small value reflects the small dispersion of the gamma fit, not a suspiciously good one.

```

import numpy as np
import statsmodels.api as sm

```

34.5.5 Estimating the dispersion

For the binomial and Poisson families $\phi = 1$ by construction; if the data contradict that, the remedy is a different model, which is [Chapter 38](#). For the normal, gamma and inverse Gaussian families ϕ is free. Maximum likelihood would take it from the full likelihood, which for the gamma involves the digamma function and behaves badly under misspecification. The standard choice is instead the **Pearson estimate**

$$\hat{\phi} = \frac{X^2}{n - p} = \frac{1}{n - p} \sum_{i=1}^n \frac{w_i (y_i - \hat{\mu}_i)^2}{V(\hat{\mu}_i)}. \quad (34.5.6)$$

The motivation is the moment identity $E\{w_i(Y_i - \mu_i)^2/V(\mu_i)\} = \phi$, exact at the true mean; replacing μ_i by $\hat{\mu}_i$ costs p degrees of freedom, by analogy with $s^2 = \text{SSE}/(n - p)$, the exact normal-theory case ([Theorem 5.6.1](#)). The alternative $D/(n - p)$ is also in use; for Engel's data the two give 0.01758 and 0.01803. They can differ sharply for skewed data, and the Pearson version is the more reliable, since it does not depend on the far tail of the assumed density.

Because the likelihood equations do not involve ϕ ([Theorem 34.3.1\(a\)](#)), estimating it does not disturb $\hat{\beta}$. It does enter every standard error, through $\hat{\mathbf{A}}_n^{-1} = \hat{\phi}(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$, and its own variability is why the tests are then referred to an F distribution.

34.5.6 Residuals and diagnostics

The raw residual $y_i - \hat{\mu}_i$ is uninformative on its own, because its variance depends on $\hat{\mu}_i$. Three standardizations are in use.

Definition 34.5.2 — Pearson, deviance and Anscombe residuals

For a fitted generalized linear model, with d_i the deviance contributions of [Eq. 34.5.4](#) and h_{ii} the diagonal of the weighted hat matrix $\mathbf{H} = \hat{\mathbf{W}}^{1/2} \mathbf{X}(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \mathbf{X}^\top \hat{\mathbf{W}}^{1/2}$, define

$$r_i^P = \frac{\sqrt{w_i}(y_i - \hat{\mu}_i)}{\sqrt{\hat{\phi} V(\hat{\mu}_i)}}, \quad r_i^D = \text{sign}(y_i - \hat{\mu}_i) \sqrt{d_i / \hat{\phi}},$$

$$r_i^A = \frac{\sqrt{w_i} \{A(y_i) - A(\hat{\mu}_i)\}}{\sqrt{\hat{\phi} A'(\hat{\mu}_i) \sqrt{V(\hat{\mu}_i)}}},$$

where $A(\mu) = \int^\mu V(t)^{-1/3} dt$. The **standardized** versions divide by $\sqrt{1 - h_{ii}}$.

The Pearson residuals have squares adding to $X^2/\hat{\phi}$, the deviance residuals squares adding to $D/\hat{\phi}$; each splits its own discrepancy measure into per-observation pieces, so a large deviance residual marks an observation the likelihood explains badly. The Anscombe residual first applies the transformation that brings the family closest to normal, $A(\mu) = \frac{3}{2}\mu^{2/3}$ for the Poisson and $3\mu^{1/3}$ for the gamma.

Example. (Which residual is closest to normal)

Two thousand observations were simulated from a Poisson log-linear model with fitted means between about 1 and 6, and the model refitted. [Figure 34.5.3](#) shows normal quantile plots of the three residual types. The Pearson residuals are visibly right-skewed, with sample skewness 0.618 — the skewness $\mu^{-1/2}$ of [Exercise \(B3\)](#), averaged over the fitted means. The deviance residuals have skewness -0.010 and the Anscombe residuals -0.081 ; both are far closer to normal, and neither is uniformly better. Discreteness remains visible in all three as short horizontal runs. The leverages sum to 2 ([Proposition 6.8.1\(b\)](#)) and the largest is 0.0029.

```
rng = np.random.default_rng(3405)
N = 2000
Xp = np.column_stack([np.ones(N), rng.uniform(-1, 1, N)])
mu_true = np.exp(Xp @ np.array([1.0, 0.8]))
```

means between about 1

Figure 34.5.3: Normal quantile plots of the three residual types for a Poisson log-linear fit with small means. The reference line is the identity. Pearson residuals inherit the skewness of the family; deviance and Anscombe residuals largely remove it.

```

    and 6
yp = rng.poisson(mu_true).astype(float)
pois = sm.GLM(yp, Xp, family=sm.families.Poisson()).fit()
mu_p = pois.fittedvalues

pearson = (yp - mu_p) / np.sqrt(mu_p)                                # r = (y -
    mu)/sqrt(V)
d_i = 2 * (np.where(yp > 0, yp * np.log(np.maximum(yp, 1e-300) / mu_p), 0.0) - (yp -
    mu_p))
deviance_r = np.sign(yp - mu_p) * np.sqrt(d_i)                        # signed
    root of d_i
anscombe = 1.5 * (yp ** (2 / 3) - mu_p ** (2 / 3)) / mu_p ** (1 / 6)  # A(mu) =
    1.5 mu^{2/3}

W = mu_p                                                            # working weights for
    Poisson/log
root = np.sqrt(W)[: , None] * Xp
H = root @ np.linalg.inv(root.T @ root) @ root.T                    # the weighted hat matrix
h = np.diag(H)

for name, r in [("Pearson", pearson), ("deviance", deviance_r), ("Anscombe",
    anscombe)]:
    print(f"{name:9s} sd {r.std(ddof=2):6.3f} skewness {stats.skew(r):7.3f}")
print(f"leverages: sum {h.sum():.4f}, largest {h.max():.4f}")

```

The rest of [Chapter 20](#) transfers under the substitution $\mathbf{X} \mapsto \hat{\mathbf{W}}^{1/2}\mathbf{X}$, which is Pregibon's (1981) extension of the linear-model diagnostics: the leverages of [Proposition 6.8.1](#), a Cook-type measure $C_i = (r_i^P)^2 h_{ii} / \{p(1-h_{ii})^2\}$ ([Definition 20.4.1](#)), and the one-step deletion approximations of [Theorem 20.3.1](#) with the working response in place of $\mathbf{y}$. The exact deletion identities do not, because dropping a case changes the weights too. For ungrouped binary data the residuals take only two values at each $\hat{\mu}_i$, so only smoothed plots carry a signal — a point [Proposition 35.4.1](#) develops.

34.5.7 Model selection

Because the fit is by maximum likelihood, [Definition 29.2.2](#) applies directly, with $\text{AIC} = -2\ell(\hat{\beta}) + 2d$ and $d = p$ when ϕ is known, $p + 1$ when it is estimated; for a $\phi = 1$ family comparing AIC is comparing $D + 2p$. The rest of [Chapter 29](#) transfers unchanged, [Proposition 29.5.1](#) included.

34.5.8 Exercises

34.5.8.1 A. Check your understanding

Exercise A1.

Verify the normal and Poisson rows of the deviance table from [Eq. 34.5.4](#). For the Poisson, show that if the model has an intercept then $\sum_i (y_i - \hat{\mu}_i) = 0$ by [Corollary 34.3.2](#), so the deviance reduces to $2 \sum_i y_i \log(y_i / \hat{\mu}_i)$.

Exercise A2.

A binomial model is fitted to 60 groups with 4 parameters, and the residual deviance is 71.2 on 56 degrees of freedom. When is comparing it with $\chi^2(56)$ legitimate, and what would you need to know about the data first?

Solution. By [Theorem 34.5.5\(b\)](#) the comparison needs the number of groups fixed and the group sizes large, so one needs the m_i : if they are all in the hundreds the comparison is reasonable, and if many are 1 or 2 it is not, whatever the total sample size. A rough rule is that the expected counts $m_i \hat{\mu}_i$ and $m_i(1 - \hat{\mu}_i)$ should all exceed about five.

34.5.8.2 B. Practice

Exercise B1.

Let $\hat{\beta}$ have asymptotic standard error s . Compute the Wald statistic for $H_0 : \beta = 0$ and, using the delta method, the Wald statistic for the equivalent hypothesis $H_0 : e^\beta = 1$. Show that their ratio is $\{(e^{\hat{\beta}} - 1)/\hat{\beta}\}^2 e^{-2\hat{\beta}}$, and evaluate it at $\hat{\beta} = 1$ and $\hat{\beta} = 3$. Why is the likelihood ratio statistic unaffected?

Exercise B2.

Show that $E\{w_i(Y_i - \mu_i)^2 / V(\mu_i)\} = \phi$ exactly, for every observation in an exponential dispersion family. Deduce that X^2/n is unbiased for ϕ when the true means are used, and explain why $X^2/(n - p)$ is only approximately unbiased when they are estimated.

Exercise B3.

Derive the Anscombe residual for the Poisson family from $A(\mu) = \int^\mu t^{-1/3} dt$, and check that the standardizing denominator is $\hat{\mu}^{1/6}$. Explain why A is *not* the variance-

stabilizing transformation $2\sqrt{\mu}$ of [Corollary 22.4.2](#), and what each one is optimizing.

Solution. $A(\mu) = \frac{3}{2}\mu^{2/3}$, so $A'(\mu) = \mu^{-1/3}$ and $A'(\hat{\mu})\sqrt{V(\hat{\mu})} = \hat{\mu}^{-1/3}\hat{\mu}^{1/2} = \hat{\mu}^{1/6}$, giving $r^A = \frac{3}{2}(y^{2/3} - \hat{\mu}^{2/3})/\hat{\mu}^{1/6}$. The variance-stabilizing transformation solves $A' \propto V^{-1/2}$ and makes the *variance* constant; the Anscombe transformation solves $A' \propto V^{-1/3}$ and makes the *third cumulant*, hence the skewness, vanish to the order considered. Different objectives, different exponents; the Anscombe residual is then standardized by hand, so it does not need the variance to be stable by itself.

Exercise B4.

Two summaries of predictive power for a generalized linear model are the sample correlation between $\mathbf{y}$ and $\hat{\boldsymbol{\mu}}$, and the likelihood-based $R_L^2 = (\ell_M - \ell_0)/(\ell_{\text{sat}} - \ell_0)$, where ℓ_0 , ℓ_M and ℓ_{sat} are the maximized log-likelihoods of the intercept-only model, the fitted model and the saturated model. Show that for a family with $\phi = 1$ the second is $(D_0 - D)/D_0$, with D_0 the null deviance, and deduce that it lies in $[0, 1]$ and never decreases when a term is added. Why does that last property make it a poor basis for choosing a model?

Solution. With $\phi = 1$, [Definition 34.5.1](#) gives $D = 2(\ell_{\text{sat}} - \ell_M)$ and $D_0 = 2(\ell_{\text{sat}} - \ell_0)$, so $\ell_M - \ell_0 = (D_0 - D)/2$ and $R_L^2 = (D_0 - D)/D_0$. Both deviances are nonnegative by [Proposition 34.5.4](#) and $D \leq D_0$, since enlarging a model cannot lower the maximized likelihood; so $R_L^2 \in [0, 1]$ and cannot decrease when a term is added. That is the defect of the unadjusted R^2 of [Section 9.5](#), the point [Proposition 9.5.3](#) makes there: it rewards complexity unconditionally. AIC instead charges 2 per parameter against -2ℓ , and so can rise.

34.5.8.3 C. Going deeper

Exercise C1.

Extend [Theorem 34.5.5\(c\)](#) to a Poisson log-linear model in which every y_i is 0 or 1: show that the deviance is again a function of $\hat{\boldsymbol{\beta}}$ alone. Then show that the argument breaks down as soon as some $y_i \geq 2$, and explain in words what extra information the larger counts supply. (This is the reason the deviance is a serviceable goodness-of-fit statistic for Poisson data with large means and a useless one for sparse counts.)

Solution. For the Poisson deviance, $D = 2 \sum_i \{y_i \log(y_i/\hat{\mu}_i) - (y_i - \hat{\mu}_i)\}$. When every $y_i \in \{0, 1\}$ the term $y_i \log y_i$ is zero, so $D = -2 \sum_i y_i \log \hat{\mu}_i + 2 \sum_i (y_i - \hat{\mu}_i)$; the second sum vanishes by [Corollary 34.3.2](#) if the model has an intercept, and the first is $-2\hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top \mathbf{y} = -2\hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top \hat{\boldsymbol{\mu}}$, again by [Corollary 34.3.2](#). So D is a function of $\hat{\boldsymbol{\beta}}$. If some $y_i \geq 2$, the term $\sum_i y_i \log y_i$ is a nonzero function of the data that is *not* determined by $\mathbf{X}^\top \mathbf{y}$: two data sets with the same sufficient statistic, one with counts $(2, 0)$ at two identical covariate values and one with $(1, 1)$, have the same $\hat{\boldsymbol{\beta}}$ but different deviances. The larger counts carry information about the spread of the responses within a covariate pattern, which is precisely what a goodness-of-fit statistic needs and what binary data cannot supply.

34.6 Summary and Notes

34.6.1 Summary

Idea.

1. An exponential dispersion family has density $\exp[w\{y\theta - b(\theta)\}/\phi + c(y, \phi, w)]$ with natural parameter θ , cumulant function b , dispersion ϕ and known weight w (Definition 34.1.1). The natural parameter space is convex and b is strictly convex on it (Lemma 34.1.1).
2. All moments come from b : $\mu = b'(\theta)$, $\text{Var}(Y) = \phi b''(\theta)/w$, and the r th cumulant is $(\phi/w)^{r-1} b^{(r)}(\theta)$ (Proposition 34.1.2). Reparameterizing by the mean gives the variance function $V(\mu)$ (Definition 34.1.2), which determines the family: $V = 1, \mu, \mu^2, \mu^3, \mu(1 - \mu), \mu(1 + \mu/k)$.
3. A generalized linear model is a random component from such a family, a linear predictor $\mathbf{X}\boldsymbol{\beta}$, and a link $g(\mu_i) = \eta_i$ (Definition 34.2.1); the canonical link $g = (b')^{-1}$ makes $\theta_i = \eta_i$ (Definition 34.2.2). The link and the variance function are separate decisions, and neither transforms the data.
4. The score is $\phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu})$ with working weights $\mathbf{W}_{ii} = w_i h'(\eta_i)^2 / V(\mu_i)$; the expected information is $\phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$, and under the canonical link the observed information equals it (Theorem 34.3.1). The likelihood equations do not involve ϕ .
5. Under the canonical link the fit reproduces the weighted column totals of $\mathbf{X}$ exactly (Corollary 34.3.2), and the log-likelihood is strictly concave, so the maximum is unique when it exists (Theorem 34.3.3). Existence can fail, as in separation.
6. Fisher scoring is weighted least squares on the working response $z_i = \eta_i + (y_i - \mu_i)g'(\mu_i)$ with weights $\mathbf{W}$, iterated (Theorem 34.4.1). It is Newton's method exactly when the link is canonical, which is why canonical-link fits converge quadratically and others linearly.
7. Under stated regularity conditions — notably $\max_i q_{ni} \rightarrow 0$, the leverage-like condition Eq. 34.5.1 — the estimate exists with probability tending to one, is consistent, and $\mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0)$ is asymptotically standard normal (Theorem 34.5.1 for the canonical link, Proposition 34.5.2 for the rest). Wald, score and likelihood ratio statistics are asymptotically equivalent and $\chi^2(q)$ (Proposition 34.5.3), but the Wald statistic is not invariant and can fall as the evidence grows (the Hauck–Donner effect).
8. The deviance is twice the gap to the saturated log-likelihood (Definition 34.5.1); every contribution is nonnegative (Proposition 34.5.4). Differences of deviances between nested models are χ^2 in the limit; the deviance itself is a goodness-of-fit statistic only for grouped data with large groups, and for ungrouped binary data it is a function of $\hat{\boldsymbol{\beta}}$ alone (Theorem 34.5.5).
9. The dispersion is estimated by $X^2/(n-p)$ (Eq. 34.5.6), which leaves $\hat{\boldsymbol{\beta}}$ unchanged. Pearson, deviance and Anscombe residuals (Definition 34.5.2) and the weighted hat matrix carry the diagnostics of Chapter 20 across, and AIC applies as in Chapter 29.

34.6.2 Notes and sources

The synthesis. Nelder and Wedderburn (1972) created the subject. Every piece existed before — probit analysis, logistic regression, log-linear models for contingency tables, the gamma model for survival times, weighted least squares — and the paper’s contribution was to see that the exponential family structure made all of them one algorithm. That is what let a single program, GLIM, fit them all, and what makes the code of [Section 34.4](#) family-agnostic. McCullagh and Nelder (1989) remains the definitive treatment; its chapter 2 is the source for the deviance and residual definitions used here, chapter 12 for the diagnostics.

Exponential dispersion families. The class of [Definition 34.1.1](#), with ϕ a genuine second parameter rather than a nuisance folded into θ , is due to Jorgensen (1987), developed in Jorgensen (1997); that paper also classifies the power variance functions $V(\mu) = \mu^\xi$, the Tweedie families of [Exercise \(C2\)](#). The analytic facts behind [Proposition 34.1.2](#) are in Widder (1941); the statistical apparatus built on them, including the convexity of the natural parameter space and the mean-value mapping, is Barndorff-Nielsen (1978) and Brown (1986); the existence criterion quoted after [Example \(Two ways the maximum fails to exist\)](#) is Barndorff-Nielsen’s.

Fitting. The scoring method is older than the subject: it appears in Fisher’s appendix to Bliss (1935) on probit analysis, as a device for fitting a dose–response curve by hand. Nelder and Wedderburn (1972) identified the general form and recognized it as weighted least squares. Green (1984) is the standard reference for iteratively reweighted least squares as a general estimation device and for the convergence issues of [Section 34.4](#). Existence and uniqueness link by link are settled by Wedderburn (1976), the source of the gamma/identity warning in [Section 34.3](#); that only the variance function enters the estimating equations, so one may drop the density, is Wedderburn (1974), which [Chapter 38](#) follows.

Asymptotics. The complete theory — consistency, asymptotic normality, and existence with probability tending to one — is Fahrmeir and Kaufmann (1985), under conditions considerably weaker than (G1)–(G4) and covering non-canonical links and stochastic regressors; [Proposition 34.5.2](#) quotes what this book needs from it. The proof of [Theorem 34.5.1](#) takes the shortcut the canonical link allows: the log-likelihood is concave and its Hessian nonrandom, so the argument reduces to the central limit theorem of [Lemma 21.2.1](#) for the score, plus the convexity lemma of Pollard (1991), which makes concavity do the work usually done by uniform convergence arguments. The condition $\max_i q_{ni} \rightarrow 0$ is the generalized-linear-model form of the bounded-leverage condition used throughout the book, and $\sum_i q_{ni} = p$ is [Proposition 6.8.1\(b\)](#) in a new setting.

The three tests. Cox and Hinkley (1974, chapter 9) is the standard general account of their asymptotic equivalence. The failure of [Example \(The Hauck–Donner effect\)](#) was identified by Hauck and Donner (1977) and named after them; it is one case of a general phenomenon, since the Wald statistic uses a quadratic approximation to the log-likelihood centred at $\hat{\beta}$, worst exactly where the estimate is most extreme. None of this arises in the normal linear model, where the log-likelihood is exactly quadratic in β for fixed σ^2 , and [Proposition 11.4.2](#) records the exact relationships that result.

The deviance and its limits. That the residual deviance of a binary logistic fit is a function of $\hat{\beta}$ alone, hence useless as a goodness-of-fit statistic, is in McCullagh and Nelder (1989, section 4.4). The regime in which the deviance *is* a goodness-of-fit statistic — groups fixed, group sizes growing — is sometimes called grouped or small-dispersion asymptotics, against the $n \rightarrow \infty$ asymptotics of [Theorem 34.5.1](#). The two give different answers for the same statistic, the source of most of the confusion in practice, and [Chapter 35](#) returns to it with [Proposition 35.4.1](#).

Anscombe residuals are from Anscombe (1953); the extension of the diagnostics of [Chapter 20](#), including the weighted hat matrix and one-step deletion approximations, is Pregibon (1981).

Textbook treatments. Agresti (2015, chapter 4) covers the same ground at a similar level and is the closest companion; its chapters 5–7 correspond to [Chapter 35](#), [Chapter 36](#) and [Chapter 37](#). Fahrmeir, Kneib, Lang and Marx (2021, section 5.4) handles the weight w and grouped data carefully, and is the source of the convention used here that y may be a group average. Dobson and Barnett (2018) is a gentler introduction; Rencher and Schaalje (2008, chapter 18) treats the subject briefly, as an extension of linear-model theory.

What comes next. [Chapter 38](#) keeps the score equations and drops the density, which handles data more variable than the family allows. [Chapter 39](#) takes up model building in practice and the Bayesian treatment, whose priors are the counterpart of the penalized likelihoods of [Chapter 27](#) and [Chapter 30](#). [Chapter 40](#) joins the subject to the mixed models of [Chapter 32](#), where the likelihood is no longer available in closed form.

Chapter 35

Binary Responses

A response that can only be zero or one is the smallest departure from the normal linear model that still changes everything. Its mean is a probability, so it lives in an interval rather than on a line; its variance is determined by its mean, so there is no free dispersion parameter; and the exact distribution theory of Parts III and IV is gone. What remains is the likelihood, and the apparatus of [Chapter 34](#) applies word for word. This chapter is what that apparatus looks like pointed at the simplest possible response, and what that response does to it: odds ratios that survive sampling schemes no other model can tolerate, a maximum likelihood estimate that sometimes fails to exist, and a deviance that, for ungrouped data, carries no information about fit at all.

What you need. [Chapter 34](#) for the exponential dispersion family, the likelihood equations, iteratively reweighted least squares, the deviance and the asymptotics; [Chapter 7](#) for maximum likelihood and Fisher information ([Theorem 7.3.1](#), [Proposition 7.4.7](#)); [Chapter 11](#) for the likelihood ratio test in the normal model ([Theorem 11.4.1](#), [Proposition 11.4.2](#)); [Chapter 20](#) for residuals, leverage and influence; [Chapter 21](#) for weighted least squares; [Chapter 22](#) for empirical logits ([Exercise \(B2\)](#)); [Chapter 25](#) for the causal reading of a coefficient; [Chapter 27](#) and [Chapter 30](#) for penalized estimation; [Chapter 29](#) for AIC and cross-validation.

35.0.1 Roadmap

- [Logistic regression](#)
- [Probit and complementary log–log links](#)
- [Separation](#)
- [Goodness of fit](#)
- [Case–control sampling](#)
- [Summary and notes](#)

35.1 Logistic regression

A binary response records whether something happened: a patient recovered, a voter turned out, a loan defaulted. Then $E(Y_i) = \Pr(Y_i = 1)$, so modelling the mean *is* modelling a probability, and a linear model for it is in trouble before it starts: $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ ranges over the whole line while a

probability may not leave $[0, 1]$, and the variance $\pi_i(1-\pi_i)$ moves with the mean. The generalized linear model of [Chapter 34](#) removes both problems by putting a link between the mean and the linear predictor.

35.1.1 The model

Let $Y_1, \dots, Y_n$ be independent with $Y_i \sim \text{Binomial}(m_i, \pi_i)$; $m_i = 1$ throughout is **ungrouped** data, and larger m_i arise when several units share a covariate vector. Dropping the index,

$$\binom{m}{y} \pi^y (1-\pi)^{m-y} = \binom{m}{y} \exp\left\{y \log \frac{\pi}{1-\pi} + m \log(1-\pi)\right\},$$

an exponential dispersion family ([Definition 34.1.1](#)) for the mean $\mu = m\pi$, with natural parameter $\theta = \log\{\pi/(1-\pi)\}$, cumulant function $b(\theta) = \log(1 + e^\theta)$, dispersion $\phi = 1$ and weight m . Differentiating b twice recovers the moments of [Proposition 34.1.2](#): $b'(\theta) = \pi$ and $b''(\theta) = \pi(1-\pi)$, so the variance function is $V(\pi) = \pi(1-\pi)$ and $\text{Var}(Y) = m\pi(1-\pi)$. The natural parameter is the **log odds**, and the canonical link is therefore the logit.

Definition 35.1.1 — Logistic regression

The **logistic regression model** for independent $Y_i \sim \text{Binomial}(m_i, \pi_i)$ is

$$\text{logit } \pi_i = \log \frac{\pi_i}{1-\pi_i} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \quad \text{equivalently} \quad \pi_i = \frac{\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})}. \quad (35.1.1)$$

The quantity $\pi/(1-\pi)$ is the **odds** of the event, and the ratio of the odds at two covariate vectors is an **odds ratio**.

The logit is one choice among many ([Section 35.2](#)). Its claim to first place is that it is canonical, so [Theorem 34.3.1](#) takes its simplest form, and that its coefficients say something people want to hear.

35.1.2 Reading the coefficients

Proposition 35.1.1 — Three readings of a logistic coefficient

In [Eq. 35.1.1](#), write $\eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ and let x_j be a covariate that appears in the linear predictor only through its own coefficient β_j . Then:

- (a) increasing x_j by c with the other covariates unchanged multiplies the odds by $e^{c\beta_j}$, whatever the values of the other covariates;
- (b) $\partial\pi/\partial x_j = \beta_j \pi(1-\pi)$, so $|\partial\pi/\partial x_j| \leq |\beta_j|/4$, with equality exactly at $\pi = 1/2$;
- (c) the average of that derivative over the sample, $n^{-1} \sum_i \beta_j \hat{\pi}_i(1-\hat{\pi}_i)$, is the **average marginal effect**: the mean change in fitted probability per unit of x_j .

Proof.

- (a) The log odds at $x_j + c$ minus the log odds at x_j is $c\beta_j$, and everything else in η cancels. (b) Differentiating $\pi = e^\eta / (1 + e^\eta)$ gives $d\pi/d\eta = \pi(1 - \pi)$, and the chain rule supplies the factor β_j . The function $\pi(1 - \pi)$ on $[0, 1]$ is maximized at $\pi = 1/2$ with value $1/4$, so the derivative has modulus at most $|\beta_j|/4$. (c) Immediate from (b).

■

Part (a) is why logistic regression is written as it is: one number summarizes the effect on the odds at every setting of the other covariates. Part (b) is Gelman and Hill's "divide by four" rule, sharp near $\pi = 1/2$; part (c) reports the same coefficient on the probability scale.

Warning. None of the three readings is causal: each compares two covariate vectors *within the fitted model*, and whether that estimates an intervention is the question of [Chapter 25](#). [Section 35.5](#) adds a wrinkle special to odds ratios.

Example. (Voting intention in the 1996 American election)

The 1996 American National Election Studies survey recorded, for 944 respondents, the candidate they expected to vote for (393 said Dole), party identification from strong Democrat (0) to strong Republican (6), age, education on a seven-point scale and household income on a 24-point scale. Fitting [Eq. 35.1.1](#) with these four covariates and age in decades gives

term	$\hat{\beta}_j$	standard error
intercept	-5.471	0.619
party identification	1.2188	0.0709
age (decades)	0.1222	0.0714
education	0.0147	0.0771
income	0.0311	0.0210

One step along the party scale multiplies the odds of a Dole vote by $e^{1.2188} = 3.383$; three steps multiply them by 38.72. Dividing by four bounds the effect on the probability by 0.305 per step, and the average marginal effect is 0.100: one step is worth about ten percentage points, averaged over the respondents ([Figure 35.1.1](#)).

```
import numpy as np
import pandas as pd
import statsmodels.api as sm

anes = sm.datasets.anes96.load_pandas().data
X = pd.DataFrame({"const": 1.0, "PID": anes["PID"], "age": anes["age"] / 10,
                  "educ": anes["educ"], "income": anes["income"]})
y = anes["vote"]  # 1 = Dole, 0 = Clinton

fit = sm.GLM(y, X, family=sm.families.Binomial()).fit()
pi_hat = fit.fittedvalues
```

Figure 35.1.1: Expected vote for Dole in the 1996 ANES survey. (a) The fitted logistic curve against party identification, the other covariates held at their means; the discs are the observed proportions in the seven party groups, with area proportional to group size. (b) The tangent at the steepest point, of slope $\hat{\beta}_j/4$.

```
print(fit.params.round(4).to_string())
print("odds ratio for one step on the party scale:", round(np.exp(fit.params["PID"])
, 3))
print("divide by four:", round(fit.params["PID"] / 4, 3))
print("average marginal effect:", round((fit.params["PID"] * pi_hat * (1 - pi_hat)).
mean(), 3))
```

35.1.3 Grouped and ungrouped data

Two data sets recording the same information can look very different: one lists 944 individual zeros and ones, the other one binomial count per distinct covariate vector.

Proposition 35.1.2 — Grouping

Let $\mathbf{y}$ be ungrouped binary data, and suppose the rows of $\mathbf{X}$ take N distinct values $\mathbf{x}_{(1)}^*, \dots, \mathbf{x}_{(N)}^*$, the k th occurring m_k times with s_k successes. Then:

- the two log-likelihoods differ by a constant free of $\boldsymbol{\beta}$, so they have the same maximizers, the same score, the same information and the same likelihood ratio statistics;
- the two deviances of Definition 34.5.1 differ by $-2\ell_{\text{sat}}$, where $\ell_{\text{sat}} = \sum_k \{s_k \log(s_k/m_k) + (m_k - s_k) \log(1 - s_k/m_k)\}$ is the maximized log-likelihood of the grouped saturated model;
- if $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, then $\sum_i m_i \hat{\pi}_i = \sum_i y_i$ in either form: the fit reproduces the total number of successes.

Proof.

(a) With $\eta_k = \mathbf{x}_{(k)}^\top \boldsymbol{\beta}$, the ungrouped log-likelihood is

$$\sum_{k=1}^N \{s_k \eta_k - m_k \log(1 + e^{\eta_k})\},$$

because the individual contributions within a group depend on the data only through s_k . The grouped log-likelihood is the same expression plus $\sum_k \log \binom{m_k}{s_k}$, a constant. (b) The deviance is twice the difference between the saturated and fitted log-likelihoods. The fitted log-likelihood is the same in both forms by (a); the ungrouped saturated model sets $\hat{\pi}_i = y_i$ and attains log-likelihood 0, while the grouped saturated model sets $\hat{\pi}_k = s_k/m_k$ and attains $\ell_{\text{sat}} \leq 0$. (c) Under the canonical link the likelihood equations are $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$ ([Theorem 34.3.1](#)); the column **1** gives $\sum_i (y_i - m_i \hat{\pi}_i) = 0$.

■

Part (b) is worth pausing over: the deviance of a logistic fit depends on how the data were typed in. *Differences* of deviances between nested models do not, because the saturated term cancels, and those are what [Theorem 34.5.5](#) licenses.

Example. (The same fit, two deviances)

Fit logit $\pi = \beta_0 + \beta_1(\text{party}) + \beta_2(\text{education})$ to the survey of [Example \(Voting intention in the 1996 American election\)](#). The 944 respondents occupy 47 distinct covariate cells. Grouped, the deviance is 45.99 on 44 degrees of freedom; ungrouped, it is 533.34 on 941. The coefficients and their standard errors agree to machine precision.

```
# the same model in grouped form: one binomial count per distinct covariate pattern
cols = ["PID", "educ"]
cells = anes.groupby(cols)["vote"].agg(["sum", "count"]).reset_index()
Xg = sm.add_constant(cells[cols])
counts = np.column_stack([cells["sum"], cells["count"] - cells["sum"]])
grouped = sm.GLM(counts, Xg, family=sm.families.Binomial()).fit()

Xu = sm.add_constant(anes[cols])
ungrouped = sm.GLM(anes["vote"], Xu, family=sm.families.Binomial()).fit()

print("grouped  ", grouped.params.round(4).to_numpy(), "deviance", round(grouped.
    deviance, 2))
print("ungrouped", ungrouped.params.round(4).to_numpy(), "deviance", round(ungrouped.
    deviance, 2))
```

35.1.4 Estimation

There is no closed form for $\hat{\boldsymbol{\beta}}$. Under the canonical link [Theorem 34.3.1](#) reduces to

$$\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}, \quad \mu_i = m_i \pi_i = \frac{m_i \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})}{1 + \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})}, \quad (35.1.2)$$

a system of p smooth equations in p unknowns. Specializing [Theorem 34.4.1](#) gives the algorithm every implementation uses.

Proposition 35.1.3 — Fisher scoring for logistic regression

For [Eq. 35.1.1](#) the Fisher scoring step from $\mathbf{b}$ is the weighted least squares fit of the working response $\mathbf{z}$ on $\mathbf{X}$ with weights $\mathbf{W}$, where

$$w_i = m_i \pi_i (1 - \pi_i), \quad z_i = \eta_i + \frac{y_i - m_i \pi_i}{m_i \pi_i (1 - \pi_i)},$$

both evaluated at $\mathbf{b}$. The observed and expected information coincide and equal $\mathbf{X}^\top \mathbf{W} \mathbf{X}$; the log-likelihood is concave in $\boldsymbol{\beta}$, and strictly concave when $\text{rank}(\mathbf{X}) = p$ and $0 < \pi_i < 1$.

Proof. The weights and working response are the general formulae of [Theorem 34.4.1](#) with $V(\pi) = \pi(1 - \pi)$ and $d\eta/d\mu = 1/\{m\pi(1 - \pi)\}$. Differentiating [Eq. 35.1.2](#) once more gives the Hessian $-\mathbf{X}^\top \mathbf{W} \mathbf{X}$, so the observed information equals the expected information, as [Theorem 34.3.1](#) gives for every canonical link. The matrix $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ is nonnegative definite, and positive definite when the w_i are positive and $\mathbf{X}$ has full column rank, since $\mathbf{b}^\top \mathbf{X}^\top \mathbf{W} \mathbf{X} \mathbf{b} = \sum_i w_i (\mathbf{x}_{(i)}^\top \mathbf{b})^2$ vanishes only if $\mathbf{X} \mathbf{b} = \mathbf{0}$. ■

Concavity means at most one local maximum, and the step is the weighted least squares of [Theorem 21.3.1](#) with response and weights refreshed each iteration. Convergence from $\boldsymbol{\beta} = \mathbf{0}$ is usually fast, and took 6 iterations in [Example \(Voting intention in the 1996 American election\)](#); it is not guaranteed, and [Section 35.3](#) describes the configuration in which there is nothing to converge to.

35.1.5 Inference

With the estimate in hand, [Theorem 34.5.1](#) supplies its law: under the usual regularity conditions, with p fixed and the information growing without bound, $\hat{\boldsymbol{\beta}}$ is treated as $N_p(\boldsymbol{\beta}, (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1})$. The growth condition is real: it fails if a covariate is almost constant, and it fails if the fitted probabilities are driven to 0 or 1, since then $w_i = m_i \pi_i (1 - \pi_i) \rightarrow 0$. Of the three statistics of [Proposition 34.5.3](#), the Wald statistic is what software prints, and it is the one the Hauck–Donner effect spoils; the likelihood ratio statistic is invariant and survives an infinite estimate, and the score statistic needs only the null fit.

Example. (Tests and intervals in the voting model)

In [Example \(Voting intention in the 1996 American election\)](#), education has $\hat{\beta} = 0.0147$ with standard error 0.0771; its Wald statistic is 0.036 and so is the likelihood ratio statistic from dropping it, while age has $z = 1.71$ and $p = 0.087$. For the party coefficient the Wald interval is (1.080, 1.358) and the profile likelihood interval (1.086, 1.364): the log-likelihood is nearly quadratic here. [Example \(A separated subgroup\)](#) shows what happens when it is not.

The machinery of Part III survives in weakened form: simultaneous inference uses a quadratic

form in $\mathbf{A}^\top \hat{\boldsymbol{\beta}} - \mathbf{d}$ with matrix $\{\mathbf{A}^\top (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \mathbf{A}\}^{-1}$, referred to $\chi^2(q)$ in place of the F statistic of [Theorem 11.3.2](#). What does *not* survive is exactness. The right measure of how much there is to work with is the total weight $\sum_i m_i \pi_i (1 - \pi_i)$: a study of 500 subjects with twelve events has total weight about 12, the same as a balanced study of fifty, which is the arithmetic behind the events-per-variable rules of thumb in the applied literature.

35.1.6 Exercises

35.1.6.1 A. Check your understanding

Exercise A1.

A logistic model has $\hat{\beta} = 0.7$ for a binary treatment indicator. Give the estimated odds ratio, the divide-by-four bound on the change in probability, and the actual change when the control probability is 0.5, 0.1 and 0.01.

Solution. The odds ratio is $e^{0.7} = 2.014$ and the bound is $0.7/4 = 0.175$. Starting from odds 1, 1/9 and 1/99, the treated odds are 2.014, 0.2238 and 0.02034, so the probabilities become 0.668, 0.183 and 0.0199 and the changes are 0.168, 0.083 and 0.0099. The bound is nearly attained at $\pi = 1/2$ and grossly overstates the change for rare events.

Exercise A2.

Show from [Eq. 35.1.2](#) that a logistic model containing an indicator column for a group reproduces that group's observed proportion exactly. What follows for a model whose covariates are a full set of indicators for a categorical variable?

35.1.6.2 B. Practice

Exercise B1.

In logit $\pi = \beta_0 + \beta_1 x$ with $\beta_1 \neq 0$, the level at which $\pi = 1/2$ is $x_{1/2} = -\beta_0/\beta_1$ (in bioassay, the median effective dose). Derive the delta-method standard error of $\hat{x}_{1/2}$, and explain why it becomes useless as $\hat{\beta}_1$ approaches zero.

Exercise B2.

For grouped data with all m_i large, [Exercise \(B2\)](#) fits $\boldsymbol{\beta}$ by weighted least squares on the empirical logits $\ell_i = \text{logit}(s_i/m_i)$ with weights $m_i \hat{\pi}_i (1 - \hat{\pi}_i)$. Show that one Fisher scoring step of [Proposition 35.1.3](#), started from the fit that reproduces the observed proportions, is exactly that estimate.

Solution. Start from a $\boldsymbol{\beta}$ with $\pi_i = s_i/m_i$, so $\eta_i = \ell_i$. The working residual $(y_i - m_i \pi_i)/\{m_i \pi_i (1 - \pi_i)\}$ vanishes, the working response is $z_i = \ell_i$ and the weights are $m_i \hat{\pi}_i (1 - \hat{\pi}_i)$, so one step returns the weighted least squares fit. The empirical-logit fit is therefore a legitimate starting value; it is undefined when $s_i \in \{0, m_i\}$.

Exercise B3.

Two binary covariates enter with an interaction: $\text{logit } \pi = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2$. Show that β_{12} is the log of a ratio of two odds ratios, and that $\beta_{12} = 0$ does *not* make the effect of x_1 on the probability scale the same at both levels of x_2 .

35.1.6.3 C. Going deeper**Exercise C1.**

Prove that $\ell(\boldsymbol{\beta}) = -\sum_i \log\{1 + \exp(-s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}$, with $s_i = 2y_i - 1$, is concave in $\boldsymbol{\beta}$, without computing the Hessian.

Solution. The map $u \mapsto \log(1 + e^u)$ is convex, since its second derivative $e^u/(1 + e^u)^2$ is positive. A convex function composed with an affine map is convex, so each $\boldsymbol{\beta} \mapsto \log\{1 + \exp(-s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}$ is convex, and a sum of convex functions is convex. Hence ℓ is concave.

35.2 Probit and complementary log-log links

Nothing forces a binary model to use the logit. Any function mapping the real line onto $(0, 1)$ can serve as the response function $\pi = h(\eta)$, and its inverse is then the link. The candidates that survive in practice come with a story about how the binary outcome was produced, because such a story says what the coefficients mean. There are two such stories, and they give the probit and the complementary log-log link.

35.2.1 Thresholds

Definition 35.2.1 — Threshold model

Let $\varepsilon_1, \dots, \varepsilon_n$ be independent with common continuous distribution function F , and let

$$Y_i = \begin{cases} 1, & \varepsilon_i \leq \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \\ 0, & \text{otherwise.} \end{cases}$$

The variable $\mathbf{x}_{(i)}^\top \boldsymbol{\beta} - \varepsilon_i$ is the **latent response**, and Y_i records the sign of it.

Immediately $\pi_i = \Pr(\varepsilon_i \leq \mathbf{x}_{(i)}^\top \boldsymbol{\beta}) = F(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$, so a threshold model *is* a binary regression with response function F and link F^{-1} , and the content lies in which F the situation suggests.

Proposition 35.2.1 — Three links and where they come from

In [Definition 35.2.1](#):

- (a) if F is the standard logistic distribution function $F(u) = e^u/(1 + e^u)$, the model is [Eq. 35.1.1](#); if $F = \Phi$, it is the **probit model** $\Phi^{-1}(\pi_i) = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. Both F are symmetric about zero, so both links satisfy $g(\pi) = -g(1 - \pi)$;
- (b) if $F(u) = 1 - \exp(-e^u)$, the distribution function of the smallest extreme value law, the model is the **complementary log-log** model $\log\{-\log(1 - \pi_i)\} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. This F is not symmetric: π leaves 0 slowly and approaches 1 abruptly. Reflecting it, that is, applying the complementary log-log link to $1 - \pi$ and changing the sign of $\boldsymbol{\beta}$, gives the **log-log** model $-\log\{-\log \pi_i\} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, with the two tails exchanged;
- (c) suppose a positive lifetime T has hazard function $\lambda(t | \mathbf{x}) = \lambda_0(t) \exp(\mathbf{x}^\top \boldsymbol{\gamma})$, and that Y records whether the event has occurred by a fixed time t_0 . Then Y follows a complementary log-log model with linear predictor $\log \Lambda_0(t_0) + \mathbf{x}^\top \boldsymbol{\gamma}$, where Λ_0 is the integrated baseline hazard. Moreover, if g is a continuous strictly increasing link with the property that for every $c > 0$ replacing the hazard λ by $c\lambda$ changes $g(\pi)$ by a quantity $\kappa(c)$ depending on c alone, and not on $\Lambda_0(t_0)$ or $\mathbf{x}$, then g is an increasing affine function of the complementary log-log link.

Proof.

- (a) and (b) are the identity $\pi = F(\eta)$ read backwards, together with the computation $F^{-1}(\pi) = \log\{\pi/(1 - \pi)\}$, $\Phi^{-1}(\pi)$ and $\log\{-\log(1 - \pi)\}$ for the three F . For the reflection in (b), if $1 - \pi = 1 - \exp(-e^{-\eta})$ then $\log\{-\log \pi\} = -\eta$.
- (b) The survivor function of a hazard model is $\Pr(T > t_0 | \mathbf{x}) = \exp\{-\int_0^{t_0} \lambda(u | \mathbf{x}) du\} = \exp\{-\Lambda_0(t_0)e^{\mathbf{x}^\top \boldsymbol{\gamma}}\}$. Hence

$$1 - \pi = \exp(-e^{\log \Lambda_0(t_0) + \mathbf{x}^\top \boldsymbol{\gamma}}),$$

and taking $\log(-\log \cdot)$ of both sides gives the claim. For uniqueness, write $H = \Lambda_0(t_0)e^{\mathbf{x}^\top \boldsymbol{\gamma}}$ for the cumulative hazard and $G(u) = g(1 - e^{-e^u})$ with $u = \log H$, so that u ranges over the whole line as c and the baseline vary. The hypothesis reads $G(u + \log c) = G(u) + \kappa(c)$ for all real u and all $c > 0$, so that $\kappa(v) = G(u + v) - G(u)$ does not depend on u , and hence $\kappa(v + v') = \kappa(v) + \kappa(v')$ for all real v, v' . Continuity of g makes κ continuous, and the only continuous solutions of that additive Cauchy equation are the linear ones, so $\kappa(v) = av$; monotonicity gives $a > 0$. Then $G(u) = G(0) + au$. Undoing the substitution, $g(\pi) = a \log\{-\log(1 - \pi)\} + b$.

■

Part (c) is why the complementary log-log link is standard for binary data derived from times: a “yes” by a fixed follow-up date, a machine failed within a warranty period. Its coefficients are log hazard ratios, whereas logistic coefficients for the same data would be log odds ratios depending on t_0 ([Exercise \(B2\)](#)).

35.2.2 What the latent scale can and cannot tell you

Proposition 35.2.2 — Scale is not identified

In [Definition 35.2.1](#), replace ε_i by $\sigma\varepsilon_i + \tau$ with $\sigma > 0$, and $\boldsymbol{\beta}$ by $\sigma\boldsymbol{\beta} + \tau\mathbf{e}_1$, where $\mathbf{e}_1$ picks out an intercept column. The observed responses have exactly the same distribution. Consequently $\boldsymbol{\beta}$ is identified only up to the location and scale of the latent errors, while ratios β_j/β_k of coefficients of non-intercept covariates are identified.

Proof. The event $\{\sigma\varepsilon_i + \tau \leq \mathbf{x}_{(i)}^\top(\sigma\boldsymbol{\beta} + \tau\mathbf{e}_1)\}$ is $\{\varepsilon_i \leq \mathbf{x}_{(i)}^\top\boldsymbol{\beta}\}$, because the intercept column is identically 1 so $\mathbf{x}_{(i)}^\top\mathbf{e}_1 = 1$ and the τ cancels, after which dividing by σ removes it. The two models therefore give the same π_i for every i . Ratios of non-intercept coefficients are unchanged by the substitution. ■

This is why the probit fixes $\text{Var}(\varepsilon) = 1$ and the logistic model fixes $\text{Var}(\varepsilon) = \pi^2/3$: a convention must be adopted. It is also why probit and logit coefficients are not comparable until one is rescaled. Matching the standard deviations multiplies a probit coefficient by $\pi/\sqrt{3} = 1.8138$; matching the slope at $\pi = 1/2$ instead, where the logistic density is $1/4$ and the normal density is $\phi(0)$, multiplies it by $4\phi(0) = 1.5958$. The conventions differ by about fourteen per cent, a fair measure of how meaningless the comparison is in the tails.

Warning. The latent-variable story tempts one into calling the probit coefficients “the real effects, on the underlying continuous variable”. They are not: the latent variable is not observed and its scale is a convention that [Proposition 35.2.2](#) says the data cannot pin down. What the story buys is a rationale for a particular F .

35.2.3 How much does the choice matter?

Near $\pi = 1/2$ all reasonable links agree, because smooth response curves look alike near their steepest point. They separate in the tails: the logistic tails are exponential, the normal tails decay like $e^{-\eta^2/2}$, and the complementary log-log is not symmetric at all.

Example. (The survey under three links)

Fitting the model of [Example \(Voting intention in the 1996 American election\)](#) with the three links gives the following coefficients of party identification.

link	$\hat{\beta}$	rescaled by 1.8138	maximized log-likelihood
logit	1.219	—	−264.14
probit	0.673	1.221	−265.96
complementary log-log	0.801	—	−273.48

Figure 35.2.1: (a) The three response curves, each rescaled to pass through $(0, 1/2)$ with slope $1/4$; the symmetric ones are close everywhere. (b) Fitted probabilities for the survey of [Example \(Voting intention in the 1996 American election\)](#): the probit differs from the logit by at most 0.03, the complementary log-log by five times as much.

The rescaled probit coefficient reproduces the logistic one to two decimals, and the largest difference between the two sets of fitted probabilities is 0.0305. The complementary log-log fit is a different animal: its fitted probabilities differ from the logistic ones by as much as 0.1596, and with equal numbers of parameters AIC prefers the logit by 18.67. Here the choice between symmetric links is immaterial and the choice of an asymmetric one is not ([Figure 35.2.1](#)).

```
import numpy as np
import pandas as pd
import statsmodels.api as sm

anes = sm.datasets.anes96.load_pandas().data
X = pd.DataFrame({"const": 1.0, "PID": anes["PID"], "age": anes["age"] / 10,
                  "educ": anes["educ"], "income": anes["income"]})
y = anes["vote"]

links = {"logit": sm.families.links.Logit(), "probit": sm.families.links.Probit(),
         "cloglog": sm.families.links.CLogLog()}
fits = {k: sm.GLM(y, X, family=sm.families.Binomial(link=v)).fit() for k, v in links.items()}

table = pd.DataFrame({k: f.params for k, f in fits.items()})
table["probit x 1.814"] = table["probit"] * np.pi / np.sqrt(3)
print(table.round(3).to_string())
print("maximized log-likelihoods:",
      {k: round(f.llf, 2) for k, f in fits.items()})
```

The choice therefore matters when the interesting probabilities are extreme, where the links disagree and few observations settle the disagreement; when a mechanism names the link, as in [Proposition 35.2.1\(c\)](#); and under the retrospective sampling of [Section 35.5](#), where the logit is the only link whose coefficients survive.

35.2.4 Exercises

35.2.4.1 A. Check your understanding

Exercise A1.

Show that the logit and probit links satisfy $g(\pi) = -g(1 - \pi)$ while the complementary log-log link does not. Deduce that for the first two, exchanging the labels 0 and 1 merely reverses the sign of every coefficient, and say what the exchange does under the complementary log-log link.

Solution. For the logit, $\log\{(1 - \pi)/\pi\} = -\log\{\pi/(1 - \pi)\}$; for the probit, $\Phi^{-1}(1 - \pi) = -\Phi^{-1}(\pi)$. Relabelling therefore turns η into $-\eta$, so $\boldsymbol{\beta}$ becomes $-\boldsymbol{\beta}$ and the fit is the same model. For the complementary log-log link, relabelling produces the *log-log* model of Proposition 35.2.1(b): a genuinely different fit.

35.2.4.2 B. Practice

Exercise B1.

Verify that $F(u) = 1 - \exp(-e^u)$ is a distribution function, and that if ε has this law then $E\varepsilon = -\gamma$ and $\text{Var } \varepsilon = \pi^2/6$, where $\gamma = 0.5772$ is Euler's constant. Deduce the factor that makes a complementary log-log coefficient's latent scale comparable with a logistic one.

Solution. F is continuous and increasing with limits 0 and 1. Substituting $v = e^u$ turns $-\varepsilon$ into a standard Gumbel variable, whose mean is γ and whose variance is $\pi^2/6$; reflecting gives the stated moments. The standard deviation is $\pi/\sqrt{6} = 1.2825$ against $\pi/\sqrt{3} = 1.8138$ for the logistic, so the multiplier is $\sqrt{2}$. The location differs too, which shifts the intercept, so only the slopes are comparable.

Exercise B2.

Follow-up is divided into intervals $(t_{k-1}, t_k]$. Let $Y_{ik} = 1$ if subject i has the event in interval k , given that it has not had it before. Show that a proportional hazards model for the underlying continuous time implies $\log\{-\log(1 - \Pr(Y_{ik} = 1))\} = \alpha_k + \mathbf{x}_{(i)}^\top \boldsymbol{\gamma}$ with $\alpha_k = \log\{\Lambda_0(t_k) - \Lambda_0(t_{k-1})\}$, and explain how to fit it with ordinary binary regression software.

35.2.4.3 C. Going deeper

Exercise C1.

Consider the asymmetric family of Aranda-Ordaz (1981), $\pi = 1 - (1 + \alpha e^\eta)^{-1/\alpha}$ for $\alpha > 0$. Show that $\alpha = 1$ gives the logistic response function and $\alpha \rightarrow 0$ the complementary log-log one. Explain how to test $\alpha = 1$ with grouped data, and why the test has little power with ungrouped data.

35.3 Separation

Proposition 35.1.3 says the logistic log-likelihood is strictly concave when the model matrix has full column rank. That guarantees at most one maximum, not at least one, and for binary data the failure is common: it happens whenever some linear combination of the covariates predicts the response perfectly, as in small samples, with rare outcomes, and whenever a categorical covariate has a level with only one outcome in it.

35.3.1 Three configurations

Write $s_i = 2y_i - 1 \in \{-1, 1\}$ for the signed response of an ungrouped binary observation. The logistic log-likelihood is then

$$\ell(\boldsymbol{\beta}) = \sum_{i=1}^n \{y_i \log \pi_i + (1 - y_i) \log(1 - \pi_i)\} = - \sum_{i=1}^n \log \{1 + \exp(-s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}, \quad (35.3.1)$$

because $\pi_i = 1/\{1 + \exp(-\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}$ and $1 - \pi_i$ is the same expression with the sign of the linear predictor reversed. Every term is negative and rises towards zero as $s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ increases, so the whole question is whether some direction raises all of them at once.

Definition 35.3.1 — Separation and overlap

Let $\mathbf{X}$ be $n \times p$ with rows $\mathbf{x}_{(i)}^\top$, and let $s_i = 2y_i - 1$. The data are

- (a) **completely separated** if there is a $\mathbf{b} \neq \mathbf{0}$ with $s_i \mathbf{x}_{(i)}^\top \mathbf{b} > 0$ for every i ;
- (b) **quasi-completely separated** if they are not completely separated but there is a $\mathbf{b} \neq \mathbf{0}$ with $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ for every i ;
- (c) in **overlap** if $\mathbf{b} = \mathbf{0}$ is the only $\mathbf{b}$ with $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ at every observation.

A vector $\mathbf{b}$ of the kind in (a) or (b) is a **separating direction**.

The three cases are mutually exclusive and exhaustive, and a linear programme decides which holds: maximize t over $\mathbf{b}$ in the unit cube subject to $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq t$. A positive optimum is complete separation; an optimum of zero attained only at $\mathbf{b} = \mathbf{0}$ is overlap, and otherwise quasi-complete separation.

35.3.2 Existence

Theorem 35.3.1 — Existence and uniqueness of the maximum likelihood estimate

Let $\text{rank}(\mathbf{X}) = p$ and let ℓ be the logistic log-likelihood of Eq. 35.3.1. Then:

- (a) if the data are completely or quasi-completely separated, ℓ has no maximizer: for

- every β there is a β' with $\ell(\beta') > \ell(\beta)$;
- (b) under complete separation $\sup_{\beta} \ell(\beta) = 0$, and the supremum is approached along any separating ray $\beta = t\mathbf{b}$, $t \rightarrow \infty$, with every fitted probability tending to 0 or 1;
- (c) if the data are in overlap, ℓ attains its supremum at exactly one $\hat{\beta} \in \mathbb{R}^p$, and $\hat{\beta}$ solves Eq. 35.1.2.

Proof.

- (a) Let $\mathbf{b} \neq \mathbf{0}$ satisfy $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ for all i . Not every one of these numbers can be zero: if $\mathbf{x}_{(i)}^\top \mathbf{b} = 0$ for all i then $\mathbf{X}\mathbf{b} = \mathbf{0}$, and $\text{rank}(\mathbf{X}) = p$ forces $\mathbf{b} = \mathbf{0}$. So $s_k \mathbf{x}_{(k)}^\top \mathbf{b} > 0$ for at least one k . Each summand of Eq. 35.3.1 is a strictly decreasing function of $-s_i \mathbf{x}_{(i)}^\top \beta$, hence a nondecreasing function of t along $\beta + t\mathbf{b}$, and the k th is strictly increasing. Therefore $\ell(\beta + \mathbf{b}) > \ell(\beta)$ for every β , and no maximizer exists.
- (b) Under complete separation put $\delta = \min_i s_i \mathbf{x}_{(i)}^\top \mathbf{b} > 0$. Then $\ell(t\mathbf{b}) \geq -n \log(1 + e^{-t\delta}) \rightarrow 0$, while $\ell < 0$ everywhere, so the supremum is 0 and is not attained. Since $s_i \mathbf{x}_{(i)}^\top(t\mathbf{b}) \rightarrow \infty$, the fitted probability π_i tends to 1 when $y_i = 1$ and to 0 when $y_i = 0$.
- (c) First, ℓ is strictly concave. Its Hessian is $-\mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{W} = \text{diag}\{\pi_i(1 - \pi_i)\}$ positive definite (Proposition 35.1.3), and $\mathbf{b}^\top \mathbf{X}^\top \mathbf{W} \mathbf{X} \mathbf{b} = 0$ forces $\mathbf{X}\mathbf{b} = \mathbf{0}$, hence $\mathbf{b} = \mathbf{0}$. Second, ℓ is coercive: $\ell(\beta) \rightarrow -\infty$ as $\|\beta\| \rightarrow \infty$. Suppose not. Then there are β_k with $\|\beta_k\| \rightarrow \infty$ and $\ell(\beta_k) \geq -c$ for some $c < \infty$. Put $\mathbf{b}_k = \beta_k / \|\beta_k\|$; since the unit sphere is compact, a subsequence converges to some $\mathbf{b}$ with $\|\mathbf{b}\| = 1$. If $s_i \mathbf{x}_{(i)}^\top \mathbf{b} < 0$ for some i , then along that subsequence $s_i \mathbf{x}_{(i)}^\top \beta_k = \|\beta_k\| s_i \mathbf{x}_{(i)}^\top \mathbf{b}_k \rightarrow -\infty$, so the i th term of Eq. 35.3.1 tends to $-\infty$; as all the other terms are at most 0, this gives $\ell(\beta_k) \rightarrow -\infty$, a contradiction. Hence $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ for every i with $\mathbf{b} \neq \mathbf{0}$, contradicting overlap. So ℓ is coercive, and the set $\{\beta : \ell(\beta) \geq \ell(\mathbf{0})\}$ is closed and bounded. A continuous function attains its maximum on a compact set, and strict concavity makes the maximizer unique. It is an interior maximum of a differentiable function, so the gradient vanishes there, which is Eq. 35.1.2. ■

Parts (a) and (c) say that **the maximum likelihood estimate exists if and only if the data are in overlap**, a characterization due to Silvapulle (1981) and, in this form, to Albert and Anderson (1984).

Remark (What quasi-complete separation leaves behind). Under quasi-complete separation let $\mathbf{b}$ be a separating direction and $S = \{i : \mathbf{x}_{(i)}^\top \mathbf{b} = 0\}$. Along $\beta + t\mathbf{b}$ the terms outside S tend to zero and those inside do not move, so the supremum of ℓ is that of the subsample S alone, approached with the coefficients along $\mathbf{b}$ running off to infinity while the rest settle down: which is why software reports some coefficients that look sensible alongside others in the tens with standard errors in the millions.

35.3.3 What the computer does

Fisher scoring does not know any of this: given separated data it climbs the ray until it hits the iteration limit or the weights underflow, so the size of the reported coefficients is set by the iteration count, and the standard errors are larger still, because $(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$ explodes as the

weights vanish.

Example. (A separated subgroup)

Of the 944 respondents of [Example \(Voting intention in the 1996 American election\)](#), 13 reported that their schooling stopped at or before the eighth grade. Among them party identification predicts the intended vote perfectly: the ten at 0, 1 or 2 on the party scale all expected to vote Clinton, the three at 4 or 6 all Dole. The direction $\mathbf{b} = (-3, 1)^\top$, the linear predictor party -3 , satisfies $s_i \mathbf{x}_{(i)}^\top \mathbf{b} > 0$ for all thirteen, so the data are completely separated and no maximum likelihood estimate exists.

Asked to fit logit $\pi = \beta_0 + \beta_1 \text{ party}$, software stopped at ten iterations reports $\hat{\beta}_1 = 8.75$ with standard error 29.3; at twenty-five iterations it reports 23.75 with a standard error of order 10^4 . The deviance falls below 10^{-3} after ten steps and below 10^{-9} after twenty-five, and the Wald test is nowhere near significant at either stopping point.

Inference is nevertheless possible, from the likelihood ratio. The profile log-likelihood rises to its supremum of zero, so the set of β_1 not rejected at the five per cent level is the half-line $(0.902, \infty)$: a one-sided interval, correctly reporting that the data bound the effect from below and not from above.

```
import numpy as np
import pandas as pd
import statsmodels.api as sm

anes = sm.datasets.anes96.load_pandas().data
sub = anes[anes["educ"] == 1]                                # schooling stopped at or before
    grade eight
X = sm.add_constant(sub[["PID"]]).to_numpy()
y = sub["vote"].to_numpy()

print(pd.crosstab(sub["PID"], sub["vote"]))
for maxiter in (5, 10, 25, 50):
    f = sm.GLM(y, X, family=sm.families.Binomial()).fit(maxiter=maxiter, tol=1e-16)
    print(f"{maxiter:3d} steps: slope {f.params[1]:10.3f}    standard error {f.bse
        [1]:14.3f}"
        f"    deviance {f.deviance:.2e}")
```

Example. (An empty cell)

Among the 127 respondents with a doctorate, model the vote by party identification as a seven-level factor with the independent-Republican category (PID = 4) as baseline, that being the only middle level with both outcomes present. Three levels have no variation at all, and exactly 3 of the six contrasts run off to infinity. The others behave normally: the contrast for weak Democrats is -3.140 with standard error 0.916. The deviance, 53.808, is well defined, because the diverging coefficients drive their own cells' fitted probabilities to 0 or 1, contributing nothing to it.

35.3.4 Penalized likelihood

The estimate fails to exist because the likelihood has no interior maximum, so every remedy adds something that does; three are in general use. Firth (1993) proposed adding half the log determinant of the Fisher information to the log-likelihood, the log of the Jeffreys prior density, as a way of removing the leading $O(n^{-1})$ bias of the maximum likelihood estimate; that it also cures separation was noticed later, by Heinze and Schemper (2002). The modified score equations take a memorable form.

Proposition 35.3.2 — Firth's modified score

For ungrouped logistic regression with $\text{rank}(\mathbf{X}) = p$, let $\ell^*(\boldsymbol{\beta}) = \ell(\boldsymbol{\beta}) + \frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{W} \mathbf{X})$ with $\mathbf{W} = \text{diag}\{\pi_i(1 - \pi_i)\}$. Let $h_i = \pi_i(1 - \pi_i) \mathbf{x}_{(i)}^\top (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{x}_{(i)}$ be the i th diagonal entry of the weighted hat matrix $\mathbf{W}^{1/2} \mathbf{X} (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}^{1/2}$. Then

$$\frac{\partial \ell^*}{\partial \boldsymbol{\beta}} = \mathbf{X}^\top \left\{ \mathbf{y} - \boldsymbol{\pi} + \mathbf{h} \circ \left(\frac{1}{2} \mathbf{1} - \boldsymbol{\pi} \right) \right\}, \quad (35.3.2)$$

where $\circ$ is the entrywise product. Equivalently, the Firth estimate is a fixed point: it is the ordinary maximum likelihood estimate for pseudo-data in which observation i has $y_i + h_i/2$ successes out of $1 + h_i$ trials, with h_i evaluated at that same estimate. Along any ray $t\mathbf{b}$ that completely separates the data, $\ell^*(t\mathbf{b}) \rightarrow -\infty$.

Proof. Write $F(\boldsymbol{\beta}) = \mathbf{X}^\top \mathbf{W} \mathbf{X}$ and $w_i = \pi_i(1 - \pi_i)$. Since $\partial \pi_i / \partial \beta_j = x_{ij} w_i$ and $dw/d\pi = 1 - 2\pi$,

$$\frac{\partial w_i}{\partial \beta_j} = x_{ij} w_i (1 - 2\pi_i), \quad \frac{\partial F}{\partial \beta_j} = \mathbf{X}^\top \mathbf{D}_j \mathbf{X},$$

with $\mathbf{D}_j = \text{diag}\{x_{ij} w_i (1 - 2\pi_i)\}$. By the derivative of a log determinant,

$$\begin{aligned} \frac{\partial \log \det F}{\partial \beta_j} &= \text{tr}(F^{-1} \mathbf{X}^\top \mathbf{D}_j \mathbf{X}) = \sum_i x_{ij} w_i (1 - 2\pi_i) \mathbf{x}_{(i)}^\top F^{-1} \mathbf{x}_{(i)} \\ &= \sum_i x_{ij} (1 - 2\pi_i) h_i. \end{aligned}$$

Halving and adding the ordinary score $\sum_i x_{ij} (y_i - \pi_i)$ gives Eq. 35.3.2, since $\frac{1}{2}(1 - 2\pi_i) = \frac{1}{2} - \pi_i$. For the pseudo-data statement, the ordinary score for $y_i^* = y_i + h_i/2$ successes out of $m_i^* = 1 + h_i$ trials is $\sum_i x_{ij} (y_i^* - m_i^* \pi_i)$, which is the same expression.

For the last claim, let $\delta = \min_i s_i \mathbf{x}_{(i)}^\top \mathbf{b} > 0$. At $\boldsymbol{\beta} = t\mathbf{b}$ every fitted probability is within $e^{-t\delta}$ of 0 or 1, so $w_i \leq e^{-t\delta}$ and $\mathbf{X}^\top \mathbf{W} \mathbf{X} \preceq e^{-t\delta} \mathbf{X}^\top \mathbf{X}$ in the nonnegative definite order. Hence $\log \det(\mathbf{X}^\top \mathbf{W} \mathbf{X}) \leq -pt\delta + \log \det(\mathbf{X}^\top \mathbf{X})$, while $\ell \leq 0$. Therefore $\ell^*(t\mathbf{b}) \leq -\frac{1}{2}pt\delta + \text{constant} \rightarrow -\infty$. ■

The penalty pulls the estimate towards zero exactly where the likelihood is flat: along the offending ray it falls linearly while the likelihood has nothing left to gain. That the Firth estimate is finite for *every* configuration with $\text{rank}(\mathbf{X}) = p$ was proved by Kosmidis and Firth (2021), by a longer argument.

Figure 35.3.1: Profile log-likelihoods for the slope in [Example \(A separated subgroup\)](#), each relative to its own supremum. The ordinary profile (solid) increases to zero and is never attained, so the interval cut out by the horizontal line at $-\chi^2_{0.95}(1)/2$ is a half-line. Firth's penalized profile (dashed) has an interior maximum, marked by the vertical line.

Example. (The separated subgroup, penalized)

Applied to [Example \(A separated subgroup\)](#), Firth's method gives $\hat{\beta}_1 = 1.362$ with standard error 0.708 and intercept -4.049 . The Wald statistic is 1.92, short of the conventional threshold, but the interval from inverting the *penalized* likelihood ratio is (0.364, 4.045), which excludes zero comfortably. With thirteen observations and a log-likelihood as asymmetric as [Figure 35.3.1](#) shows, the quadratic approximation behind the Wald statistic is simply not available.

```
def firth(X, y, steps=200):
    """Maximize the log-likelihood penalized by (1/2) log det(X'WX): Firth's
    estimate."""
    beta = np.zeros(X.shape[1])
    for _ in range(steps):
        mu = 1 / (1 + np.exp(-X @ beta))
        w = mu * (1 - mu)
        F = X.T @ (w[:, None] * X)                # the expected
        information
        h = w * np.einsum("ij,jk,ik->i", X, np.linalg.inv(F), X)
        beta = beta + np.linalg.solve(F, X.T @ (y - mu + h * (0.5 - mu)))
    return beta

beta_firth = firth(X, y)
print("Firth estimate:", beta_firth.round(3))
```

35.3.5 Ridge and Cauchy priors

A quadratic penalty works too, for a simpler reason. Maximizing $\ell(\boldsymbol{\beta}) - \frac{1}{2}\lambda\|\boldsymbol{\beta}\|^2$ is the logistic analogue of ridge regression ([Definition 27.2.1](#)), and the objective is strictly concave and coercive

whatever the data, so a unique maximizer always exists ([Exercise \(B1\)](#)). It is the posterior mode under independent $N(0, \lambda^{-1})$ priors, which is how [Chapter 30](#) reads every penalty in [Proposition 30.1.4](#). In practice, and in the code below, the intercept is left out of the penalty, so that the prior reading is a flat one there; the maximizer still exists, provided both outcomes occur ([Exercise \(B1\)](#)). The cost is bias towards zero that depends on the scale of the covariates, and a λ that must come from somewhere, usually cross-validation ([Chapter 29](#)).

```
def ridge_logistic(X, y, lam, steps=200):
    """Maximize the log-likelihood minus (lam/2) times the squared norm of the
    slopes."""
    d = np.ones(X.shape[1])
    d[0] = 0.0                                     # leave the intercept
    unpenalized
    beta = np.zeros(X.shape[1])
    for _ in range(steps):
        mu = 1 / (1 + np.exp(-X @ beta))
        w = mu * (1 - mu)
        H = X.T @ (w[:, None] * X) + lam * np.diag(d)
        beta = beta + np.linalg.solve(H, X.T @ (y - mu) - lam * d * beta)
    return beta

for lam in (0.1, 1.0, 10.0):
    print(f"ridge, lambda = {lam:4.1f}: {ridge_logistic(X, y, lam).round(3)}")
```

On the separated subgroup the ridge estimate of the slope is 2.601 at $\lambda = 0.1$, 1.356 at $\lambda = 1$ and 0.502 at $\lambda = 10$: the whole range is “the answer” for some penalty, which is the point. Gelman, Jakulin, Pittau and Su (2008) proposed instead independent Cauchy priors of scale 2.5 on standardized covariates, whose heavy tails leave a genuinely large coefficient nearly alone. Firth’s penalty alone is invariant to how the covariates are parameterized.

35.3.6 Exact conditional inference

A third route abandons the normal approximation. The sufficient statistic for β is $\mathbf{X}^\top \mathbf{y}$, by [Lemma 7.4.1](#) applied to [Eq. 35.3.1](#), so the conditional distribution of the component belonging to one coefficient, given the rest, depends on that coefficient alone. Enumerating it gives exact p -values and a median-unbiased estimate that is finite even under separation. The idea is Cox’s (1970) and the network algorithms are those of Hirji, Mehta and Patel (1987); the limit is computational.

Idea. Separation is not a defect of the data; it is the data saying that the effect is larger than the sample can measure, and every remedy decides how much larger. A one-sided likelihood ratio interval is the most honest of them, because it does not decide.

35.3.7 Exercises

35.3.7.1 A. Check your understanding

Exercise A1.

A model contains an indicator for one level of a categorical covariate, and every observation at that level has $y_i = 1$. Exhibit a separating direction, say which of the three cases of [Definition 35.3.1](#) holds, and describe the fit.

Solution. Let $\mathbf{b}$ have 1 in the coordinate of that indicator and zeros elsewhere. For observations at that level $s_i \mathbf{x}_{(i)}^\top \mathbf{b} = +1 > 0$; for the others $\mathbf{x}_{(i)}^\top \mathbf{b} = 0$. So $\mathbf{b}$ separates with some margins zero: quasi-complete separation, unless the remaining data are themselves completely separated. The coefficient of that indicator diverges, its fitted probabilities go to 1, and the other coefficients converge to the estimates from the remaining observations.

35.3.7.2 B. Practice**Exercise B1.**

Show that for any data and any $\lambda > 0$ the function $\boldsymbol{\beta} \mapsto \ell(\boldsymbol{\beta}) - \frac{1}{2}\lambda\|\boldsymbol{\beta}\|^2$ has exactly one maximizer, without assuming $\text{rank}(\mathbf{X}) = p$. Show also that if $\text{rank}(\mathbf{X}) = p$ and both outcomes occur the same is true when the intercept is left unpenalized.

Solution. By [Eq. 35.3.1](#), $\ell \leq 0$, so the objective is at most $-\frac{1}{2}\lambda\|\boldsymbol{\beta}\|^2$, which tends to $-\infty$: the objective is coercive and continuous, so it attains its maximum on a compact sublevel set. It is the sum of the concave ℓ ([Exercise C1](#)) and a strictly concave quadratic, hence strictly concave, so the maximizer is unique. Neither step used the rank of $\mathbf{X}$. With the intercept β_0 unpenalized, write $\boldsymbol{\gamma}$ for the slopes. If $\|\boldsymbol{\gamma}\| \rightarrow \infty$ the penalty alone sends the objective to $-\infty$, since $\ell \leq 0$; if $\boldsymbol{\gamma}$ stays bounded and $|\beta_0| \rightarrow \infty$, then some observation has $s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta} \rightarrow -\infty$, because an observation with $y_i = 1$ supplies one as $\beta_0 \rightarrow -\infty$ and one with $y_i = 0$ as $\beta_0 \rightarrow +\infty$. So the objective is again coercive, and strict concavity now comes from ℓ itself.

Exercise B2.

Take a 2×2 table with a single binary covariate, coded as an intercept and an indicator. Compute the h_i of [Proposition 35.3.2](#), and show that Firth's pseudo-data amount to adding $\frac{1}{2}$ to each of the four cell counts. What is the resulting estimate of the log odds ratio?

Exercise B3.

For a single binary covariate with fitted probabilities $\hat{\pi}_1$ and $\hat{\pi}_0$ in groups of sizes m_1 and m_0 , show that as $\hat{\pi}_1 \rightarrow 1$, with everything else fixed, the Wald statistic tends to zero while the likelihood ratio statistic increases to a positive limit.

35.3.7.3 C. Going deeper**Exercise C1.**

Suppose the rows $\mathbf{x}_{(i)}$ are independent draws from a distribution symmetric about the

origin in $\mathbb{R}^p$ and the responses are independent coin flips. Cover's counting argument gives the probability of complete separation as $2^{1-n} \sum_{k=0}^{p-1} \binom{n-1}{k}$. Deduce that separation is almost certain when $n < 2p$ and almost impossible when $n \gg 2p$, and relate this to [Chapter 28](#).

Solution. The sum is $\Pr\{B \leq p-1\}$ with $B \sim \text{Binomial}(n-1, \frac{1}{2})$, so with $E B = (n-1)/2$ it is near 1 when $p-1$ exceeds $(n-1)/2$, roughly $n < 2p$, and near 0 when p is well below $n/2$, the transition having width of order $\sqrt{n}$. So with pure noise maximum likelihood fails to exist below about $n = 2p$: twice the sample size at which least squares begins to interpolate in [Chapter 28](#). Both thresholds mark the point past which an unpenalized fit reproduces the labels exactly, and both are why penalization is the default in high dimensions.

35.4 Goodness of fit

In the normal linear model the residual sum of squares both estimates σ^2 and measures fit, and its known distribution makes a fit too poor to be chance announce itself ([Chapter 14](#)). Binary data have no free dispersion parameter, so the deviance has only the second role, and often cannot fill it either.

35.4.1 Two statistics for grouped data

Definition 35.4.1 — Pearson and deviance statistics

For grouped binomial data $y_i \sim \text{Binomial}(m_i, \pi_i)$, $i = 1, \dots, N$, with fitted probabilities $\hat{\pi}_i$ from a model with p parameters, the **Pearson statistic** and the **deviance** are

$$\begin{aligned} X^2 &= \sum_{i=1}^N \frac{(y_i - m_i \hat{\pi}_i)^2}{m_i \hat{\pi}_i (1 - \hat{\pi}_i)}, \\ D &= 2 \sum_{i=1}^N \left\{ y_i \log \frac{y_i}{m_i \hat{\pi}_i} + (m_i - y_i) \log \frac{m_i - y_i}{m_i - m_i \hat{\pi}_i} \right\}, \end{aligned} \tag{35.4.1}$$

with the convention $0 \log 0 = 0$. Both compare the fit with the **saturated** model that gives each group its own probability.

X^2 is the sum over all $2N$ cells of successes and failures of $(\text{observed} - \text{fitted})^2 / \text{fitted}$, and D is twice the sum of $\text{observed} \times \log(\text{observed}/\text{fitted})$: the classical categorical-data statistics, specialized to the binomial.

Proposition 35.4.1 — What the two statistics measure

- (a) (*Grouped data.*) Fix N and the model, let $m_i \rightarrow \infty$ for every i with π_i bounded away from 0 and 1, and suppose the model holds. Then X^2 and D both converge

in distribution to $\chi^2(N - p)$, and $X^2 - D \rightarrow 0$ in probability.

- (b) (*Ungrouped data, canonical link.*) If $m_i = 1$ for every i and $\hat{\beta}$ solves the logistic likelihood equations Eq. 35.1.2, then

$$D = -2 \sum_{i=1}^n \{ \hat{\pi}_i \log \hat{\pi}_i + (1 - \hat{\pi}_i) \log(1 - \hat{\pi}_i) \}. \quad (35.4.2)$$

The deviance is therefore a function of the fitted probabilities alone: it does not depend on which observations were successes, it is bounded above by $2n \log 2$, and it has no $\chi^2(n - p)$ limit.

- (c) (*Differences.*) For nested models $\omega \subset \Omega$ with q parameters between them, $D_\omega - D_\Omega$ does not depend on the grouping and converges to $\chi^2(q)$ under the smaller model, grouped or not.

Proof.

- (a) The statement about D is Theorem 34.5.5 specialized to the binomial family: with N fixed and every $m_i \rightarrow \infty$, the model is a smooth submodel of an N -parameter family whose maximum likelihood estimates are asymptotically normal, so the likelihood ratio statistic against the saturated model has $N - p$ degrees of freedom. For X^2 , put $b = m_i \hat{\pi}_i$ and $r_i = (y_i - b) / \{m_i \hat{\pi}_i (1 - \hat{\pi}_i)\}^{1/2}$, so that $r_i = O_p(1)$ and $y_i - b = O_p(m_i^{1/2})$. The i th deviance summand is $g(y_i)$ for $g(a) = 2\{a \log(a/b) + (m_i - a) \log((m_i - a)/(m_i - b))\}$, and $g(b) = g'(b) = 0$ and $g''(b) = 2/\{m_i \hat{\pi}_i (1 - \hat{\pi}_i)\}$, while the third derivative is $O(m_i^{-2})$ near that point. Taylor's theorem therefore gives $g(y_i) = r_i^2 + O_p(m_i^{-1/2})$, using $\hat{\pi}_i$ bounded away from 0 and 1. Summing over the N fixed groups, $D - X^2 \rightarrow 0$ in probability, so X^2 has the same limit as D .
- (b) Write $\hat{\eta}_i = \mathbf{x}_{(i)}^\top \hat{\beta}$, so that $\hat{\eta}_i = \log \hat{\pi}_i - \log(1 - \hat{\pi}_i)$. For ungrouped data the saturated model sets $\hat{\pi}_i = y_i$ and has log-likelihood zero, so

$$\begin{aligned} D &= -2 \sum_i \{ y_i \log \hat{\pi}_i + (1 - y_i) \log(1 - \hat{\pi}_i) \} \\ &= -2 \sum_i \{ y_i \hat{\eta}_i + \log(1 - \hat{\pi}_i) \} \\ &= -2 \left\{ \hat{\beta}^\top \mathbf{X}^\top \mathbf{y} + \sum_i \log(1 - \hat{\pi}_i) \right\}. \end{aligned}$$

The likelihood equations say $\mathbf{X}^\top \mathbf{y} = \mathbf{X}^\top \hat{\pi}$, so $\mathbf{X}^\top \mathbf{y}$ may be replaced by $\mathbf{X}^\top \hat{\pi}$, giving $D = -2 \sum_i \{ \hat{\pi}_i \hat{\eta}_i + \log(1 - \hat{\pi}_i) \}$, which is Eq. 35.4.2 after substituting for $\hat{\eta}_i$. Each summand of Eq. 35.4.2 is at most $2 \log 2$, attained at $\hat{\pi}_i = 1/2$, which gives the bound. For the last claim write $H(\pi) = -\{\pi \log \pi + (1 - \pi) \log(1 - \pi)\}$ and $f_n(\beta) = 2 \sum_i H(\pi_i)$ with $\pi_i = \pi_i(\beta)$, so that $D = f_n(\hat{\beta})$ identically: D is a smooth deterministic function of $\hat{\beta}$, with no other dependence on the data. Now $dH/d\eta = -\eta \pi(1 - \pi)$, and $\pi(1 - \pi) \leq e^{-|\eta|}$, so $|dH/d\eta| \leq |\eta| e^{-|\eta|} \leq e^{-1}$ and $\|\nabla f_n\| \leq 2e^{-1} \sum_i \|\mathbf{x}_{(i)}\| = O(n)$ for bounded covariates. With $\hat{\beta} - \beta = O_p(n^{-1/2})$ from Theorem 34.5.1, the mean value theorem gives $D - f_n(\beta) = O_p(n^{1/2})$, so

$$n^{-1} D - 2n^{-1} \sum_{i=1}^n H(\pi_i) \rightarrow 0 \text{ in probability,}$$

whereas $n^{-1} \chi^2(n - p) \rightarrow 1$. The two agree only by accident: the simulation of

Example (Three deviances that mean nothing) has $n^{-1}D$ averaging $206.8/200 = 1.03$ under one correct model and $263.6/200 = 1.32$ under another. So D has no $\chi^2(n-p)$ limit. The same bound leaves D fluctuating about $f_n(\beta)$ by $O_p(n^{1/2})$, which is the order of the standard deviations in Example (Three deviances that mean nothing); what fails is not the spread of D but its location.

- (c) The saturated log-likelihood is common to both deviances and cancels, so the difference is twice a log-likelihood ratio between two nested smooth models with q free parameters between them, and Theorem 34.5.5 applies with q fixed.

■

Example. (Is the party scale linear on the logit scale?)

Collapse the survey of Example (Voting intention in the 1996 American election) onto its seven party groups, of between 37 and 200 respondents each, and fit logit $\pi = \beta_0 + \beta_1 \text{ party}$. The deviance is 12.765 on 5 degrees of freedom ($p = 0.0257$) and the Pearson statistic is 11.899 ($p = 0.0362$). The Pearson residuals locate the misfit: -2.067 at “independent-Democrat”, where the model predicts 0.132 against an observed 0.065, and 2.122 at “independent-Republican”, where it predicts 0.640 against 0.745. The transition across the middle of the scale is sharper than a straight line in the log odds allows, and a quadratic term does not help: the deviance falls only to 12.762, so the misfit is a step, not a curve.

```
import numpy as np
import pandas as pd
import statsmodels.api as sm
from scipy import stats

anes = sm.datasets.anes96.load_pandas().data
cells = anes.groupby("PID")["vote"].agg(["sum", "count"]).reset_index()
counts = np.column_stack([cells["sum"], cells["count"] - cells["sum"]])
Xg = sm.add_constant(cells[["PID"]])

g = sm.GLM(counts, Xg, family=sm.families.Binomial()).fit()
print(cells.to_string(index=False))
print(f"deviance {g.deviance:.3f} on {g.df_resid} df, p = {stats.chi2.sf(g.deviance,
    g.df_resid):.4f}")
print(f"Pearson {g.pearson_chi2:.3f} on {g.df_resid} df, "
    f"p = {stats.chi2.sf(g.pearson_chi2, g.df_resid):.4f}")
```

The conditions in part (a) are not decoration. If N grows with n instead, as it does whenever a continuous covariate is in the model, the approximation fails, worst of all in the extreme case $m_i \equiv 1$ of part (b).

35.4.2 The ungrouped deviance measures nothing

Eq. 35.4.2 deserves to be read twice. The left-hand side looks like a discrepancy between data and fit; the right-hand side contains no data at all. It is twice the total Bernoulli entropy of the fitted probabilities, a measure of how *undecided* the model is: probabilities near $1/2$ give a deviance near $2n \log 2$ and extreme ones give a small deviance, whether or not the model is

correct.

Example. (Three deviances that mean nothing)

Simulate $n = 200$ observations with one covariate and an intercept in three ways: a correct model with a strong slope, a correct model with a weak slope, and a model that leaves a genuine quadratic effect out of the fitted predictor. All three fit two parameters, so $n - p = 198$ and a chi-squared reference would have mean 198 and standard deviation 19.9. Over 2000 replications:

data-generating mechanism	mean deviance	standard deviation
correct, strong slope	206.8	14.3
correct, weak slope	263.6	7.0
quadratic omitted	252.2	8.5

Two *correct* models with the same n and p differ by nearly sixty in mean deviance, and the badly misspecified model has a *smaller* deviance than one of them: no reference distribution can serve all three (Figure 35.4.1).

The survey model of [Example \(Voting intention in the 1996 American election\)](#) has ungrouped deviance 528.29 on 939 degrees of freedom; dropping every covariate but education gives an obviously wrong model with deviance 1275.16 on 942. Neither number can be referred to a table.

```
# the ungrouped deviance is a function of the fitted probabilities alone
X = pd.DataFrame({"const": 1.0, "PID": anes["PID"], "age": anes["age"] / 10,
                  "educ": anes["educ"], "income": anes["income"]})
y = anes["vote"].to_numpy()
fit = sm.GLM(y, X, family=sm.families.Binomial()).fit()
p = fit.fittedvalues.to_numpy()

entropy = -2 * np.sum(p * np.log(p) + (1 - p) * np.log(1 - p))
print("deviance reported ", round(fit.deviance, 6))
print("entropy of the fit ", round(entropy, 6))
```

```
def deviance_null(n, B, seed=0):
    """Ungrouped deviances under three data-generating mechanisms: a correct model
    with a
    strong slope, a correct model with a weak slope, and a model that omits a real
    quadratic
    effect. All three fit an intercept and one slope to n observations."""
    rng = np.random.default_rng(seed)
    out = np.empty((B, 3))
    for b in range(B):
        x = rng.normal(size=n)
        Z = np.column_stack([np.ones(n), x])
        for j, eta in enumerate([0.4 + 1.5 * x, 0.4 + 0.3 * x, 0.4 + 1.5 * x - 1.8 *
                                x ** 2]):
            yb = (rng.random(n) < 1 / (1 + np.exp(-eta))).astype(float)
            out[b, j] = sm.GLM(yb, Z, family=sm.families.Binomial()).fit().deviance
    return out
```

Figure 35.4.1: (a) Simulated null distributions of the ungrouped deviance with $n = 200$ and two fitted parameters, under the three mechanisms of [Example \(Three deviances that mean nothing\)](#), against the $\chi^2(198)$ density. (b) Cross-validated calibration of the survey model in ten bins, with pointwise intervals. (c) ROC curves for the four-regressor model and for party identification alone.

```
demo = deviance_null(200, 100, seed=1)
print("n = 200 and p = 2, so a chi-squared reference would have mean 198 and "
      f"standard deviation {np.sqrt(2 * 198):.1f}")

                           "quadratic omitted "]):
    print(f"{label}: mean {demo[:, j].mean():6.1f}, "
          f"standard deviation {demo[:, j].std():4.1f}")
```

The Pearson statistic escapes [Eq. 35.4.2](#), since $X^2 = \sum_i \{y_i/\hat{\pi}_i + (1 - y_i)/(1 - \hat{\pi}_i)\} - n$ does depend on $\mathbf{y}$, but gains nothing by it ([Exercise \(B1\)](#)). What survives is part (c): for ungrouped data, test the model against enlargements of it rather than against the saturated alternative, and use AIC or cross-validation ([Chapter 29](#)) when the comparisons are not nested.

35.4.3 Grouping by fitted values

Hosmer and Lemeshow (1980) proposed making grouped data out of ungrouped: sort by $\hat{\pi}_i$, cut into G groups of roughly equal size, and compare

$$\hat{C} = \sum_{k=1}^G \frac{(O_k - E_k)^2}{E_k(1 - E_k/n_k)}, \quad O_k = \sum_{i \in k} y_i, \quad E_k = \sum_{i \in k} \hat{\pi}_i,$$

referred to $\chi^2(G - 2)$. The reference distribution has no proof behind it: it was established by simulation, and the two lost degrees of freedom are an empirical finding. The statistic is a useful descriptive check and an unstable test.

Example. (The same model, three verdicts)

For the four-regressor model of [Example \(Voting intention in the 1996 American election\)](#):

groups G	$\hat{C}$	p
8	8.670	0.193
10	12.232	0.141
12	16.119	0.096

The p -value halves as G goes from 8 to 12, and different software makes different choices about G , about how to break ties in $\hat{\pi}_i$, and about whether to use equal-sized groups or equally spaced cut-points. None of these choices is more principled than any other.

```
def hosmer_lemeshow(y, p, groups):
    """The Hosmer-Lemeshow statistic and its nominal p-value with the given number
    of groups."""
    order = np.argsort(p)
    chunks = np.array_split(order, groups)
    stat = 0.0
    for c in chunks:
        e = p[c].sum()
        stat += (y[c].sum() - e) ** 2 / (e * (1 - e / len(c)))
    return stat, stats.chi2.sf(stat, groups - 2)

for gr in (8, 10, 12):
    stat, pv = hosmer_lemeshow(y, p, gr)
    print(f"{gr:2d} groups: statistic {stat:6.3f}, p = {pv:.3f}")
```

35.4.4 Calibration and discrimination

Two questions hide inside “does the model fit”. **Calibration** asks whether the fitted probabilities are right: among observations with $\hat{\pi}_i \approx 0.3$, do about thirty per cent have $y_i = 1$? **Discrimination** asks whether they order the observations correctly, and a model can have either without the other. Classification tables of sensitivity against specificity answer a third question, and depend on a threshold and on a loss they rarely state; pseudo- R^2 measures such as $1 - D/D_{\text{null}}$ have no interpretation of their own, and by Proposition 35.4.1(b) the ungrouped version of that ratio is a ratio of entropies.

Proposition 35.4.2 — In-sample calibration is automatic

Let $\hat{\beta}$ solve Eq. 35.1.2 with $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, let $\hat{\eta}_i = \mathbf{x}_{(i)}^\top \hat{\beta}$, and suppose $\hat{\eta}$ is not constant. Fit the two-parameter logistic model $\text{logit } \pi_i = a + b\hat{\eta}_i$ to the same responses. Then $\hat{a} = 0$ and $\hat{b} = 1$ exactly.

Proof. The likelihood equations of the two-parameter model at $(a, b) = (0, 1)$ are $\sum_i (y_i - \hat{\pi}_i) = 0$ and $\sum_i \hat{\eta}_i (y_i - \hat{\pi}_i) = 0$. The first holds because $\mathbf{1} \in \mathcal{C}(\mathbf{X})$ and $\mathbf{X}^\top (\mathbf{y} - \hat{\boldsymbol{\pi}}) = \mathbf{0}$; the second because $\hat{\boldsymbol{\eta}} = \mathbf{X}\hat{\boldsymbol{\beta}} \in \mathcal{C}(\mathbf{X})$, so $\hat{\boldsymbol{\eta}}^\top (\mathbf{y} - \hat{\boldsymbol{\pi}}) = \hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top (\mathbf{y} - \hat{\boldsymbol{\pi}}) = 0$. So $(0, 1)$ solves the two-parameter likelihood equations; it remains to see that a maximizer exists. The design $[\mathbf{1}, \hat{\boldsymbol{\eta}}]$ has rank two, since $\hat{\eta}$ is not constant. Suppose some $(a, b) \neq (0, 1)$ had $s_i(a + b\hat{\eta}_i) \geq 0$ for every i . As $\mathbf{1} \in \mathcal{C}(\mathbf{X})$ there is an $\mathbf{e}$ with $\mathbf{X}\mathbf{e} = \mathbf{1}$, and $\mathbf{b}^* = a\mathbf{e} + b\hat{\boldsymbol{\beta}}$ satisfies $\mathbf{X}\mathbf{b}^* = a\mathbf{1} + b\hat{\boldsymbol{\eta}} \neq \mathbf{0}$, so $\mathbf{b}^* \neq \mathbf{0}$ separates $\mathbf{X}$ — contradicting the overlap that the

finiteness of $\hat{\beta}$ guarantees (Theorem 35.3.1). The two-parameter data are therefore in overlap, and Theorem 35.3.1(c) gives a unique maximizer, which must be the stationary point $(0, 1)$. ■

The **calibration slope** $\hat{b}$ is therefore worthless on the data that produced $\hat{\beta}$. It becomes informative when $\hat{\eta}$ comes from a held-out fold or a new sample, where $\hat{b} < 1$ is the signature of overfitting. On the survey model of Example (Voting intention in the 1996 American election), ten-fold cross-validated predictions give a slope of 0.983 and an intercept of 0.005: four regressors and 944 observations is not a regime in which overfitting bites.

Proposition 35.4.3 — What the area under the ROC curve is, and is not

Let $\hat{s}_i$ be any scores, let I be a uniformly chosen index with $y_I = 1$ and J an independent uniformly chosen index with $y_J = 0$. The area under the curve traced by (false positive rate, true positive rate) as a threshold moves through the scores equals

$$\text{AUC} = \Pr(\hat{s}_I > \hat{s}_J) + \frac{1}{2} \Pr(\hat{s}_I = \hat{s}_J),$$

the normalized Mann–Whitney statistic. Consequently the AUC depends on the scores only through their ranks, so it is unchanged by every strictly increasing transformation of $\hat{s}$, and in particular it says nothing whatever about calibration.

Proof. Order the distinct score values downwards. Moving the threshold past one of them advances the curve by the fraction ΔFPR of controls and the fraction ΔTPR of cases at that value, adding the trapezoid $\Delta\text{FPR}\{\text{TPR} + \frac{1}{2}\Delta\text{TPR}\}$. Summing, the first part counts pairs with $\hat{s}_I > \hat{s}_J$ and the second counts ties with weight $\frac{1}{2}$, each divided by $n_1 n_0$. Invariance is immediate, since an increasing transformation preserves every comparison $\hat{s}_I > \hat{s}_J$. ■

So a model whose probabilities are all wrong by a factor of ten has the same AUC as the correctly calibrated model with the same ordering. The AUC is insensitive in the other direction too: for Example (Voting intention in the 1996 American election) party identification alone gives $\text{AUC} = 0.942$, and adding age, education and income raises it to 0.944. An increment of 0.002 in a rank-based summary is the wrong scale on which to judge the three covariates.

35.4.5 Residuals and influence

The diagnostics of Chapter 20 carry over, with the working weights as the metric.

Definition 35.4.2 — Residuals for binomial data

With $\hat{w}_i = m_i \hat{\pi}_i (1 - \hat{\pi}_i)$, $\hat{\mathbf{W}} = \text{diag}(\hat{w}_i)$ and $\hat{h}_i$ the i th diagonal entry of $\hat{\mathbf{W}}^{1/2} \mathbf{X} (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \mathbf{X}^\top \hat{\mathbf{W}}^{1/2}$,

the **Pearson** and **deviance** residuals are

$$r_i = \frac{y_i - m_i \hat{\pi}_i}{\sqrt{\hat{w}_i}}, \quad d_i = \text{sign}(y_i - m_i \hat{\pi}_i) \sqrt{D_i},$$

where D_i is the i th summand of the deviance in [Eq. 35.4.1](#). Their **standardized** forms divide by $(1 - \hat{h}_i)^{1/2}$.

By construction $\sum_i r_i^2 = X^2$ and $\sum_i d_i^2 = D$. The matrix in the definition is the hat matrix of the last weighted least squares step of [Proposition 35.1.3](#), so it is symmetric and idempotent with trace $\text{rank}(\mathbf{X})$, and [Section 6.8](#) applies to it unchanged. The analogue of Cook's distance ([Definition 20.4.1](#)) is $r_i^2 \hat{h}_i / \{p(1 - \hat{h}_i)^2\}$.

Two things change. For ungrouped data r_i takes only two values once $\hat{\pi}_i$ is given, so plots against a covariate show two curves rather than a cloud and must be smoothed or binned. And $\hat{h}_i$ carries the factor $\hat{w}_i$, so high leverage now means a covariate vector that is extreme *and* a fitted probability near 1/2; a point whose outcome the model regards as certain has low leverage wherever its covariates lie, the opposite of the linear-model intuition.

35.4.6 Exercises

35.4.6.1 A. Check your understanding

Exercise A1.

Use [Eq. 35.4.2](#) to find the largest and smallest possible values of the ungrouped deviance of a logistic fit, and describe the fits that attain them.

Solution. Each summand $-2\{\hat{\pi} \log \hat{\pi} + (1 - \hat{\pi}) \log(1 - \hat{\pi})\}$ lies in $[0, 2 \log 2]$, so $0 \leq D \leq 2n \log 2$. The upper bound is attained when every $\hat{\pi}_i = 1/2$, as for the intercept-only model fitted to equal numbers of successes and failures. The lower bound is approached only as the fitted probabilities go to 0 and 1, which by [Theorem 35.3.1](#) needs complete separation, so 0 is an infimum and not a minimum.

35.4.6.2 B. Practice

Exercise B1.

Show that for ungrouped data $X^2 = \sum_i \{y_i / \hat{\pi}_i + (1 - y_i) / (1 - \hat{\pi}_i)\} - n$, and deduce that for the intercept-only model $X^2 = n$ exactly, whatever the data. What does that say about X^2 as a test of fit?

Solution. With $m_i = 1$, $(y_i - \hat{\pi}_i)^2 / \{\hat{\pi}_i(1 - \hat{\pi}_i)\}$ equals $(1 - \hat{\pi}_i) / \hat{\pi}_i$ when $y_i = 1$ and $\hat{\pi}_i / (1 - \hat{\pi}_i)$ when $y_i = 0$, and both equal $y_i / \hat{\pi}_i + (1 - y_i) / (1 - \hat{\pi}_i) - 1$; summing gives the identity. For the intercept-only model $\hat{\pi}_i = \bar{y}$ for every i , so $X^2 = n\bar{y}/\bar{y} + n(1 - \bar{y})/(1 - \bar{y}) - n = n$. A statistic that equals the sample size for every data set cannot test anything.

Exercise B2.

Let $\hat{\eta}$ be fitted on one sample and evaluated on an independent sample from the same population. Show that the calibration slope b has probability limit 1 if the model is correct and $\hat{\beta}$ is consistent, and explain why a value below one indicates overfitting.

Exercise B3.

Suppose the covariate is $N(\mu_1, 1)$ among cases and $N(\mu_0, 1)$ among controls. Compute the AUC of the correctly specified logistic model in terms of $\Delta = \mu_1 - \mu_0$, and find the Δ needed for an AUC of 0.9.

Solution. The fitted score is monotone in the covariate, so the AUC is $\Pr(X_1 > X_0) = \Phi(\Delta/\sqrt{2})$, since $X_1 - X_0 \sim N(\Delta, 2)$. Setting this to 0.9 gives $\Delta = \sqrt{2} \Phi^{-1}(0.9) = 1.812$. An AUC of 0.65 needs only $\Delta \approx 0.55$, a difference highly significant in a large sample yet nearly useless for classifying an individual.

35.5 Case-control sampling

A rare disease affects one person in a thousand, so a prospective study hoping to see a hundred cases must follow a hundred thousand people, most of whom carry almost none of the weight $\pi_i(1 - \pi_i)$. The economy is to go looking for the cases. In a **retrospective**, or **case-control**, design the response decides who enters the sample and the covariates are observed afterwards. This inverts the conditioning, and one might expect nothing to be estimable. In fact, for the logit link and no other, almost everything is.

35.5.1 Only the intercept moves

Theorem 35.5.1 — Retrospective sampling under a logistic model

Let $(\mathbf{X}, Y)$ follow $\text{logit } \Pr(Y = 1 \mid \mathbf{X} = \mathbf{x}) = \alpha + \mathbf{x}^\top \boldsymbol{\beta}$ in the population, and let $S \in \{0, 1\}$ indicate inclusion in the sample, with

$$\Pr(S = 1 \mid Y = y, \mathbf{X} = \mathbf{x}) = \rho_y \in (0, 1], \quad y = 0, 1,$$

depending on y but not on $\mathbf{x}$. Then:

- $\text{logit } \Pr(Y = 1 \mid \mathbf{X} = \mathbf{x}, S = 1) = \alpha + \log(\rho_1/\rho_0) + \mathbf{x}^\top \boldsymbol{\beta}$. The slopes are unchanged; only the intercept moves, and it moves by a constant that does not involve $\mathbf{x}$;
- let F be a continuous strictly increasing distribution function, suppose $\Pr(Y = 1 \mid \mathbf{x}) = F(\alpha + \mathbf{x}^\top \boldsymbol{\beta})$, and suppose that for every ratio $r = \rho_1/\rho_0$ in some open interval containing 1 there is a constant $c(r)$ with $\Pr(Y = 1 \mid \mathbf{x}, S = 1) = F\{\alpha + c(r) + \mathbf{x}^\top \boldsymbol{\beta}\}$ for all $\mathbf{x}$. If the linear predictor $\alpha + \mathbf{x}^\top \boldsymbol{\beta}$ ranges over an interval J with nonempty interior as $\mathbf{x}$ varies, then $F(u) = \{1 + e^{-(au+b)}\}^{-1}$ for every $u \in J$ and some $a > 0$, b : wherever the population identifies it, the link is logistic;
- if ρ_1 and ρ_0 are known, or if the population prevalence $\bar{\pi} = \Pr(Y = 1)$ is known and the sample contains n_1 cases and n_0 controls, then α itself is estimable: in the second case $\hat{\alpha} = \hat{\alpha}_S - \log\{(n_1/n_0)(1 - \bar{\pi})/\bar{\pi}\}$, where $\hat{\alpha}_S$ is the intercept fitted

to the sample.

Proof.

- (a) By Bayes' theorem, writing $\pi = \Pr(Y = 1 \mid \mathbf{x})$,

$$\Pr(Y = 1 \mid \mathbf{x}, S = 1) = \frac{\rho_1 \pi}{\rho_1 \pi + \rho_0 (1 - \pi)},$$

so that

$$\frac{\Pr(Y = 1 \mid \mathbf{x}, S = 1)}{\Pr(Y = 0 \mid \mathbf{x}, S = 1)} = \frac{\rho_1}{\rho_0} \cdot \frac{\pi}{1 - \pi}.$$

Taking logarithms and using $\text{logit } \pi = \alpha + \mathbf{x}^\top \boldsymbol{\beta}$ gives the claim. The step needs ρ_y to be free of $\mathbf{x}$, and nothing else.

- (b) Put $G = \text{logit} \circ F$, a continuous strictly increasing function, and write $\eta = \alpha + \mathbf{x}^\top \boldsymbol{\beta}$. The computation in (a) used only Bayes' theorem, so it holds for any F : $\text{logit } \Pr(Y = 1 \mid \mathbf{x}, S = 1) = \log r + G(\eta)$. The hypothesis says this equals $G\{\eta + c(r)\}$. Hence

$$G\{\eta + c(r)\} - G(\eta) = \log r \quad \text{for all } \eta \text{ in an interval } J.$$

Since G is strictly increasing, c is strictly increasing in r with $c(1) = 0$, and as r runs over an open interval containing 1, $v = c(r)$ runs over an open interval V containing 0. The displayed identity says that $\kappa(v) = G(\eta + v) - G(\eta)$ is the same for every $\eta \in J$ with $\eta + v \in J$. Taking v, v' and η with $v, v', v + v' \in V$ and $\eta, \eta + v, \eta + v + v'$ all in J , which the nonempty interior of J permits, gives $\kappa(v + v') = \kappa(v) + \kappa(v')$; κ is continuous, so $\kappa(v) = av$ near 0, with $a > 0$ by monotonicity. Fix η_0 in the interior of J . Then $G(\eta) = G(\eta_0) + a(\eta - \eta_0)$ for $\eta \in J$ within V of η_0 , and chaining such steps along the interval J extends the identity to all of J . Inverting, $F(u) = \text{logit}^{-1}(au + b)$ on J : nothing pins F down outside J , and nothing can, since the sampling scheme says nothing about linear predictors the population never produces.

- (c) By (a) the fitted intercept estimates $\alpha + \log(\rho_1/\rho_0)$, so knowing the ratio recovers α . If instead $\bar{\pi}$ is known and the population has N members, then $\rho_1 = n_1/(N\bar{\pi})$ and $\rho_0 = n_0/\{N(1 - \bar{\pi})\}$ in expectation, so $\rho_1/\rho_0 = (n_1/n_0)(1 - \bar{\pi})/\bar{\pi}$. ■

Part (a) is why the odds ratio dominates epidemiology. It is not that odds ratios are more natural than risk ratios — they are less natural — but that they are the only effect measure a retrospective study can estimate without knowing how the sample was drawn. Part (b) says this belongs to the logit alone.

Remark (Why the prospective likelihood is legitimate). Part (a) says the *model* transfers, not that maximizing the ordinary prospective likelihood on retrospective data is a correct procedure: the actual likelihood of such a sample is $\prod_i f(\mathbf{x}_{(i)} \mid y_i)$, which involves the unknown population distribution of $\mathbf{X}$. Prentice and Pyke (1979) settled this. Treating that distribution nonparametrically and profiling it out of the retrospective likelihood yields exactly the prospective logistic likelihood, so the ordinary fit is the semiparametric maximum likelihood estimate of $\boldsymbol{\beta}$ and the usual inverse informa-

Figure 35.5.1: Retrospective estimates of a slope from 400 case-control samples, with the whole population estimate marked. (a) Logistic data under the logit link: centred on the population value. (b) Probit data under the probit link: systematically too large.

tion is its correct asymptotic covariance. Their argument profiles an infinite-dimensional nuisance parameter and is not reproduced here.

Example. (A simulated retrospective study)

Take a population of 200000 with a continuous exposure $x_1 \sim N(0, 1)$, an independent binary covariate x_2 , and logit $\pi = -5 + 1.2x_1 + 0.8x_2$. The prevalence is 0.0178, so there are 3565 cases, and fitting the whole population gives $\hat{\alpha} = -4.959$, $\hat{\beta}_1 = 1.202$, $\hat{\beta}_2 = 0.748$.

Now take every case and four random controls per case, and fit the same model to those records as if they had been collected prospectively. Averaged over 400 control samples the slopes are recovered, at $\hat{\beta}_1 = 1.201$ and $\hat{\beta}_2 = 0.755$, while the intercept averages -2.339 against the predicted $\hat{\alpha} + \log(\rho_1/\rho_0) = -4.959 + 2.623 = -2.337$.

With data generated from a *probit* model and fitted with a probit link, the population slope is 0.547 while the retrospective samples average 0.719, too large by a factor of 1.31 (Figure 35.5.1).

35.5.2 Matched designs

Controls are often matched to cases on variables that matter but are not of interest: age, sex, neighbourhood. A matched set is one case and M controls sharing those variables, and the model gives each set its own intercept:

$$\text{logit } \Pr(Y_{kj} = 1 \mid \mathbf{x}_{kj}) = \alpha_k + \mathbf{x}_{kj}^\top \boldsymbol{\beta}, \quad k = 1, \dots, K, \quad j = 0, 1, \dots, M.$$

Estimating the K intercepts along with $\boldsymbol{\beta}$ is the incidental-parameter situation of [Example \(Many means, one variance\)](#), in which maximum likelihood is not consistent. Conditioning removes them.

Proposition 35.5.2 — Conditional logistic regression

In the model above, suppose exactly one member of each set is a case, and condition on that fact. Then:

- (a) the conditional probability that member j^* of set k is the case, given the covariates of the set and that exactly one member is, is

$$\frac{\exp(\mathbf{x}_{kj^*}^\top \boldsymbol{\beta})}{\sum_{j=0}^M \exp(\mathbf{x}_{kj}^\top \boldsymbol{\beta})}, \quad (35.5.1)$$

free of α_k ;

- (b) the product of these over k is the **conditional likelihood**; maximizing it gives a consistent, asymptotically normal estimate of $\boldsymbol{\beta}$ as $K \rightarrow \infty$ with M fixed, and the ordinary inverse-information standard errors apply to it;
- (c) for $M = 1$ (matched pairs), let $\mathbf{d}_k = \mathbf{x}_{k1} - \mathbf{x}_{k0}$ be the case-minus-control difference in a discordant pair. The conditional log-likelihood is $-\sum_k \log\{1 + \exp(-\boldsymbol{\beta}^\top \mathbf{d}_k)\}$, while the profile log-likelihood obtained by maximizing the *unconditional* likelihood over the α_k is $-2 \sum_k \log\{1 + \exp(-\frac{1}{2} \boldsymbol{\beta}^\top \mathbf{d}_k)\}$. Consequently the unconditional

estimate is exactly twice the conditional one, and converges to 2β .

Proof.

- (a) With $\pi_{kj} = \text{logit}^{-1}(\alpha_k + \mathbf{x}_{kj}^\top \boldsymbol{\beta})$, the probability that j^* alone is a case is $\pi_{kj^*} \prod_{j \neq j^*} (1 - \pi_{kj})$. Dividing by the sum of the same expression over all choices, and cancelling $\prod_j (1 - \pi_{kj})$ from numerator and denominator, leaves $\{\pi_{kj^*} / (1 - \pi_{kj^*})\} / \sum_j \{\pi_{kj} / (1 - \pi_{kj})\}$. Each odds is $e^{\alpha_k} e^{\mathbf{x}_{kj}^\top \boldsymbol{\beta}}$, and e^{α_k} cancels, giving [Eq. 35.5.1](#).
- (b) The sets are independent and [Eq. 35.5.1](#) is a genuine probability model for a fixed parameter $\boldsymbol{\beta}$ of fixed dimension, so the standard likelihood asymptotics apply as $K \rightarrow \infty$. (It is the likelihood of a multinomial logit model, which [Chapter 36](#) studies in its own right.)
- (c) Part (a) with $M = 1$ gives $\{1 + \exp(-\boldsymbol{\beta}^\top \mathbf{d}_k)\}^{-1}$, whose logarithm summed over k is the stated conditional log-likelihood. For the unconditional calculation, write $u = \alpha_k + \frac{1}{2} \boldsymbol{\beta}^\top (\mathbf{x}_{k1} + \mathbf{x}_{k0})$ and $c = \frac{1}{2} \boldsymbol{\beta}^\top \mathbf{d}_k$, so the two linear predictors are $u + c$ and $u - c$. The pair's log-likelihood is $(u + c) - \log(1 + e^{u+c}) - \log(1 + e^{u-c})$; differentiating in u gives $1 - \text{logit}^{-1}(u + c) - \text{logit}^{-1}(u - c) = 0$, that is, $\text{logit}^{-1}(u + c) = \text{logit}^{-1}(c - u)$, whose unique solution is $u = 0$. Substituting $u = 0$,

$$c - \log(1 + e^c) - \log(1 + e^{-c}) = -2 \log(1 + e^{-c}),$$

which is the stated profile contribution with $c = \frac{1}{2} \boldsymbol{\beta}^\top \mathbf{d}_k$. A concordant pair contributes a supremum of 0, approached as $\alpha_k \rightarrow \pm\infty$ and free of $\boldsymbol{\beta}$. The profile log-likelihood is therefore twice the conditional log-likelihood evaluated at $\boldsymbol{\beta}/2$, so its maximizer is twice the conditional maximizer; since the latter is consistent for $\boldsymbol{\beta}$, the former converges to $2\boldsymbol{\beta}$. ■

Example. (Doubling the effect)

Simulate 3000 matched pairs with one covariate, stratum intercepts drawn from a normal distribution and $\beta = 1$, keeping only the discordant pairs. The conditional estimate is 0.942 with standard error 0.037. Profiling the unconditional likelihood numerically over the three thousand intercepts gives 1.884, twice that to three decimals as [Proposition 35.5.2\(c\)](#) requires, and about twenty-four standard errors from the truth.

```
from scipy.optimize import minimize

def matched_pairs(K=3000, beta=1.0, seed=11):
    """K strata, each with one case and one control, and a stratum-specific
    intercept."""
    rng = np.random.default_rng(seed)
    a = rng.normal(-1.0, 2.0, K)                # the nuisance intercepts
    xc, xk = np.empty(K), np.empty(K)
    for k in range(K):
        while True:                             # sample the stratum until
            it is discordant
            x = rng.normal(size=2)
            pr = 1 / (1 + np.exp(-(a[k] + beta * x)))
```

```

yy = rng.random(2) < pr
if yy[0] != yy[1]:
    xc[k], xk[k] = (x[0], x[1]) if yy[0] else (x[1], x[0])
    break
return xc, xk                                # exposure of the case, of
the control

x_case, x_control = matched_pairs()
# the conditional likelihood for 1:1 matching depends on beta only through the
  difference
d = x_case - x_control
cond = minimize(lambda b: np.sum(np.log1p(np.exp(-b[0] * d))), [0.0]).x[0]
print("conditional estimate:", round(cond, 3))

```

Matching buys precision when the matching variables are strong confounders, and costs all information about them, since they are absorbed into the α_k . Overmatching, matching on a variable on the causal path from exposure to outcome, removes part of the effect one is measuring: a bad control ([Theorem 25.5.1](#)).

35.5.3 Two warnings about odds ratios

Example. (The odds ratio does not collapse)

Generate a population of 200000 with two *independent* covariates, x_1 standard normal and x_2 Bernoulli with probability 0.3, and logit $\pi = 1.0x_1 + 4.0x_2$, giving a prevalence of 0.638. Fitting both covariates and an intercept recovers the coefficient of x_1 as 1.006. Fitting an intercept and x_1 alone, and thereby averaging over x_2 , gives 0.745, a quarter smaller. There is no confounding here: the two covariates are independent by construction, and the marginal and conditional odds ratios simply differ.

The odds ratio is not *collapsible*: the best logistic approximation to an average of logistic curves is flatter than they are, by an amount growing with the variance of the omitted term ([Exercise \(C1\)](#)). Conditional and marginal odds ratios therefore answer different questions, and adding a covariate moves the other coefficients away from zero even when it is independent of them, so the reasoning “the coefficient changed, therefore the new variable is a confounder” is invalid here. Risk differences and risk ratios do collapse.

The second warning is causal. [Theorem 35.5.1](#) requires selection to depend on Y alone; if recruitment also depends on the exposure, say because the cases come from a hospital serving an exposed population, then S is a collider on a path between $\mathbf{X}$ and Y and conditioning on $S = 1$ opens it ([Proposition 25.2.1](#)). And the conditional odds ratio it estimates is the causal effect only if the covariates satisfy the backdoor criterion ([Definition 25.4.1](#) and [Theorem 25.4.1](#)), which no sampling scheme can supply.

Idea. Retrospective sampling is the one design in which the choice of link is forced: [Theorem 35.5.1](#) makes the odds ratio estimable under a scheme that destroys every other effect measure. The price is that odds ratios do not collapse, do not approximate risk ratios unless the outcome is rare, and are causal only under the usual assumptions.

35.5.4 Exercises

35.5.4.1 A. Check your understanding

Exercise A1.

A case-control study has 200 cases and 600 controls, and the disease affects 2% of the population. The fitted intercept is -0.8 . Estimate the population intercept, and the probability of disease at the reference covariate values.

Solution. By Theorem 35.5.1(c), $\log\{(200/600)(0.98/0.02)\} = \log(16.333) = 2.793$, so $\hat{\alpha} = -0.8 - 2.793 = -3.593$ and the probability is $1/(1 + e^{3.593}) = 0.0268$, close to the population prevalence as it should be.

35.5.4.2 B. Practice

Exercise B1.

Suppose $\Pr(S = 1 \mid Y = y, \mathbf{X} = \mathbf{x}) = \rho_y g(\mathbf{x})$ for some g with values in $(0, 1]$. Show that Theorem 35.5.1(a) still holds. Then suppose instead that cases are sampled at rate $\rho_1 e^{\mathbf{x}^\top \boldsymbol{\gamma}}$ while controls are sampled at a rate free of $\mathbf{x}$; find the bias in the estimated slopes.

Exercise B2.

For matched pairs with a single binary exposure, let n_{10} be the number of pairs with an exposed case and unexposed control and n_{01} the reverse. Show that the conditional estimate of the log odds ratio is $\log(n_{10}/n_{01})$, and that the conditional test of $\beta = 0$ is a binomial test of $1/2$ in $n_{10} + n_{01}$ trials.

Solution. With a binary exposure $d_k \in \{-1, 0, 1\}$, and pairs with $d_k = 0$ contribute a constant. The conditional log-likelihood is $-n_{10} \log(1 + e^{-\beta}) - n_{01} \log(1 + e^{\beta})$; setting the derivative to zero gives $e^{\beta} = n_{10}/n_{01}$. Writing $p = e^{\beta}/(1 + e^{\beta})$, the conditional likelihood is that of n_{10} successes in $n_{10} + n_{01}$ Bernoulli trials, and $\beta = 0$ is $p = 1/2$. The resulting test is McNemar's, its exact version the binomial test.

Exercise B3.

With n_1 cases fixed and $n_0 = Mn_1$ controls, show that for a single binary exposure and a rare disease the asymptotic variance of the log odds ratio is proportional to $1 + 1/M$, and deduce that there is little gain beyond $M = 4$ or 5 .

35.5.4.3 C. Going deeper

Exercise C1.

Let $\text{logit} \Pr(Y = 1 \mid X, Z) = \beta X + \gamma Z$ with Z independent of X . Show that $\Pr(Y = 1 \mid X)$ is not of the form $\text{logit}^{-1}(\beta^* X)$, and explain why the best logistic approximation

has $|\beta^*| < |\beta|$. What happens as $\gamma \rightarrow 0$?

Solution. $\Pr(Y = 1 \mid X = x) = E_Z \text{logit}^{-1}(\beta x + \gamma Z)$ is a mixture of horizontally shifted logistic curves, and a nondegenerate such mixture is not itself logistic: its derivative at its median is strictly smaller than that of a single component with the same slope, by concavity of the response function above the median and convexity below. The marginal curve is flatter, so the best logistic fit has a smaller slope in modulus. As $\gamma \rightarrow 0$, $\beta^* \rightarrow \beta$; the attenuation grows with $\gamma^2 \text{Var } Z$, which is why the effect in [Example \(The odds ratio does not collapse\)](#) is large.

35.6 Summary and Notes

35.6.1 Summary

Idea.

1. A binary response is a binomial exponential dispersion family with variance function $\pi(1 - \pi)$, dispersion one and natural parameter the log odds; the canonical link is the logit ([Definition 35.1.1](#)).
2. A logistic coefficient is a log odds ratio, constant over the other covariates; $|\beta_j|/4$ bounds its effect on the probability scale, and the average marginal effect converts it to a change in probability ([Proposition 35.1.1](#)).
3. Grouping observations with identical covariates changes the log-likelihood by a constant, so the estimate, its covariance and every likelihood ratio are unchanged; the deviance is not ([Proposition 35.1.2](#)).
4. Fisher scoring is iteratively reweighted least squares with weights $m_i \pi_i(1 - \pi_i)$; observed and expected information coincide, and the log-likelihood is strictly concave when $\text{rank}(\mathbf{X}) = p$ ([Proposition 35.1.3](#)).
5. Every binary regression is a threshold model: logistic, normal and smallest extreme-value latent errors give the logit, probit and complementary log-log links, and a proportional hazards process observed at a fixed time gives the last of them and no other ([Definition 35.2.1](#) and [Proposition 35.2.1](#)).
6. The latent scale is not identified, so probit and logit coefficients are comparable only after rescaling, by 1.8138 or 1.5958 depending on the convention ([Proposition 35.2.2](#)).
7. The maximum likelihood estimate exists if and only if the data are in overlap; under separation some coefficients diverge and the Wald test collapses while the likelihood ratio does not ([Definition 35.3.1](#) and [Theorem 35.3.1](#)).
8. Firth's penalty $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{W} \mathbf{X})$ removes the leading bias and gives finite estimates; a ridge or Cauchy penalty does the same more crudely ([Proposition 35.3.2](#)).
9. Grouped Pearson and deviance statistics have $\chi^2(N - p)$ limits as the group sizes grow. The ungrouped deviance is exactly $-2 \sum_i \{\hat{\pi}_i \log \hat{\pi}_i + (1 - \hat{\pi}_i) \log(1 - \hat{\pi}_i)\}$, a function of the fit alone with no χ^2 limit; differences of deviances remain valid ([Proposition 35.4.1](#)).
10. In-sample calibration is automatic, so calibration must be judged out of sample,

and the area under the ROC curve is a rank statistic, blind to calibration ([Proposition 35.4.2](#) and [Proposition 35.4.3](#)).

11. Retrospective sampling on Y alone shifts the intercept by $\log(\rho_1/\rho_0)$ and leaves the slopes alone, and the logit is the only link with that property ([Theorem 35.5.1](#)).
12. Matched sets are handled by conditioning; fitting the stratum intercepts instead is inconsistent, and for matched pairs gives exactly twice the conditional estimate ([Proposition 35.5.2](#)).

35.6.2 Notes and sources

Coverage. The topics follow Agresti (2015, chapter 5) and Fahrmeir, Kneib, Lang and Marx (2021, sections 5.1–5.2), with proofs, examples and exercises of this book’s own. Collett (2003) and Hosmer, Lemeshow and Sturdivant (2013) are the standard applied accounts, and the source of the events-per-variable guidance alluded to in [Section 35.1](#); McCullagh and Nelder (1989, chapter 4) is the compact theoretical reference.

Origins. The logistic function entered statistics through bioassay: probit analysis came first, with Bliss (1934) and Finney (1971), and Berkson (1944) argued for the logistic alternative against considerable resistance. Cox (1958a) gave the modern regression treatment of binary sequences and Cox (1970) the first book on binary data. The complementary log–log link is the binary face of the proportional hazards model of Cox (1972), with the discrete-time version of [Exercise \(B2\)](#) due to Prentice and Gloeckler (1978); the link family of [Exercise \(C1\)](#) is Aranda-Ordaz’s (1981). The “divide by four” rule is from Gelman and Hill (2007).

Separation. Silvapulle (1981) proved existence of the estimate under a convexity condition equivalent to overlap; Albert and Anderson (1984) introduced the terminology of complete and quasi-complete separation and the linear-programming diagnostic, and Santner and Duffy (1986) corrected a gap in their argument. The proof of [Theorem 35.3.1](#) given here is the direct one: strict concavity leaves only coercivity to establish, and coercivity is exactly overlap. The counting formula of [Exercise \(C1\)](#) is Cover’s (1965). Firth (1993) introduced the Jeffreys-prior penalty as a bias-reduction device; Heinze and Schemper (2002) recognized it as a remedy for separation, and Kosmidis and Firth (2021) proved the resulting estimate always finite. The Cauchy prior is from Gelman, Jakulin, Pittau and Su (2008); exact conditional inference is due to Cox (1970) and Hirji, Mehta and Patel (1987); and the Wald pathology of [Exercise \(B3\)](#) is Hauck and Donner’s (1977).

Goodness of fit. That the ungrouped deviance depends on the data only through the fitted values is standard and appears in McCullagh and Nelder (1989, section 4.4); the exact identity [Eq. 35.4.2](#) and the simulation of [Example \(Three deviances that mean nothing\)](#) are this book’s way of making the point. The Hosmer–Lemeshow statistic is from Hosmer and Lemeshow (1980), its instability discussed at length in Hosmer, Lemeshow and Sturdivant (2013); a smoothed alternative is le Cessie and van Houwelingen (1991). Calibration in the sense of [Proposition 35.4.2](#) goes back to Cox (1958b). The ROC curve entered medical statistics through Hanley and McNeil (1982), and Pepe, Janes, Longton, Leisenring and Newcomb (2004) documented how insensitive its area is to genuinely informative covariates.

Case–control studies. The retrospective likelihood argument that justifies using the prospective fit is Prentice and Pyke (1979); Breslow and Day (1980) is the classical monograph and Breslow (1996) a readable retrospective on the design. The conditional likelihood of [Proposition 35.5.2](#) comes from the tradition of Andersen (1970), itself an instance of the incidental-parameter problem of Neyman and Scott (1948) met in [Example \(Many means, one variance\)](#).

Noncollapsibility is analysed by Greenland, Robins and Pearl (1999), who separate it carefully from confounding.

What comes next. Chapter 38 takes up quasi-likelihood and overdispersion, which matter for grouped binary data whose variance exceeds $m\pi(1 - \pi)$; Chapter 39 treats fitting in practice and the Bayesian thread, including the priors touched on in Section 35.3; Chapter 40 joins generalized linear models to the random effects of Chapter 32; and Chapter 41 covers missing data. Responses with more than two categories are the subject of Chapter 36. The 1996 American National Election Studies survey used throughout is public domain; it illustrates method only, and nothing here should be read as a claim about the election.

Chapter 36

Multinomial and Ordinal Responses

A response with two categories has one logit. A response with c categories has $c - 1$ of them, and the modelling question is which $c - 1$ comparisons to make. If the categories are names — a brand, a party, a mode of travel — the natural comparisons are with a fixed baseline, and the result is the *baseline-category logit model*, a generalized linear model whose response is a vector of counts. If the categories are ordered, that choice wastes information: a model ignoring the order needs $(c - 1)p$ coefficients to say what a single slope may say. Ordinal models get back down to p by cutting the scale and giving every cut the same coefficients. Where the cut is made is the whole story. Cut *at* a level and you get the cumulative, or proportional odds, model; cut *conditionally on having got that far* and you get the sequential, or continuation-ratio, model. These answer different questions, and the data can tell them apart.

What you need. [Chapter 34](#) (exponential families, the likelihood equations, Fisher scoring, the deviance and the three test statistics) and [Chapter 35](#) (logistic regression, the alternative links, separation, goodness of fit). From earlier parts: [Chapter 11](#) for the likelihood ratio test [Theorem 11.4.1](#) and the three flavours of test statistic [Proposition 11.4.2](#), [Chapter 21](#) for weighted least squares and the sandwich estimator ([Theorem 21.4.2](#)), and [Chapter 29](#) for the information criteria ([Definition 29.2.2](#)). Nothing here needs normality of anything.

36.0.1 Roadmap

- [Baseline-category logits](#)
- [Cumulative logit models](#)
- [Proportional odds and its checks](#)
- [Sequential models](#)
- [Summary and notes](#)

36.1 Baseline-category logits

Let the response of observation i fall in one of c categories, recorded as a vector of counts $\mathbf{Y}_i = (Y_{i1}, \dots, Y_{ic})^\top$ with $\sum_r Y_{ir} = m_i$. When each row is a single subject, $m_i = 1$ and $\mathbf{Y}_i$ is an indicator vector; when rows are covariate patterns, m_i counts the subjects sharing that pattern. As with grouped and ungrouped binary data in [Chapter 35](#), the two cases are the same model

with different bookkeeping, and the distinction matters only for the deviance as a goodness-of-fit statistic.

36.1.1 The multinomial distribution is an exponential family

Chapter 34 was built on a one-dimensional exponential dispersion family (Definition 34.1.1). A categorical response is a *vector* with $c - 1$ free coordinates, and the structure survives the move, with the natural parameter and the cumulant function becoming vector-valued.

Lemma 36.1.1 — The multinomial as an exponential family

Let $\mathbf{Y} \sim \text{Mult}(m, \boldsymbol{\pi})$ with $\pi_r > 0$ for every r and $\sum_{r=1}^c \pi_r = 1$. Write $\tilde{\mathbf{Y}} = (Y_1, \dots, Y_{c-1})^\top$ for the first $c - 1$ counts and

$$\eta_r = \log \frac{\pi_r}{\pi_c}, \quad r = 1, \dots, c - 1.$$

Then the probability mass function is

$$f(\mathbf{y}) = h(\mathbf{y}) \exp\{\tilde{\mathbf{y}}^\top \boldsymbol{\eta} - m b(\boldsymbol{\eta})\}, \quad b(\boldsymbol{\eta}) = \log\left(1 + \sum_{s=1}^{c-1} e^{\eta_s}\right), \quad (36.1.1)$$

with $h(\mathbf{y}) = m!/(y_1! \cdots y_c!)$. The map $\boldsymbol{\eta} \mapsto \boldsymbol{\pi}$ is a bijection from $\mathbb{R}^{c-1}$ onto the interior of the probability simplex, with inverse

$$\pi_r = \frac{e^{\eta_r}}{1 + \sum_{s < c} e^{\eta_s}} \quad (r < c), \quad \pi_c = \frac{1}{1 + \sum_{s < c} e^{\eta_s}}, \quad (36.1.2)$$

and the first two moments are

$$\mathbb{E}(\tilde{\mathbf{Y}}) = m \nabla b(\boldsymbol{\eta}) = m \tilde{\boldsymbol{\pi}}, \quad \text{Cov}(\tilde{\mathbf{Y}}) = m \nabla^2 b(\boldsymbol{\eta}) = m(\text{diag}(\tilde{\boldsymbol{\pi}}) - \tilde{\boldsymbol{\pi}} \tilde{\boldsymbol{\pi}}^\top), \quad (36.1.3)$$

where $\tilde{\boldsymbol{\pi}} = (\pi_1, \dots, \pi_{c-1})^\top$.

Proof. Since $\sum_r y_r = m$,

$$\prod_{r=1}^c \pi_r^{y_r} = \pi_c^m \prod_{r < c} \left(\frac{\pi_r}{\pi_c}\right)^{y_r} = \exp\left\{\sum_{r < c} y_r \eta_r + m \log \pi_c\right\},$$

and $\log \pi_c = -b(\boldsymbol{\eta})$ by the definition of η_r , which gives Eq. 36.1.1. Solving $\eta_r = \log \pi_r - \log \pi_c$ with $\sum_r \pi_r = 1$ gives Eq. 36.1.2, and every $\boldsymbol{\pi}$ with positive entries arises from exactly one $\boldsymbol{\eta}$, so the map is a bijection.

For the moments, sum [Eq. 36.1.1](#) over the support. By the multinomial theorem,

$$M(\boldsymbol{\eta}) = \sum_{\mathbf{y}} h(\mathbf{y}) \exp(\tilde{\mathbf{y}}^\top \boldsymbol{\eta}) = \left(1 + \sum_{s < c} e^{\eta_s}\right)^m = e^{mb(\boldsymbol{\eta})},$$

a finite sum, which may therefore be differentiated term by term without any regularity condition. Since $\log M = mb$ is the cumulant generating function of $\tilde{\mathbf{Y}}$ shifted to $\boldsymbol{\eta}$, its first two derivatives are $E(\tilde{\mathbf{Y}}) = m\nabla b$ and $\text{Cov}(\tilde{\mathbf{Y}}) = m\nabla^2 b$. Finally

$$\frac{\partial b}{\partial \eta_r} = \frac{e^{\eta_r}}{1 + \sum_{s < c} e^{\eta_s}} = \pi_r, \quad \frac{\partial^2 b}{\partial \eta_r \partial \eta_s} = \pi_r(\delta_{rs} - \pi_s),$$

where δ_{rs} is one if $r = s$ and zero otherwise. ■

Remark (What is new and what is not). [Eq. 36.1.1](#) has the shape of [Definition 34.1.1](#) with the scalar natural parameter replaced by a vector and the dispersion ϕ/w_i by $1/m$: the number of trials plays the role of a prior weight. The identity “mean is the gradient of the cumulant function, variance its second derivative” is [Proposition 34.1.2](#), proved there by the same argument. New is only that $\nabla^2 b$ is a matrix, and a singular one once the baseline coordinate is put back: $\text{diag}(\boldsymbol{\pi}) - \boldsymbol{\pi}\boldsymbol{\pi}^\top$ kills $\mathbf{1}$, because the c counts sum to the fixed total m .

36.1.2 The model

Definition 36.1.1 — Baseline-category logit model

Let $\mathbf{Y}_1, \dots, \mathbf{Y}_n$ be independent with $\mathbf{Y}_i \sim \text{Mult}(m_i, \boldsymbol{\pi}_i)$, and let $\mathbf{x}_{(i)} \in \mathbb{R}^p$ be the i th row of a model matrix $\mathbf{X}$ whose first column is $\mathbf{1}$. The **baseline-category logit model** with baseline c is

$$\log \frac{\pi_{ir}}{\pi_{ic}} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r, \quad r = 1, \dots, c-1, \quad (36.1.4)$$

with unknown $\boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_{c-1} \in \mathbb{R}^p$. Equivalently, writing $\boldsymbol{\beta}_c = \mathbf{0}$, $\pi_{ir} = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r) / \sum_{s=1}^c \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}_s)$ for every r .

This is a generalized linear model in the sense of [Definition 34.2.1](#), with the multinomial random component of [Lemma 36.1.1](#) and the *canonical* link, since [Eq. 36.1.4](#) sets η_{ir} itself equal to a linear predictor. The one departure from [Chapter 34](#) is that each observation carries a vector of natural parameters, so the model’s coefficient vector is the stack $\boldsymbol{\beta} = (\boldsymbol{\beta}_1^\top, \dots, \boldsymbol{\beta}_{c-1}^\top)^\top$ of length $(c-1)p$. Every regressor buys $c-1$ coefficients: the price of treating the categories as unordered names.

36.1.3 The likelihood equations

Theorem 36.1.2 — Score, information and concavity

Under [Definition 36.1.1](#) the log-likelihood, as a function of $\boldsymbol{\beta} = (\boldsymbol{\beta}_1^\top, \dots, \boldsymbol{\beta}_{c-1}^\top)^\top$, is

$$\ell(\boldsymbol{\beta}) = \sum_{i=1}^n \left\{ \sum_{r < c} y_{ir} \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r - m_i b(\boldsymbol{\eta}_i) \right\}, \quad \eta_{ir} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r.$$

Then:

- (a) the score has blocks $\partial \ell / \partial \boldsymbol{\beta}_r = \sum_i (y_{ir} - m_i \pi_{ir}) \mathbf{x}_{(i)} = \mathbf{X}^\top (\mathbf{y}_r - \boldsymbol{\mu}_r)$, where $\boldsymbol{\mu}_r$ is the vector with entries $m_i \pi_{ir}$;
- (b) the observed and expected information coincide and have blocks $\mathbf{X}^\top \mathbf{W}_{rs} \mathbf{X}$ with $\mathbf{W}_{rs} = \text{diag}\{m_i \pi_{ir} (\delta_{rs} - \pi_{is})\}_{i=1}^n$;
- (c) ℓ is concave, and strictly concave when $\text{rank}(\mathbf{X}) = p$; in that case it has at most one maximizer, and the maximizer, if it exists, is the unique solution of the likelihood equations $\mathbf{X}^\top (\mathbf{y}_r - \boldsymbol{\mu}_r) = \mathbf{0}$ for $r = 1, \dots, c-1$.

Proof.

- (a) Differentiate: $\partial b(\boldsymbol{\eta}_i) / \partial \eta_{ir} = \pi_{ir}$ by [Lemma 36.1.1](#), and $\partial \eta_{ir} / \partial \boldsymbol{\beta}_r = \mathbf{x}_{(i)}$.
- (b) Differentiating again, and using $\partial^2 b / \partial \eta_{ir} \partial \eta_{is} = \pi_{ir} (\delta_{rs} - \pi_{is})$,

$$-\frac{\partial^2 \ell}{\partial \boldsymbol{\beta}_r \partial \boldsymbol{\beta}_s^\top} = \sum_i m_i \pi_{ir} (\delta_{rs} - \pi_{is}) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top.$$

The data enter only through the score, so the second derivative is nonrandom and observed information equals expected information. This is the canonical-link simplification of [Theorem 34.3.1](#).

- (c) Take $\mathbf{a} = (\mathbf{a}_1^\top, \dots, \mathbf{a}_{c-1}^\top)^\top$ and put $t_{ir} = \mathbf{x}_{(i)}^\top \mathbf{a}_r$ for $r < c$ and $t_{ic} = 0$. By (b),

$$\mathbf{a}^\top (-\nabla^2 \ell) \mathbf{a} = \sum_i m_i \left\{ \sum_{r=1}^c \pi_{ir} t_{ir}^2 - \left(\sum_{r=1}^c \pi_{ir} t_{ir} \right)^2 \right\},$$

the inner brace being the variance of the random variable that takes the value t_{ir} with probability π_{ir} . A variance is nonnegative, so ℓ is concave. It vanishes only if $t_{i1} = \dots = t_{ic}$, and since $t_{ic} = 0$ this forces $\mathbf{x}_{(i)}^\top \mathbf{a}_r = 0$ for every i and every $r < c$, that is $\mathbf{X} \mathbf{a}_r = \mathbf{0}$. When $\text{rank}(\mathbf{X}) = p$ this gives $\mathbf{a} = \mathbf{0}$, so the Hessian is negative definite everywhere and ℓ is strictly concave. A strictly concave function has at most one stationary point, and a stationary point is its maximum. ■

Idea. The likelihood equations say $\mathbf{X}^\top \mathbf{y}_r = \mathbf{X}^\top \hat{\boldsymbol{\mu}}_r$ for each non-baseline category: *fitted counts reproduce observed counts in every direction spanned by a regressor*, so with an intercept each category's fitted total is its observed total. This is the canonical-link moment matching of [Theorem 34.3.1](#), one copy per logit.

Because the information is the expected information, Newton–Raphson and Fisher scoring are

the same algorithm, and by [Theorem 34.4.1](#) each step is a weighted least squares fit, with block weights $\mathbf{W}_i = m_i(\text{diag}(\tilde{\boldsymbol{\pi}}_i) - \tilde{\boldsymbol{\pi}}_i\tilde{\boldsymbol{\pi}}_i^\top)$ and working response $\boldsymbol{\eta}_i + \mathbf{W}_i^{-1}(\mathbf{y}_i - m_i\boldsymbol{\pi}_i)_{1:c-1}$. The only change from [Chapter 34](#) is that the weights are $(c-1) \times (c-1)$ blocks rather than scalars, so each step is a generalized rather than a diagonally weighted least squares problem ([Theorem 21.3.1](#)).

Warning (Existence). Concavity guarantees uniqueness, not existence. As for binary data, the maximum is attained unless the categories can be separated. Take $m_i = 1$ and $\text{rank}(\mathbf{X}) = p$ as in [Theorem 36.1.2\(c\)](#), with observation i in category y_i . If there are vectors $\mathbf{a}_1, \dots, \mathbf{a}_c$, not all equal, with $\mathbf{x}_{(i)}^\top(\mathbf{a}_{y_i} - \mathbf{a}_r) \geq 0$ for every i and r , then differentiating ℓ along that direction gives $\sum_i \sum_r \pi_{ir} \mathbf{x}_{(i)}^\top(\mathbf{a}_{y_i} - \mathbf{a}_r) \geq 0$ at *every* point of the ray, the fitted probabilities being positive throughout. By [Theorem 36.1.2\(c\)](#) the restriction of ℓ to the ray is strictly concave, so its derivative is strictly decreasing; were it zero somewhere it would be negative beyond, contradicting the display. It is therefore positive throughout, and the supremum is approached only at infinity. (Without the rank condition the derivative can vanish along the whole ray, which forces every $\mathbf{x}_{(i)}$ orthogonal to every difference $\mathbf{a}_s - \mathbf{a}_t$; the maximum is then attained, but not unique.) The binary case, with its proof and its remedies, is [Theorem 35.3.1](#); the multinomial statement is Albert and Anderson (1984). With many categories and small cells separation is common, and the remedies are the same: a penalty as in [Definition 27.2.1](#), or the equivalent proper prior of [Proposition 30.1.4](#) — see [Chapter 27](#) and [Chapter 30](#).

36.1.4 Reading the coefficients

Two facts about [Eq. 36.1.4](#) are easy to state and easy to misuse.

Proposition 36.1.3 — Changing the baseline

Let $\hat{\boldsymbol{\beta}}_1, \dots, \hat{\boldsymbol{\beta}}_{c-1}$ maximize the likelihood of [Definition 36.1.1](#), and set $\hat{\boldsymbol{\beta}}_c = \mathbf{0}$. Fix any $s \in \{1, \dots, c\}$. Then:

- (a) for every pair of categories r, r' , $\log(\pi_{ir}/\pi_{ir'}) = \mathbf{x}_{(i)}^\top(\boldsymbol{\beta}_r - \boldsymbol{\beta}_{r'})$; in particular a model with baseline s is the same model, with coefficients $\boldsymbol{\beta}_r^{(s)} = \boldsymbol{\beta}_r - \boldsymbol{\beta}_s$;
- (b) refitting the model with baseline s gives $\hat{\boldsymbol{\beta}}_r^{(s)} = \hat{\boldsymbol{\beta}}_r - \hat{\boldsymbol{\beta}}_s$, the same maximized log-likelihood and the same fitted probabilities;
- (c) the estimated covariance matrix of $\hat{\boldsymbol{\beta}}^{(s)}$ obtained from the refitted model equals $\mathbf{L} \hat{\text{Cov}}(\hat{\boldsymbol{\beta}}) \mathbf{L}^\top$, where $\mathbf{L}$ is the linear map of (a); so standard errors of pairwise contrasts do not depend on which baseline was used.

Proof.

- (a) Subtract two instances of [Eq. 36.1.4](#); the baseline cancels because $\log(\pi_{ir}/\pi_{ir'}) = \log(\pi_{ir}/\pi_{ic}) - \log(\pi_{ir'}/\pi_{ic})$.
- (b) The map $\mathbf{L} : \boldsymbol{\beta} \mapsto \boldsymbol{\beta}^{(s)}$ defined by $\boldsymbol{\beta}_r^{(s)} = \boldsymbol{\beta}_r - \boldsymbol{\beta}_s$ for $r \neq s$ is linear, and it is invertible: from $\boldsymbol{\beta}^{(s)}$ one recovers $\boldsymbol{\beta}_r = \boldsymbol{\beta}_r^{(s)} + \boldsymbol{\beta}_s$ with $\boldsymbol{\beta}_s^{(s)} = \mathbf{0}$. By (a) the two parameterizations give exactly the same family of probability vectors $\boldsymbol{\pi}_i$, so the two likelihoods are the same function composed with $\mathbf{L}$. A reparameterization by a bijection carries maximizers to maximizers and leaves the maximum value and every fitted quantity unchanged.

- (c) Under a linear reparameterization $\boldsymbol{\psi} = \mathbf{L}\boldsymbol{\beta}$ the information transforms as $\mathbf{J}^{(s)} = \mathbf{L}^{-\top} \mathbf{J} \mathbf{L}^{-1}$, by the chain rule applied to the score. Hence $(\mathbf{J}^{(s)})^{-1} = \mathbf{L} \mathbf{J}^{-1} \mathbf{L}^{\top}$, which is exactly the delta-method covariance of $\mathbf{L}\hat{\boldsymbol{\beta}}$ — and the delta method is exact here because $\mathbf{L}$ is linear.

■

So the coefficients are log odds ratios: $\hat{\beta}_{rj}$ is the estimated change in $\log(\pi_r/\pi_c)$ per unit of regressor j , and differences of coefficients are log odds ratios between two non-baseline categories. The baseline is a choice of *display*, not of model. What is not invariant is the reading of a single coefficient, and here is the trap.

Proposition 36.1.4 — A coefficient is not a derivative of a probability

In Definition 36.1.1, with $\boldsymbol{\beta}_c = \mathbf{0}$ and x_j a continuous regressor,

$$\frac{\partial \pi_{ir}}{\partial x_{ij}} = \pi_{ir} \left(\beta_{rj} - \sum_{s=1}^c \pi_{is} \beta_{sj} \right). \quad (36.1.5)$$

So the c derivatives sum to zero, the derivative for category r is positive exactly when β_{rj} exceeds the probability-weighted average $\bar{\beta}_j(\mathbf{x}_{(i)}) = \sum_s \pi_{is} \beta_{sj}$, and the baseline, whose coefficient is zero by construction, has a strictly positive derivative whenever $\bar{\beta}_j(\mathbf{x}_{(i)}) < 0$.

Proof. Write $\pi_{ir} = e^{\eta_{ir}} / \sum_s e^{\eta_{is}}$ with $\partial \eta_{is} / \partial x_{ij} = \beta_{sj}$. The quotient rule gives

$$\frac{\partial \pi_{ir}}{\partial x_{ij}} = \pi_{ir} \beta_{rj} - \pi_{ir} \frac{\sum_s e^{\eta_{is}} \beta_{sj}}{\sum_s e^{\eta_{is}}} = \pi_{ir} \left(\beta_{rj} - \sum_s \pi_{is} \beta_{sj} \right).$$

Summing over r gives $\bar{\beta}_j - \bar{\beta}_j = 0$. The remaining statements read off the sign of the bracket, with $\beta_{cj} = 0$.

■

Since $\bar{\beta}_j(\mathbf{x})$ moves with $\mathbf{x}$, a fitted probability can rise over one range of the regressor and fall over another, whatever the sign of its coefficient. Read coefficients as odds ratios; read effects on probabilities off the fitted curves.

36.1.5 Travel mode choice

Example. (Choosing how to travel)

Two hundred and ten travellers on the Sydney–Melbourne corridor each chose one of four modes: air (58), train (63), bus (30) or car (59). The regressors are the household income in units of \$10,000 and the size of the travelling party. Take car as the baseline. Fitting Definition 36.1.1 by Newton–Raphson from $\boldsymbol{\beta} = \mathbf{0}$ takes 7 steps to full double

precision, and gives the following coefficients, with standard errors from the inverse information in parentheses.

logit	intercept	income (per \$10,000)	party size
air vs car	0.9435 (0.5498)	0.0354 (0.1030)	−0.6006 (0.1992)
train vs car	2.4938 (0.5357)	−0.5731 (0.1184)	−0.3098 (0.1956)
bus vs car	1.9780 (0.6717)	−0.3033 (0.1322)	−0.9404 (0.3245)

Income does not distinguish air from car ($z = 0.34$) but moves people strongly away from the ground alternatives: each extra \$10,000 of household income multiplies the odds of train rather than car by $e^{-0.5731} = 0.5638$. Read through [Proposition 36.1.3](#), the same fit raises the odds of air over train by $e^{0.6085}$ per \$10,000. Party size pushes travellers towards the car, most sharply away from the bus. The likelihood ratio statistic against the intercept-only model is $2(-253.3408 + 283.7588) = 60.836$ on six degrees of freedom.

```
import numpy as np
import statsmodels.api as sm

MODES = ["air", "train", "bus", "car"]          # car is category 4, the baseline

raw = sm.datasets.modechoice.load_pandas().data
chosen = raw[raw["choice"] == 1].sort_values("individual").reset_index(drop=True)
y = chosen["mode"].astype(int).to_numpy()      # 1 air, 2 train, 3 bus, 4 car
n, c = len(y), 4
X = np.column_stack([np.ones(n), chosen["hinc"] / 10.0, chosen["psize"]])
Y = np.zeros((n, c))
Y[np.arange(n), y - 1] = 1.0                  # indicator matrix, baseline last

print("chosen mode counts:", Y.sum(axis=0))
```

The fit itself is [Theorem 36.1.2](#) written out: build the probabilities, form the score and the block information, solve, repeat.

```
def probs(X, B):
    """Fitted probabilities of the baseline-category logit model; B is p x (c-1)."""
    eta = np.column_stack([X @ B, np.zeros(len(X))]) # baseline has eta = 0
    eta = eta - eta.max(axis=1, keepdims=True)       # stabilize the
    exponentials
    E = np.exp(eta)
    return E / E.sum(axis=1, keepdims=True)

def loglik(X, Y, B):
    return float(np.sum(Y * np.log(probs(X, B))))

def mnlogit(X, Y, tol=1e-10, maxit=50):
    """Newton-Raphson (= Fisher scoring, the link is canonical) for baseline logits.
    """
    n, p = X.shape
    c = Y.shape[1]
    B = np.zeros((p, c - 1))
```

```

for it in range(1, maxit + 1):
    P = probs(X, B)
    U = (X.T @ (Y[:, :c - 1] - P[:, :c - 1])).T.ravel()      # score, stacked
    by category
    J = np.zeros(((c - 1) * p, (c - 1) * p))                # expected =
    observed information
    for r in range(c - 1):
        for s in range(c - 1):
            w = P[:, r] * ((r == s) - P[:, s])
            J[r * p:(r + 1) * p, s * p:(s + 1) * p] = X.T @ (w[:, None] * X)
        step = np.linalg.solve(J, U)
        B = B + step.reshape(c - 1, p).T
        if np.max(np.abs(step)) < tol:
            break
    return B, J, it

B, J, iters = mnlogit(X, Y)
se = np.sqrt(np.diag(np.linalg.inv(J))).reshape(c - 1, X.shape[1]).T

for r in range(c - 1):
    print(f"{MODES[r]:>6s} vs car: " + " ".join(f"{b:7.4f} ({s:.4f})" for b, s in
        zip(B[:, r], se[:, r])))
print(f"log-likelihood {loglik(X, Y, B):.4f} after {iters} Newton steps")

```

The script behind this section checks the output against the `MNLogit` routine of `statsmodels`, coefficient by coefficient. It also carries out the substitution of [Proposition 36.1.3](#), refitting with train as the baseline and confirming that subtracting the train column from the fitted coefficient matrix reproduces the refit and leaves every fitted probability unchanged.

```

# changing the baseline: subtract the train column (category 2) from every column
Btrain = B - B[:, [1]]
Btrain = np.delete(np.column_stack([Btrain, -B[:, 1]]), 1, axis=1)      # drop train
    , add car
Ytrain = Y[:, [0, 2, 3, 1]]      # put train
    last
Bcheck, _, _ = mnlogit(X, Ytrain)

print("air vs train, refitted :", np.round(Bcheck[:, 0], 6))
print("air vs train, subtracted:", np.round(Btrain[:, 0], 6))
print("fitted probabilities identical:", np.allclose(probs(X, Bcheck[:, [0, 3, 1,
    2]], probs(X, B)))

```

[Figure 36.1.1](#) plots the fitted probabilities against income, and the bus curve in the left panel is [Proposition 36.1.4](#) made visible: the coefficient of income in the bus logit is -0.3033 , yet the fitted probability of the bus *rises* over the first twenty thousand dollars before falling. At an income of \$10,000 with a party of one the fitted probabilities are (0.1528, 0.5243, 0.2182, 0.1047) for air, train, bus and car, with derivatives per \$10,000 of (0.0606, -0.1111 , 0.0126, 0.0378); the car, whose coefficient is fixed at zero, has the second largest of the four, behind air alone.

```

# the derivative of a fitted probability is not the coefficient
Bfull = np.column_stack([B, np.zeros(X.shape[1])])      # append the baseline's
    column of zeros
x0 = np.array([1.0, 1.0, 1.0])      # income $10,000, party
    of one
p0 = probs(x0[None, :], B)[0]

```

Figure 36.1.1: Fitted mode probabilities from the baseline-category logit model, against household income, for a traveller alone (left) and in a party of three (right). Coefficients are log odds ratios against the car; the curves show what those coefficients do to the probabilities themselves.

```
dp0 = p0 * (Bfull[1] - p0 @ Bfull[1]) # d pi_r / d (income in
    $10,000s)

print("fitted probabilities", np.round(p0, 4))
print("derivatives", np.round(dp0, 4))
print("income coefficients ", np.round(Bfull[1], 4))
```

Remark (Fitting one logit at a time). It is tempting to estimate β_r by discarding every observation outside $\{r, c\}$ and running an ordinary binary logistic regression. By [Eq. 36.1.4](#),

$$P(Y_i = r \mid Y_i \in \{r, c\}, \mathbf{x}_{(i)}) = \frac{\pi_{ir}}{\pi_{ir} + \pi_{ic}} = \frac{e^{\mathbf{x}_{(i)}^\top \beta_r}}{1 + e^{\mathbf{x}_{(i)}^\top \beta_r}},$$

so the conditional model is exactly the binary logistic model of [Definition 35.1.1](#) with the same β_r , and the individualized fit is consistent. It is not efficient, and the $c - 1$ fits are correlated in a way the separate outputs do not report. Begg and Gray (1984) quantified the loss, small when the baseline is a large category and severe otherwise.

36.1.6 Inference

The argument of [Theorem 34.5.1](#) carries over verbatim in block notation, although the theorem there is stated for a scalar response: by [Theorem 36.1.2](#) the score is again a sum of independent mean-zero vectors, the information is again nonrandom, and the global concavity its proof leans on is [Theorem 36.1.2\(c\)](#). Under the analogues of its conditions — categories and regressors fixed, sample size growing, the leverages of the stacked design tending to zero, the true parameter interior — the maximum likelihood estimate is consistent and asymptotically normal with covariance the inverse information; nested models are compared by the analysis of deviance of [Theorem 34.5.5](#).

Two cautions are specific to categorical responses. The deviance is *not* a goodness-of-fit statistic for ungrouped data: when every $m_i = 1$ the saturated model has as many parameters as obser-

vations and the χ^2 approximation fails, as [Theorem 34.5.5](#) says in general and [Proposition 35.4.1](#) for binary data. And a regressor is not one coefficient here but $c - 1$, so “does income matter?” has $c - 1$ degrees of freedom; testing the coefficients separately and reporting the smallest p -value is the multiplicity error of [Chapter 13](#) in a new costume.

36.1.7 Exercises

36.1.7.1 A. Check your understanding

Exercise A1.

A response has $c = 5$ categories and the model matrix has $p = 4$ columns including the intercept. How many free coefficients has the baseline-category logit model? How many has the saturated model for n ungrouped observations? How many degrees of freedom does the test that one regressor may be dropped have?

Solution. The model has $(c - 1)p = 16$ free coefficients. The saturated model for ungrouped data gives each observation its own probability vector, $n(c - 1)$ free parameters. Dropping one regressor removes one coefficient from each of the $c - 1$ logits, so the test has $c - 1 = 4$ degrees of freedom.

36.1.7.2 B. Practice

Exercise B1.

From the fitted coefficients of [Example \(Choosing how to travel\)](#), compute the estimated log odds ratio of bus against train per \$10,000 of income, and the estimated odds ratio of air against bus per extra person in the party. State which of these depend on the choice of baseline.

Solution. By [Proposition 36.1.3](#) the bus-against-train income coefficient is $-0.3033 - (-0.5731) = 0.2698$, so the odds of bus rather than train rise by a factor $e^{0.2698}$ per \$10,000. For party size, air against bus is $-0.6006 - (-0.9404) = 0.3398$, an odds ratio of $e^{0.3398}$. Neither depends on the baseline: by [Proposition 36.1.3\(a\)](#) a difference of coefficients is the pairwise log odds ratio $\log(\pi_{ir}/\pi_{ir'})$ per unit of the regressor, which the model specifies without reference to any baseline.

Exercise B2.

Show directly that the $c \times c$ matrix $\Sigma(\boldsymbol{\pi}) = \text{diag}(\boldsymbol{\pi}) - \boldsymbol{\pi}\boldsymbol{\pi}^\top$ is nonnegative definite with $\Sigma\mathbf{1} = \mathbf{0}$, and that its restriction to the first $c - 1$ coordinates is positive definite when every $\pi_r > 0$.

Solution. For any $\mathbf{t}$, $\mathbf{t}^\top \Sigma \mathbf{t} = \sum_r \pi_r t_r^2 - (\sum_r \pi_r t_r)^2$ is the variance of a random variable taking the value t_r with probability π_r , hence nonnegative, and it vanishes iff all t_r with $\pi_r > 0$ are equal. Taking $\mathbf{t} = \mathbf{1}$ gives $\Sigma\mathbf{1} = \mathbf{0}$. If $\mathbf{t}$ has $t_c = 0$ and $\mathbf{t}^\top \Sigma \mathbf{t} = 0$, then all t_r are equal to $t_c = 0$; so the leading $(c - 1) \times (c - 1)$ block is positive definite.

36.1.7.3 C. Going deeper

Exercise C1.

The **adjacent-category logit model** for an ordered response specifies $\log(\pi_{i,r+1}/\pi_{ir}) = \theta_r + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ for $r = 1, \dots, c-1$, with $\mathbf{x}_{(i)}$ not containing an intercept. Show that it is the baseline-category model [Definition 36.1.1](#) with slope vectors $\boldsymbol{\beta}_r = (c-r)\boldsymbol{\beta}^*$ for a single vector $\boldsymbol{\beta}^*$, plus a free intercept for each r : a submodel obtained by $(c-2)p$ linear restrictions, fitted with the same software after recoding the model matrix.

Solution. Summing the adjacent logits from r to $c-1$ gives $\log(\pi_{ic}/\pi_{ir}) = \sum_{s=r}^{c-1} \theta_s + (c-r)\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, so $\log(\pi_{ir}/\pi_{ic}) = -\sum_{s \geq r} \theta_s - (c-r)\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. This is [Eq. 36.1.4](#) with a free intercept for each r and slope vector proportional to $\boldsymbol{\beta}^* = -\boldsymbol{\beta}$ with the known factor $c-r$. Fitting is a baseline-category fit on the model matrix whose slope block for logit r is $(c-r)\mathbf{X}$.

Exercise C2.

Show that in [Definition 36.1.1](#) the ratio $\pi_{ir}/\pi_{ir'}$ does not involve any third category — the *independence of irrelevant alternatives*. Construct a three-category example in which this is substantively absurd, and say what the assumption forces about the fitted probabilities when a new category is added that is nearly a copy of an existing one.

36.2 Cumulative logit models

Suppose the c categories are ordered: none, mild, severe; strongly disagree through strongly agree; extremely liberal through extremely conservative. The baseline-category model of [Section 36.1](#) fits such data perfectly well — it fits *any* categorical response — but throws the ordering away. It spends $(c-1)p$ coefficients where a model that knows the order can often spend p , and its fit is unchanged if the category labels are shuffled. That last property is the diagnosis: a likelihood invariant to permuting the categories cannot be using the order.

36.2.1 Cutting the scale

The device that uses the ordering is to *cut*: for each r between 1 and $c-1$, collapse the response into the binary event $\{Y_i \leq r\}$ and model its probability. Write

$$\gamma_{ir} = P(Y_i \leq r \mid \mathbf{x}_{(i)}) = \pi_{i1} + \dots + \pi_{ir}, \quad r = 1, \dots, c-1, \quad (36.2.1)$$

for the **cumulative probabilities**, with $\gamma_{i0} = 0$ and $\gamma_{ic} = 1$. The category probabilities are recovered by differencing, $\pi_{ir} = \gamma_{ir} - \gamma_{i,r-1}$, so modelling the $c-1$ cumulative probabilities is modelling the whole distribution.

Definition 36.2.1 — Cumulative link model

Let G be a continuous, strictly increasing distribution function on $\mathbb{R}$ and let $\mathbf{x}_{(i)}$ be a vector of p regressors *without* an intercept. The **cumulative link model** is

$$G^{-1}(\gamma_{ir}) = \theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r, \quad r = 1, \dots, c-1, \quad (36.2.2)$$

with **cutpoints** $\theta_1, \dots, \theta_{c-1}$ and slope vectors $\boldsymbol{\beta}_1, \dots, \boldsymbol{\beta}_{c-1}$. With $G = \Lambda$, the standard logistic distribution function $\Lambda(z) = e^z / (1 + e^z)$, [Eq. 36.2.2](#) is the **cumulative logit model**

$$\log \frac{P(Y_i \leq r \mid \mathbf{x}_{(i)})}{P(Y_i > r \mid \mathbf{x}_{(i)})} = \theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r;$$

with $G = \Phi$ it is the **cumulative probit model**, and with $G(z) = 1 - \exp(-e^z)$ the **cumulative complementary log-log model**. The special case $\boldsymbol{\beta}_1 = \dots = \boldsymbol{\beta}_{c-1} = \boldsymbol{\beta}$ is the **proportional odds model** when $G = \Lambda$, and is the subject of [Section 36.3](#).

Two conventions deserve comment. The intercept is not in $\mathbf{x}_{(i)}$ because the cutpoints already play that role: shifting every θ_r and a hypothetical intercept by the same constant would change nothing, so the two cannot both be free. And the minus sign before $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r$ is worth the confusion it causes once, because it makes a *positive* coefficient mean “larger values of this regressor push the response towards the higher categories”. The cutpoints are unconstrained parameters only if the model is coherent, which is the one real difficulty of this family.

36.2.2 The ordering constraint**Proposition 36.2.1 — Cutpoints must stay in order**

[Eq. 36.2.2](#) defines a probability distribution over the c categories at $\mathbf{x}_{(i)}$ if and only if

$$\theta_1 - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_1 < \theta_2 - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_2 < \dots < \theta_{c-1} - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_{c-1}. \quad (36.2.3)$$

If the slopes are common, $\boldsymbol{\beta}_r = \boldsymbol{\beta}$ for all r , this reduces to $\theta_1 < \dots < \theta_{c-1}$, a constraint on the parameters alone. If the slopes differ, the constraint involves $\mathbf{x}_{(i)}$, and for any two cuts with $\boldsymbol{\beta}_r \neq \boldsymbol{\beta}_{r+1}$ there are values of $\mathbf{x}$ at which it fails.

Proof. The category probabilities are $\pi_{ir} = \gamma_{ir} - \gamma_{i,r-1}$, so they are all positive exactly when $\gamma_{i1} < \dots < \gamma_{i,c-1}$, and they automatically sum to one. Since G is strictly increasing, this is [Eq. 36.2.3](#). With common slopes the terms $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ cancel from every inequality. If $\mathbf{d} = \boldsymbol{\beta}_{r+1} - \boldsymbol{\beta}_r \neq \mathbf{0}$, the r th inequality reads $\mathbf{x}^\top \mathbf{d} < \theta_{r+1} - \theta_r$, a half-space; any $\mathbf{x}$ far enough in the direction $\mathbf{d}$ violates it. ■

Warning (What the constraint costs). The proportional odds model is safe: the constraint holds for every $\mathbf{x}$ at once, and by [Exercise \(B1\)](#) it is satisfied automatically at the maximum likelihood estimate. A model with cut-specific slopes is *not* a model over

the whole of $\mathbb{R}^p$, only on the region where [Eq. 36.2.3](#) holds; one fits it, checks that the fitted probabilities are positive wherever one intends to predict, and reports the check. For a concrete failure take $c = 3$, one regressor, $\theta_1 = 0$, $\beta_1 = 1$, $\theta_2 = 1$, $\beta_2 = 2$: at $x = 0$ the linear predictors are 0 and 1, in order; at $x = 2$ they are -2 and -3 , out of order, and the fitted probability of the middle category is negative.

36.2.3 Fitting

The cumulative link model is not a generalized linear model in the strict sense of [Definition 34.2.1](#): the response is a vector and the parameters are shared across its $c - 1$ coordinates in a way no single link expresses. The likelihood machinery survives intact, because the response is still multinomial and the mean is still a smooth function of the parameters.

Proposition 36.2.2 — Score and expected information for a smooth mean

Let $\mathbf{Y}_i \sim \text{Mult}(m_i, \boldsymbol{\pi}_i)$ independently, $i = 1, \dots, n$, with $\boldsymbol{\pi}_i = \boldsymbol{\pi}_i(\boldsymbol{\psi})$ a smooth function of a parameter $\boldsymbol{\psi} \in \mathbb{R}^q$ and every $\pi_{ir} > 0$. Write $\tilde{\boldsymbol{\pi}}_i$ for the first $c - 1$ probabilities, $\mathbf{D}_i = \partial \tilde{\boldsymbol{\pi}}_i / \partial \boldsymbol{\psi}^\top$ and $\mathbf{V}_i = \text{diag}(\tilde{\boldsymbol{\pi}}_i) - \tilde{\boldsymbol{\pi}}_i \tilde{\boldsymbol{\pi}}_i^\top$. Then the score and the expected information are

$$\mathbf{u}(\boldsymbol{\psi}) = \sum_{i=1}^n \mathbf{D}_i^\top \mathbf{V}_i^{-1} (\tilde{\mathbf{y}}_i - m_i \tilde{\boldsymbol{\pi}}_i), \quad \mathbf{J}(\boldsymbol{\psi}) = \sum_{i=1}^n m_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i. \quad (36.2.4)$$

Proof. The inverse of $\mathbf{V}_i$ is $\text{diag}(1/\tilde{\boldsymbol{\pi}}_i) + \pi_{ic}^{-1} \mathbf{1}\mathbf{1}^\top$, as multiplying out and using $\mathbf{1}^\top \tilde{\boldsymbol{\pi}}_i = 1 - \pi_{ic}$ shows. Also $\partial \ell / \partial \boldsymbol{\psi} = \sum_i \sum_{r < c} (y_{ir} / \pi_{ir}) \partial \pi_{ir} / \partial \boldsymbol{\psi}$. Fix i , drop it from the notation, and substitute the inverse:

$$\mathbf{D}^\top \mathbf{V}^{-1} (\tilde{\mathbf{y}} - m \tilde{\boldsymbol{\pi}}) = \sum_{r < c} \frac{\partial \pi_r}{\partial \boldsymbol{\psi}} \frac{y_r - m \pi_r}{\pi_r} + \left(\sum_{r < c} \frac{\partial \pi_r}{\partial \boldsymbol{\psi}} \right) \frac{\sum_{s < c} (y_s - m \pi_s)}{\pi_c}.$$

Because the probabilities sum to one, $\sum_{r < c} \partial \pi_r / \partial \boldsymbol{\psi} = -\partial \pi_c / \partial \boldsymbol{\psi}$, and because the counts sum to m , $\sum_{s < c} (y_s - m \pi_s) = -(y_c - m \pi_c)$. The second term is therefore $(\partial \pi_c / \partial \boldsymbol{\psi})(y_c - m \pi_c) / \pi_c$, and the two terms combine into $\sum_{r < c} (\partial \pi_r / \partial \boldsymbol{\psi})(y_r - m \pi_r) / \pi_r$, which equals $\sum_{r < c} (y_r / \pi_r) \partial \pi_r / \partial \boldsymbol{\psi}$ since $\sum_r \partial \pi_r / \partial \boldsymbol{\psi} = \mathbf{0}$. Summing over i gives the score. For the information, $\text{Cov}(\tilde{\mathbf{Y}}_i) = m_i \mathbf{V}_i$ by [Lemma 36.1.1](#), and the summands of the score are independent with mean zero, so $\text{Cov}(\mathbf{u}) = \sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} (m_i \mathbf{V}_i) \mathbf{V}_i^{-1} \mathbf{D}_i = \sum_i m_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i$. ■

For [Eq. 36.2.2](#) the derivatives are immediate: writing $\eta_{ir} = \theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r$ and $g = G'$ for the density,

$$\frac{\partial \gamma_{ir}}{\partial \theta_s} = g(\eta_{ir}) \delta_{rs}, \quad \frac{\partial \gamma_{ir}}{\partial \boldsymbol{\beta}_s} = -g(\eta_{ir}) \mathbf{x}_{(i)} \delta_{rs},$$

and $\mathbf{D}_i$ is obtained by differencing these rows. Fisher scoring $\boldsymbol{\psi} \leftarrow \boldsymbol{\psi} + \mathbf{J}^{-1} \mathbf{u}$ converges quickly from ordered starting cutpoints and zero slopes. Because [Eq. 36.2.4](#) has the form “derivative of the mean, weighted by the inverse covariance, times the residual”, each step is again a weighted

least squares fit — the block-weighted version of [Theorem 34.4.1](#) and [Proposition 20.6.1](#) — with $\mathbf{V}_i$ in the place of scalar weights.

Remark (Why the fitting is well behaved). Suppose the link density $g = G'$ is log-concave, as it is for the logistic, the normal and the extreme-value distribution behind the complementary log-log link. Then

$$G(a) - G(b) = \int g(u) \mathbf{1}\{b < u \leq a\} du$$

integrates over u a function of (u, a, b) that is log-concave on $\mathbb{R}^3$, being a log-concave function of u times the indicator of a convex set; a marginal of a log-concave function is log-concave, so $\log\{G(a) - G(b)\}$ is concave on $\{b < a\}$. The observation in category r contributes $\log\{G(\eta_{ir}) - G(\eta_{i,r-1})\}$ with η_{ir} affine in the parameters, so the log-likelihood is concave on the region where [Eq. 36.2.3](#) holds at the observed $\mathbf{x}_{(i)}$ — an intersection of half-spaces, hence convex. That is Pratt (1981) and Burridge (1981). Concavity excludes local maxima that are not global, which is what makes scoring from any ordered start dependable; by itself it gives neither existence nor uniqueness, and with cut-specific slopes the region it holds on is cut out by the data.

Remark (Asymptotics, and what they rest on). This is not the canonical-link generalized linear model [Theorem 34.5.1](#) is stated for, so that theorem cannot be quoted here. What holds is the standard theory of maximum likelihood in a smooth parametric model: suppose the model is correctly specified and identifiable, c and p are fixed, $\boldsymbol{\psi}^0$ is interior to the region where [Eq. 36.2.3](#) holds, G is twice continuously differentiable with $g > 0$, the regressors are bounded, and $n^{-1}\mathbf{J}(\boldsymbol{\psi}) \rightarrow \mathbf{J}_\infty$ positive definite uniformly near $\boldsymbol{\psi}^0$. Then with probability tending to one the likelihood equations have a consistent solution, and $\sqrt{n}(\hat{\boldsymbol{\psi}} - \boldsymbol{\psi}^0)$ converges in distribution to $N_q(\mathbf{0}, \mathbf{J}_\infty^{-1})$, with the three statistics of [Proposition 34.5.3](#) behaving as they do there.

We do not prove it; treat it as imported. Its first two steps are those of [Theorem 34.5.1](#) — a Lyapunov limit theorem for the score, which [Proposition 36.2.2](#) exhibits as a sum of independent mean-zero terms, and a uniform quadratic expansion on compacts — but not its third, which used the global concavity of a canonical-link generalized linear model. For the classical treatment see van der Vaart (1998, chapter 5) or Lehmann and Casella (1998, chapter 6). Nothing here is exact in finite samples.

36.2.4 Where people place themselves

Example. (A seven-point scale)

The 1996 American National Election Study asked 944 respondents to place themselves on a seven-point scale from extremely liberal (1) to extremely conservative (7); the counts are 16, 103, 147, 256, 170, 218 and 34. With the respondent's age in decades, a seven-point education scale and a twenty-four-point household income scale as regressors, Fisher scoring for the common-slope cumulative logit model converges in 11 steps to

	age (decades)	education	income
$\hat{\beta}$	0.0942	−0.1249	0.0276

Figure 36.2.1: The fitted cumulative logit model for self-placement, as a function of age at education 4 and income 17. (a) The six cumulative logits are parallel, because the model gives them a common slope. (b) The same fit as category probabilities.

standard error	0.0357	0.0395	0.0104
z	2.637	-3.166	2.641

with cutpoints $\hat{\theta} = (-3.7744, -1.6378, -0.6159, 0.5580, 1.3625, 3.6442)$, in order as [Proposition 36.2.1](#) requires, and maximized log-likelihood -1613.8558 . Older and richer respondents place themselves further to the right, more educated respondents further to the left: each decade of age multiplies the odds of a higher placement by 1.0988, each step up the education scale by 0.8826. Whether one should believe a single common slope is the question of [Section 36.3](#), and for these data the answer turns out to be no.

[Figure 36.2.1](#) shows what the fit says. Panel (a) plots the six fitted cumulative logits against age: exactly parallel lines, which is what a common slope means. Panel (b) differences them into the seven category probabilities, whose bands shift smoothly to the right as age increases and can never cross — the ordering constraint in picture form.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

NAMES = ["age (decades)", "education", "income"]

anes = sm.datasets.anes96.load_pandas().data
y = anes["selfLR"].astype(int).to_numpy()          # 1 = extremely liberal ... 7 =

print(f"log-likelihood {ll_po:.4f} after {iters} Fisher scoring steps")

```

The script checks the fit, cutpoint by cutpoint, against the `OrderedModel` routine of `statsmodels`.

36.2.5 Choosing the link

The three links of [Definition 36.2.1](#) are close over the middle of the probability range and differ in the tails, as in the binary case ([Proposition 35.2.1](#)). Two things are specific to ordinal data. First, the *direction* of the scale is arbitrary. Relabelling the categories in reverse order maps the logit and probit models to themselves with β and the cutpoints negated ([Exercise \(A1\)](#)), but turns the complementary log-log model into a different one, the log-log model; with an asymmetric link the analysis depends on which end of the scale was called “1”, and the choice must be justified.

Second, the complementary log-log link has an interpretation the others lack. With $G(z) = 1 - \exp(-e^z)$ and common slopes, [Eq. 36.2.2](#) gives

$$P(Y_i > r \mid \mathbf{x}_{(i)}) = \exp\{-e^{\theta_r} e^{-\mathbf{x}_{(i)}^\top \beta}\} = [P(Y > r \mid \mathbf{0})]^{\exp(-\mathbf{x}_{(i)}^\top \beta)}, \quad (36.2.5)$$

so the regressors act multiplicatively on the cumulative hazard of the underlying scale: the grouped-data version of the proportional hazards model of Cox (1972). If the ordered categories are intervals of a survival time, reach for it.

36.2.6 Exercises

36.2.6.1 A. Check your understanding

Exercise A1.

Verify the claim that reversing the category order maps the cumulative logit model to itself with $\boldsymbol{\beta}$ and the cutpoints negated, and find what it does to the complementary log-log model.

Solution. Let $Y' = c + 1 - Y$. Then $\{Y' \leq r\} = \{Y \geq c + 1 - r\} = \{Y > c - r\}$, so $\gamma'_{ir} = 1 - \gamma_{i,c-r}$. Since $\Lambda^{-1}(1 - u) = -\Lambda^{-1}(u)$, $\Lambda^{-1}(\gamma'_{ir}) = -\theta_{c-r} + \mathbf{x}^\top \boldsymbol{\beta}$, which is [Eq. 36.2.2](#) with cutpoints $-\theta_{c-r}$ (still increasing in r) and slope $-\boldsymbol{\beta}$. The same works for Φ . For $G(z) = 1 - \exp(-e^z)$ the identity $G^{-1}(1 - u) = -G^{-1}(u)$ fails, and $G^{-1}(1 - u) = \log(-\log u)$ defines the log-log link, a different family.

36.2.6.2 B. Practice

Exercise B1.

Show that in the proportional odds model the maximum likelihood estimate automatically satisfies $\hat{\theta}_1 < \cdots < \hat{\theta}_{c-1}$, provided every category is observed, so the ordering constraint never binds. (Hint: what is the likelihood if two cutpoints coincide or cross?)

Solution. The likelihood is defined only where [Eq. 36.2.3](#) holds, and $\pi_{ir} \rightarrow 0$ for some i and r as the boundary $\theta_r = \theta_{r+1}$ is approached. If category r is observed at least once, some $y_{ir} > 0$ and $\ell \rightarrow -\infty$ there. Since ℓ is continuous on the open region and tends to $-\infty$ at the part of its boundary where two cutpoints meet, any maximizer lies in the interior, where the cutpoints are strictly ordered.

Exercise B2.

The cumulative logit model is unchanged if the latent scale is multiplied by a positive constant a and shifted by b , provided $\theta_r \mapsto a\theta_r + b$ and $\boldsymbol{\beta} \mapsto a\boldsymbol{\beta}$. Deduce that only *ratios* of coefficients, and the standardized distances between cutpoints, are free of the arbitrary scale — and that a coefficient from a logit fit is not comparable with a coefficient from a probit fit without rescaling by roughly 1.8, the standard deviation of the logistic distribution.

Exercise B3.

Refit [Example \(A seven-point scale\)](#) after collapsing the seven categories into three (1–3, 4, 5–7) and again after dichotomizing at the middle category. Compare the three sets of slopes and their standard errors, and say which comparison is a check on the model and which is a statement about information.

Solution. The estimates from the three fits are $(0.0942, -0.1249, 0.0276)$, $(0.1350, -0.1148, 0.0343)$ and $(0.1229, -0.0311, 0.0398)$, with standard errors that grow as categories are merged. That they estimate the *same* parameters is the collapsing invariance proved in [Section](#)

36.3 — a check on the model, since it holds only if the proportional odds model is true. That the standard errors grow is a statement about information: collapsing throws data away.

36.2.6.3 C. Going deeper

Exercise C1.

Suppose an underlying continuous response U_i follows the linear model $U_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \varepsilon_i$ with ε_i having distribution function G , but U_i is recorded only as the interval $(\theta_{r-1}, \theta_r]$ it falls in, with *known* cutpoints. Write down the log-likelihood, show it is the cumulative link model with the cutpoints held fixed, and say what is gained by knowing them (Exercise (B2)).

36.3 Proportional odds and its checks

Setting $\boldsymbol{\beta}_1 = \cdots = \boldsymbol{\beta}_{c-1} = \boldsymbol{\beta}$ in Eq. 36.2.2 turns $(c-1)p$ slopes into p . With the logistic link the result is the model that carries the name of its most conspicuous consequence.

Theorem 36.3.1 — The proportional odds model

Let

$$\log \frac{P(Y_i \leq r \mid \mathbf{x}_{(i)})}{P(Y_i > r \mid \mathbf{x}_{(i)})} = \theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \quad r = 1, \dots, c-1. \quad (36.3.1)$$

Then:

- (a) (*latent variable*) Eq. 36.3.1 holds exactly when there is a latent response $U_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \varepsilon_i$, with ε_i independent of $\mathbf{x}_{(i)}$ and standard logistic, and $Y_i = r$ precisely when $\theta_{r-1} < U_i \leq \theta_r$, where $-\infty = \theta_0 < \theta_1 < \cdots < \theta_{c-1} < \theta_c = \infty$. Replacing the logistic distribution by any continuous, strictly increasing G gives the general cumulative link model of Definition 36.2.1 with common slopes;
- (b) (*collapsing*) let $0 = a_0 < a_1 < \cdots < a_k = c$ be integers and define the coarsened response $Y_i^* = j$ when $a_{j-1} < Y_i \leq a_j$. Then Y_i^* follows the proportional odds model with the *same* $\boldsymbol{\beta}$ and cutpoints $\theta_j^* = \theta_{a_j}$, $j = 1, \dots, k-1$. In particular dichotomizing at any cut r gives a binary logistic model with slope $\boldsymbol{\beta}$;
- (c) (*coherence*) the ordering constraint Eq. 36.2.3 reduces to $\theta_1 < \cdots < \theta_{c-1}$ and so holds at every $\mathbf{x}$ at once;
- (d) (*interpretation*) for any two regressor vectors and every r ,

$$\frac{\text{odds}(Y > r \mid \mathbf{x}_2)}{\text{odds}(Y > r \mid \mathbf{x}_1)} = \exp\{(\mathbf{x}_2 - \mathbf{x}_1)^\top \boldsymbol{\beta}\}, \quad (36.3.2)$$

a single odds ratio that does not depend on r ; and if $(\mathbf{x}_2 - \mathbf{x}_1)^\top \boldsymbol{\beta} > 0$ then the response at $\mathbf{x}_2$ is stochastically larger than the response at $\mathbf{x}_1$.

Proof.

- (a) If such a latent variable exists, then $P(Y_i \leq r) = P(U_i \leq \theta_r) = P(\varepsilon_i \leq \theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}) = \Lambda(\theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})$, which is Eq. 36.3.1 after taking logits, since $\log\{\Lambda(z)/(1 - \Lambda(z))\} = z$. Conversely, given Eq. 36.3.1, define U_i by the displayed construction with ε_i standard logistic; the computation just made shows that the induced distribution of Y_i is the one specified by the model, and the cutpoints are increasing by (c).
- (b) The events are nested: $\{Y_i^* \leq j\} = \{Y_i \leq a_j\}$, directly from the definition. Hence $P(Y_i^* \leq j \mid \mathbf{x}_{(i)}) = \gamma_{i,a_j}$, and applying the logit to both sides, $\log\{\gamma_{i,a_j}/(1 - \gamma_{i,a_j})\} = \theta_{a_j} - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. This is Eq. 36.3.1 for Y^* with cutpoints θ_{a_j} , which are increasing because the θ_r are, and with $\boldsymbol{\beta}$ untouched. Taking $k = 2$, $a_1 = r$ gives the binary statement.
- (c) Substitute $\boldsymbol{\beta}_r = \boldsymbol{\beta}$ into Eq. 36.2.3: the terms $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ cancel, leaving $\theta_1 < \dots < \theta_{c-1}$, a condition on the parameters alone. This is the case already recorded in Proposition 36.2.1.
- (d) From Eq. 36.3.1, $\text{odds}(Y \leq r \mid \mathbf{x}) = \exp(\theta_r - \mathbf{x}^\top \boldsymbol{\beta})$, so $\text{odds}(Y > r \mid \mathbf{x}) = \exp(\mathbf{x}^\top \boldsymbol{\beta} - \theta_r)$ and the ratio is $\exp\{(\mathbf{x}_2 - \mathbf{x}_1)^\top \boldsymbol{\beta}\}$; the cutpoint cancels, which is the whole content of Eq. 36.3.2. If $(\mathbf{x}_2 - \mathbf{x}_1)^\top \boldsymbol{\beta} > 0$ the ratio exceeds one for every r , so $P(Y > r \mid \mathbf{x}_2) > P(Y > r \mid \mathbf{x}_1)$ for every r : stochastic dominance.

■

Idea. Part (b) is why the model is worth having: the slope means the same thing however finely the scale was cut, so studies using three categories and seven are comparable. It is also the model's exposed flank, since *every* dichotomization must give that slope.

Warning (What proportional odds does not say). Eq. 36.3.2 is about *cumulative* odds. It does not say that a unit of x has the same effect on every category probability: differencing $\pi_{ir} = G(\eta_{ir}) - G(\eta_{i,r-1})$ gives $\partial\pi_{ir}/\partial\mathbf{x} = \{g(\eta_{i,r-1}) - g(\eta_{ir})\} \boldsymbol{\beta}$, whose sign changes as r moves across the distribution. Nor does it say that the latent variable of part (a) exists in any physical sense: the construction is a *device for generating the model*, always available once the model holds, and it carries no empirical content. Claims that the latent scale is “really” attitude, utility or severity are claims about the world, and reading $\boldsymbol{\beta}$ causally needs the whole apparatus of Chapter 25.

36.3.1 Checking the assumption

The restriction is $(c - 2)p$ linear constraints on the unrestricted cumulative model, so the three statistics of Proposition 34.5.3 are all available. The likelihood ratio and Wald tests need the unrestricted model, which by Proposition 36.2.1 may not be fittable; the score test needs only the restricted fit, which always is.

Proposition 36.3.2 — Testing and diagnosing the proportional odds restriction

Let $A \subseteq \{1, \dots, p\}$ index the regressors whose slopes are allowed to vary, and embed Eq. 36.3.1 in the cumulative logit model $\text{logit } \gamma_{ir} = \theta_r - \mathbf{x}_{(i)}^\top (\boldsymbol{\beta} + \boldsymbol{\delta}_r)$, where $\boldsymbol{\delta}_1 = \mathbf{0}$

and δ_r is supported on A for $r \geq 2$. Write $\boldsymbol{\psi} = (\boldsymbol{\theta}, \boldsymbol{\beta}, \boldsymbol{\delta})$ and let $\hat{\boldsymbol{\psi}}_0$ be the maximum likelihood estimate under $\boldsymbol{\delta} = \mathbf{0}$. Then, under the regularity conditions recorded in Section 36.2 and if Eq. 36.3.1 holds:

- (a) the score statistic $S_{\text{sc}} = \mathbf{u}(\hat{\boldsymbol{\psi}}_0)^\top \mathbf{J}(\hat{\boldsymbol{\psi}}_0)^{-1} \mathbf{u}(\hat{\boldsymbol{\psi}}_0)$, with $\mathbf{u}$ and $\mathbf{J}$ from Eq. 36.2.4, is computable from the restricted fit alone, equals $\mathbf{u}_\delta^\top [\mathbf{J}^{-1}]_{\delta\delta} \mathbf{u}_\delta$, and converges in distribution to χ^2 with $(c-2)|A|$ degrees of freedom;
- (b) the likelihood ratio and Wald statistics for the same hypothesis have the same limit and are asymptotically equivalent to S_{sc} ;
- (c) the $c-1$ separate binary logistic regressions of $\mathbf{1}\{Y_i \leq r\}$ on $\mathbf{x}_{(i)}$ estimate the same $\boldsymbol{\beta}$, so plotting their slopes with confidence intervals shows where any departure lies. The $c-1$ fits are dependent, so the plot is a diagnostic and not a test.

Proof.

- (a) By definition of a maximum, the components of $\mathbf{u}(\hat{\boldsymbol{\psi}}_0)$ in the $(\boldsymbol{\theta}, \boldsymbol{\beta})$ block vanish: those are the likelihood equations of the restricted model, which is the full model with $\boldsymbol{\delta}$ held at zero. Writing $\mathbf{u} = (\mathbf{0}^\top, \mathbf{u}_\delta^\top)^\top$ and partitioning $\mathbf{J}^{-1}$ conformably gives the stated reduction. That $\mathbf{u}^\top \mathbf{J}^{-1} \mathbf{u}$ has the χ^2 limit with degrees of freedom the number of restrictions is the score-test half of Proposition 34.5.3, which for a generalized linear model is proved there and holds here by the same argument applied to the likelihood of Proposition 36.2.2, under the conditions imported in Section 36.2; the restrictions number $(c-2)|A|$, one vector δ_r of length $|A|$ for each of the cuts $r = 2, \dots, c-1$.
- (b) The asymptotic equivalence of the three statistics is Proposition 34.5.3, and it carries over under the same imported conditions; the hypothesis is a linear restriction on a parameter interior to the parameter space.
- (c) Dichotomizing at cut r gives, by Theorem 36.3.1(b), the binary logistic model $\text{logit } P(Y \leq r) = \theta_r - \mathbf{x}^\top \boldsymbol{\beta}$, with intercept θ_r and the same $\boldsymbol{\beta}$. Each fit is therefore a correctly specified binary logistic regression under the null and its estimate is consistent for $\boldsymbol{\beta}$ by Theorem 34.5.1. The fits use overlapping data, so their errors are correlated, which is why they cannot simply be pooled or differenced into a test.

■

Brant (1990) turns (c) into a test by estimating the joint covariance of the $c-1$ slope estimates — they solve stacked estimating equations, so a sandwich-type covariance in the spirit of Theorem 21.4.2 is available — and forming a Wald statistic for their equality. It tests the same null hypothesis and has the same chi-squared limit. It is *not* the score statistic, it is built from different estimating equations, and the two can differ appreciably in small samples.

Warning (The test is not the question). With n in the thousands the score test rejects departures too small to matter; with n in the dozens it misses departures that would change every conclusion. The plot in (c) answers the useful question — *how much* do the slopes move, and where. Report both.

36.3.2 Self-placement, checked

Figure 36.3.1: Slopes from the six separate binary logistic fits of $\mathbf{1}\{Y \leq r\}$ on the three regressors, with 95% intervals; the horizontal line and band are the proportional odds estimate and its interval. Under proportional odds the six points scatter about the line (Proposition 36.3.2). Education does not.

Example. (The proportional odds model does not hold)

The common odds ratio of Theorem 36.3.1(d) is worth having only if it is there. For Example (A seven-point scale), let all three slopes vary across the six cuts. The score statistic of Proposition 36.3.2 is 67.667 on 15 degrees of freedom, $p = 1.16 \times 10^{-8}$; the likelihood ratio statistic against the fitted unrestricted model is 67.420, agreeing to within half a percent as Proposition 36.3.2(b) predicts. One regressor at a time, on $c - 2 = 5$ degrees of freedom:

regressor	score statistic	p	likelihood ratio
age	17.542	3.58×10^{-3}	18.367
education	41.258	8.32×10^{-8}	40.190
income	20.056	1.22×10^{-3}	20.155

Education is the main offender. Figure 36.3.1 shows why: its slope is near -0.3 at the three lowest cuts, near 0 at cuts 4 and 5, and back near -0.3 at cut 6. Education sharply separates the liberal end of the scale from everything above it, says almost nothing about position within the upper middle, and then separates the extreme conservative category again. That is a fact about the data, and a single number cannot express it.

The cells on this page continue those of Section 36.2; this first one repeats the data and the fitting routine so that the page runs on its own.

36.3.3 When it fails

Rejecting proportional odds is information, not a disaster. The options, roughly in order of how much they give up.

Partial proportional odds. Free the slopes of the offending regressors only, as in [Proposition 36.3.2](#), keeping the restriction for the rest: the model of Peterson and Harrell (1990). It

costs the coherence guarantee, so [Proposition 36.2.1](#) must now be checked at every $\mathbf{x}$ of interest. Freeing education alone raises the log-likelihood to -1593.7610 , a likelihood ratio statistic of 40.190 on five degrees of freedom ($p = 1.37 \times 10^{-7}$), and lowers Akaike’s criterion ([Definition 29.2.2](#)) from 3245.71 to 3215.52; the fully unrestricted model reaches 3208.29 with ten more parameters. The fitted education slopes by cut are -0.2683 , -0.2988 , -0.2523 , -0.0206 , -0.0498 and -0.2970 , and every fitted probability stays positive.

```
# partial proportional odds: education alone gets cut-specific slopes
psi_pp, J_pp, _ = cum_fit(X, Y, c, free=(1,))
ll_pp = cum_loglik(psi_pp, X, Y, c, (1,))
educ_slopes = np.concatenate([[psi_pp[c - 1 + 1]], psi_pp[c - 1 + 1] + psi_pp[c - 1
    + p:]])

aic = lambda ll, k: -2 * ll + 2 * k
print("education slope by cut:", np.round(educ_slopes, 4))
print("AIC proportional odds %.2f | partial %.2f | unrestricted %.2f"
      % (aic(ll_po, c - 1 + p), aic(ll_pp, len(psi_pp)), aic(ll_np, len(psi_np))))
```

A different link. Non-proportionality is sometimes link misspecification in disguise: the three links disagree in the tails ([Proposition 35.2.1](#)), so data can satisfy a cumulative probit or complementary log-log model with common slopes while violating the logit version. Trying the other two costs nothing.

A scale effect. Let the latent variable of [Theorem 36.3.1\(a\)](#) have a dispersion that depends on the regressors, $\log \sigma(\mathbf{x}) = \mathbf{x}^\top \boldsymbol{\gamma}$. The cumulative logits become $(\theta_r - \mathbf{x}^\top \boldsymbol{\beta})e^{-\mathbf{x}^\top \boldsymbol{\gamma}}$, non-parallel in a particular way: they fan out rather than crossing arbitrarily ([Exercise \(B2\)](#)). This costs p parameters instead of $(c - 2)p$, and when it fits, “the effect is the same but the responses are more spread out here” is a far more useful statement than a table of slopes.

A different family. Data that violate proportional odds badly may satisfy a sequential model ([Section 36.4](#)) with common slopes; failing that, the baseline-category model abandons the ordering but is never wrong about it.

Report the cuts. Sometimes no single number describes the effect, and the honest answer is [Proposition 36.3.2\(c\)](#). What is *not* a remedy is keeping the proportional odds fit and repairing its standard errors with a sandwich estimator: [Theorem 21.4.2](#) fixes the variance of an estimator whose target is still well defined, and here the target itself has evaporated.

36.3.4 Exercises

36.3.4.1 A. Check your understanding

Exercise A1.

A proportional odds model has $c = 4$ and $p = 3$. How many parameters does it have? How many does the model with cut-specific slopes have, and what are the degrees of freedom of the score test of [Proposition 36.3.2](#) with $A = \{1, 2, 3\}$ and with $A = \{2\}$?

Exercise A2.

In a proportional odds fit the coefficient of a treatment indicator is $\hat{\beta} = 0.7$. Write down three correct sentences and one common incorrect one.

Solution. Correct: the odds that a treated subject exceeds any fixed level are $e^{0.7} \approx 2$ times the odds for a control; the same factor applies at every level; the treated response is stochastically larger. Incorrect: “treatment doubles the probability of each category” — the effect on a category probability is a difference of two logistic densities times $\hat{\beta}$, and changes sign across the scale.

36.3.4.2 B. Practice

Exercise B1.

Using [Theorem 36.3.1\(b\)](#), predict what happens to the estimated slopes when the seven categories of [Example \(A seven-point scale\)](#) are collapsed to three, and compare with the actual refit in [Exercise \(B3\)](#). Does the comparison support or undermine the proportional odds assumption here?

Solution. Under the model the collapsed fit estimates the same β , so the two should differ only by sampling error, the collapsed one being less precise. The education slope moves from -0.1249 to -0.1148 , small against its standard error of 0.0416 , and the age slope from 0.0942 to 0.1350 , about one standard error: mild evidence at worst. Collapsing to three categories hides the failure that the cut-by-cut plot makes obvious, so a check should use all the cuts.

Exercise B2.

Derive the cumulative logits of the scale-effect model $U_i = \mathbf{x}_{(i)}^\top \beta + \sigma(\mathbf{x}_{(i)})\varepsilon_i$, $\log \sigma(\mathbf{x}) = \mathbf{x}^\top \gamma$, with ε_i standard logistic. Show that it contains [Eq. 36.3.1](#) as the case $\gamma = \mathbf{0}$, and that its cumulative logits never cross as functions of $\mathbf{x}$.

Solution. $P(Y_i \leq r) = P(\varepsilon_i \leq (\theta_r - \mathbf{x}^\top \beta)e^{-\mathbf{x}^\top \gamma})$, so $\text{logit } \gamma_{ir} = (\theta_r - \mathbf{x}^\top \beta)e^{-\mathbf{x}^\top \gamma}$, which is [Eq. 36.3.1](#) when $\gamma = \mathbf{0}$. For two cuts $r < s$ the difference of the cumulative logits is $(\theta_r - \theta_s)e^{-\mathbf{x}^\top \gamma}$, which has the sign of $\theta_r - \theta_s$ for every $\mathbf{x}$, since the exponential is positive: the curves fan out but never cross, so the ordering constraint of [Proposition 36.2.1](#) holds everywhere.

36.3.4.3 C. Going deeper

Exercise C1.

Show that if the proportional odds model holds and $\beta_j > 0$, then $E\{h(Y) \mid \mathbf{x}\}$ is increasing in x_j for *every* nondecreasing function h . Deduce that the sign of β_j is a statement that survives any recoding of the categories into numbers, as long as the recoding respects the order.

Solution. By [Theorem 36.3.1\(d\)](#), increasing x_j makes the response stochastically larger. Stochastic dominance is equivalent to $E\{h(Y) \mid \mathbf{x}_2\} \geq E\{h(Y) \mid \mathbf{x}_1\}$ for every nondecreasing h : write $E h(Y) = h(1) + \sum_{r=1}^{c-1} \{h(r+1) - h(r)\}P(Y > r)$, a sum of nonnegative

coefficients times the survivor probabilities, each of which increases. Since any order-respecting scoring of the categories is such an h , the sign of β_j cannot be reversed by rescaling.

Exercise C2.

Let [Theorem 36.3.1](#) hold with a single binary regressor, let Y_1 and Y_2 be independent responses from the two groups, and let U_1, U_2 be the latent variables of part (a) of that theorem.

- Show that $P(U_2 > U_1) = E\{\Lambda(\beta - \varepsilon)\}$ with ε standard logistic, so that it is a function of β alone and strictly increasing in it.
- Show that the concordance probability of the *observed* responses, $P(Y_2 > Y_1) + \frac{1}{2}P(Y_2 = Y_1)$, is increasing in β for fixed cutpoints. (Hint: write it as $E\{h(Y_2)\}$ for a nondecreasing h that depends only on the distribution of Y_1 .) Then evaluate it at $\beta = 1$ for $c = 3$ with cutpoints $(-0.5, 0.5)$ and again with $(-3, 3)$, and conclude that, unlike the odds ratio e^β , it is not free of the cutpoints.
- The sample version of (b) is the Mann–Whitney statistic divided by $n_1 n_2$, with ties counted half. Say in what sense the proportional odds model is a regression version of the Wilcoxon–Mann–Whitney test, and in what sense it is not.

Solution.

- $U_2 - U_1 = \beta + \varepsilon_2 - \varepsilon_1$, so $P(U_2 > U_1) = P(\varepsilon_1 < \beta + \varepsilon_2) = E\{\Lambda(\beta + \varepsilon_2)\}$, which is $E\{\Lambda(\beta - \varepsilon)\}$ by symmetry of the logistic law. No cutpoint appears, and Λ is strictly increasing, so this increases strictly with β ; at $\beta = 1$ it is 0.6613.
- Conditioning on Y_1 gives $E\{h(Y_2)\}$ with $h(b) = P(Y_1 < b) + \frac{1}{2}P(Y_1 = b)$, nondecreasing in b and depending only on the distribution of Y_1 — which does not involve β , group one being the reference. Raising β makes Y_2 stochastically larger by [Theorem 36.3.1\(d\)](#), and $E\{h(Y_2)\}$ then increases, by the equivalence used in [Exercise \(C1\)](#). It is not a function of β alone: at $\beta = 1$ the cutpoints $(-0.5, 0.5)$ give 0.6370 and $(-3, 3)$ give 0.5482, while e^β is the same in both. Widely spaced cutpoints push mass into the middle category, so ties are common and the concordance probability is pulled towards $\frac{1}{2}$.
- It is a regression version in that the two-group comparison is the same stochastic-ordering comparison, extended to several regressors and to adjustment. It is not, in two ways: the rank test is distribution free where the model imposes proportional odds at every cut, a real restriction by [Example \(The proportional odds model does not hold\)](#); and what the model reports is β , not the concordance probability, which by (b) cannot be recovered from β without the cutpoints.

36.4 Sequential models

The cumulative models of the last two sections treat an ordered response as a coarsened continuum. Some ordered responses are not like that. A student reaches a master's degree only by passing through a bachelor's; an unemployment spell reaches its second year only by surviving its first. There the categories are *stages*, reached in order, and each stage is a decision taken by

those who got that far. A model built on that picture asks, for each stage, a question conditional on having reached it.

Definition 36.4.1 — Sequential model

With $\mathbf{Y}_i \sim \text{Mult}(m_i, \boldsymbol{\pi}_i)$ as in Definition 36.1.1, let

$$\delta_{ir} = P(Y_i = r \mid Y_i \geq r, \mathbf{x}_{(i)}), \quad r = 1, \dots, c-1, \quad (36.4.1)$$

be the **continuation ratios**, or discrete stopping probabilities. The **sequential model** with link F^{-1} is

$$\delta_{ir} = F(\theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_r), \quad r = 1, \dots, c-1, \quad (36.4.2)$$

for a continuous, strictly increasing distribution function F . With $F = \Lambda$ and common slopes $\boldsymbol{\beta}_r = \boldsymbol{\beta}$ it is the **continuation-ratio logit model**. The category probabilities are

$$\pi_{ir} = \delta_{ir} \prod_{s < r} (1 - \delta_{is}) \quad (r < c), \quad \pi_{ic} = \prod_{s < c} (1 - \delta_{is}). \quad (36.4.3)$$

Two features are visible at once. The sequential model is *not* symmetric in the direction of the scale: reversing the categories reverses which conditional probabilities are modelled. And the cutpoints are completely free, since Eq. 36.4.3 delivers a probability distribution for *any* θ_r and $\boldsymbol{\beta}_r$. There is no analogue of the ordering constraint Eq. 36.2.3, so cut-specific slopes cost nothing in coherence here, where in a cumulative model they cost the model's existence.

36.4.1 The likelihood falls apart

Theorem 36.4.1 — Factorization of the sequential likelihood

Let $R_{ir} = \sum_{s > r} y_{is}$ be the number of subjects at covariate pattern i still “at risk” at stage r , so that $R_{i1} = m_i$ and $R_{ir} = y_{ir} + R_{i,r+1}$. Under Definition 36.4.1,

$$\prod_{r=1}^c \pi_{ir}^{y_{ir}} = \prod_{r=1}^{c-1} \delta_{ir}^{y_{ir}} (1 - \delta_{ir})^{R_{i,r+1}}. \quad (36.4.4)$$

Consequently:

- (a) the log-likelihood is $\ell = \sum_{r=1}^{c-1} \ell_r$, where $\ell_r(\theta_r, \boldsymbol{\beta}_r) = \sum_i \{y_{ir} \log \delta_{ir} + R_{i,r+1} \log(1 - \delta_{ir})\}$ is the log-likelihood of a binary regression with R_{ir} trials and y_{ir} successes;
- (b) if the parameters $(\theta_r, \boldsymbol{\beta}_r)$ of different stages are unrestricted and distinct, the maximum likelihood estimate is obtained by $c-1$ *separate* binary regressions, one on the subjects at risk at each stage; the information matrix is block diagonal, and the estimates for different stages are asymptotically independent;

- (c) $Y_{ir} \mid R_{ir} \sim \text{Bin}(R_{ir}, \delta_{ir})$, and these conditional distributions determine the multinomial law.

Proof. Count exponents on the two sides of Eq. 36.4.4. On the left, substituting Eq. 36.4.3, the factor δ_{ir} appears only in π_{ir} for $r < c$, with exponent y_{ir} . The factor $(1 - \delta_{is})$ appears in π_{ir} for every $r > s$ and in π_{ic} , so its total exponent is $\sum_{r>s} y_{ir} = R_{i,s+1}$. That is exactly Eq. 36.4.4.

- (a) Take logarithms of Eq. 36.4.4 and sum over i ; by Eq. 36.4.2 the r th term involves only $(\theta_r, \boldsymbol{\beta}_r)$, and since $R_{ir} = y_{ir} + R_{i,r+1}$, the r th term is the binomial log-likelihood with R_{ir} trials, y_{ir} successes and success probability δ_{ir} , up to a term free of the parameters.
- (b) A sum of functions of disjoint groups of parameters is maximized by maximizing each separately, and its second derivative matrix is block diagonal with the r th block $\partial^2 \ell_r / \partial(\theta_r, \boldsymbol{\beta}_r)^{\otimes 2}$. Taking expectations, the information is block diagonal, so by Theorem 34.5.1 the joint limiting distribution of the stacked estimate is normal with block diagonal covariance: the stages are asymptotically independent.
- (c) Write the multinomial mass function as $P(\mathbf{Y}_i = \mathbf{y}_i) = h(\mathbf{y}_i) \prod_r \pi_{ir}^{y_{ir}}$ and use Eq. 36.4.4. The combinatorial factor h likewise factors as $\prod_{r<c} \binom{R_{ir}}{y_{ir}}$, because choosing which subjects stop at each stage in turn is the same as choosing the whole allocation. So the mass function is the product of $c - 1$ binomial mass functions with the stated parameters.

■

Idea. A sequential model is barely a multinomial model at all: it is $c - 1$ binary regressions with a shared parameterization. Separation (Theorem 35.3.1), the links (Proposition 35.2.1), residuals (Proposition 35.4.1) and case-control sampling of Theorem 35.5.1 apply stage by stage, with no new theory.

Corollary 36.4.2 — One regression on expanded data

Let the slopes be common, $\boldsymbol{\beta}_r = \boldsymbol{\beta}$, and the data ungrouped ($m_i = 1$). Build an expanded data set with one row for each pair (i, r) with $r \leq \min(y_i, c - 1)$, response $\mathbf{1}\{y_i = r\}$, and regressors $(\mathbf{e}_r, -\mathbf{x}_{(i)})$, where $\mathbf{e}_r$ is the r th coordinate vector of length $c - 1$. Then an ordinary binary regression with link F^{-1} on the expanded data has, as a function of $(\boldsymbol{\theta}, \boldsymbol{\beta})$, the log-likelihood of the sequential model; the two fits, their standard errors and their tests coincide.

Proof. With $m_i = 1$, $y_{ir} = \mathbf{1}\{y_i = r\}$ and $R_{i,r+1} = \mathbf{1}\{y_i > r\}$. The (i, r) term of Eq. 36.4.4 is δ_{ir} when $y_i = r$, $1 - \delta_{ir}$ when $y_i > r$, and 1 when $y_i < r$, so the rows with $r > \min(y_i, c - 1)$ contribute nothing and may be dropped. The surviving rows contribute exactly the Bernoulli likelihood with success probability $\delta_{ir} = F(\theta_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})$, which is the model with linear predictor $(\mathbf{e}_r, -\mathbf{x}_{(i)})^\top (\boldsymbol{\theta}^\top, \boldsymbol{\beta}^\top)^\top$.

■

The expanded data set has $\sum_i \min(y_i, c - 1)$ rows, one per stage each subject reached. That rows from the same subject are not independent looks alarming and is not a problem: Theorem 36.4.1

says the likelihood is *exactly* the product over rows — a factorization, not an approximation.

36.4.2 The complementary log-log link joins the two families

The cumulative and sequential families are genuinely different — except at one link, where they are the same.

Proposition 36.4.3 — Sequential and cumulative complementary log-log models agree

Take $F(z) = 1 - \exp(-e^z)$ and common slopes. If the sequential model Eq. 36.4.2 holds with cutpoints $\tilde{\theta}_1, \dots, \tilde{\theta}_{c-1}$, then the cumulative complementary log-log model Eq. 36.2.2 holds with the same $\boldsymbol{\beta}$ and cutpoints

$$\theta_r = \log\left(\sum_{s \leq r} e^{\tilde{\theta}_s}\right), \quad r = 1, \dots, c-1, \quad (36.4.5)$$

which are automatically increasing. The map $\tilde{\boldsymbol{\theta}} \mapsto \boldsymbol{\theta}$ is a bijection onto the increasing sequences, so the two models are the same family, and the maximum likelihood fits agree.

Proof. Since $\{Y_i \geq r\} = \{Y_i > r-1\}$,

$$P(Y_i > r \mid Y_i > r-1) = 1 - \delta_{ir} = \exp\{-e^{\tilde{\theta}_r} e^{-\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}\}.$$

Multiplying these for $s = 1, \dots, r$ telescopes to $P(Y_i > r) = \exp\{-H_r e^{-\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}\}$ with $H_r = \sum_{s \leq r} e^{\tilde{\theta}_s}$, so $\log\{-\log P(Y_i > r)\} = \log H_r - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, which is Eq. 36.2.2 with $G(z) = 1 - \exp(-e^z)$ and $\theta_r = \log H_r$. The H_r are strictly increasing because $e^{\tilde{\theta}_s} > 0$, and $\tilde{\theta}_r = \log(H_r - H_{r-1})$ recovers the sequential cutpoints from any increasing $\boldsymbol{\theta}$, with $H_0 = 0$; so the map is a bijection. Two parameterizations of the same set of distributions have the same maximized likelihood. ■

This is the observation of Läärä and Matthews (1985), and it explains why the complementary log-log link is the natural one for stage data: by Eq. 36.2.5 the same model is a grouped proportional hazards model, with δ_{ir} the discrete hazard of stopping at stage r . No such identity holds for the logit link, and Figure 36.4.1 shows how far apart the two families then are.

36.4.3 The two families on the same data

Example. (Self-placement, fitted sequentially)

The self-placement data of Example (A seven-point scale) are not a stage process — nobody becomes extremely conservative by first passing through “extremely liberal” —

Figure 36.4.1: Each family is simple in its own coordinates and curved in the other's. (a) Cumulative logits implied by a sequential logit model with common slopes. (b) Continuation-ratio logits implied by a proportional odds model. Parallel straight lines in one panel would mean the other family contained this one.

but the sequential model is still a parameterization of the seven category probabilities, and comparing the fits shows what each family buys.

The at-risk counts are 944, 928, 825, 678, 422 and 252, and the expanded data set has 4049 rows. One binary logistic regression on it, as in [Corollary 36.4.2](#), gives cut-points $(-3.9705, -1.9870, -1.4252, -0.3784, -0.2744, 1.9824)$ and slopes 0.0454 (age, per decade), -0.0866 (education) and 0.0174 (income), with standard errors 0.0270, 0.0303 and 0.0079. The signs agree with the proportional odds fit and the magnitudes are smaller, as one should expect: these are effects on a single stage transition, not on the whole scale. The multinomial log-likelihood is -1618.2981 , which the script confirms equals the log-likelihood the binary regression reports — [Theorem 36.4.1](#) to machine precision.

Akaike's criterion is 3254.60 for the sequential model against 3245.71 for proportional odds ([Definition 29.2.2](#)): with nine parameters each, the cumulative model describes these data better, as a scale of opinion rather than a ladder of stages should. Letting every stage have its own slopes raises the log-likelihood to -1578.3794 and lowers the criterion to 3204.76, just below the unrestricted cumulative model's 3208.29. Once the common-slope restriction goes, the two families have the same $(c-1)(1+p)$ parameters and fit these data about equally well.

```
import numpy as np
import statsmodels.api as sm

anes = sm.datasets.anes96.load_pandas().data
y = anes["selfLR"].astype(int).to_numpy()
X = np.column_stack([anes["age"] / 10.0, anes["educ"], anes["income"]])
n, p = X.shape
c = 7

def seq_probs(theta, beta, X, F=lambda z: 1.0 / (1.0 + np.exp(-z))):
    """Category probabilities of the sequential model with  $P(Y = r | Y \geq r) = F(\theta_r - x'\beta)$ ."""
```

```

delta = F(theta[None, :] - (X @ beta)[:, None])
surv = np.column_stack([np.ones(len(X)), np.cumprod(1.0 - delta, axis=1)])
return np.column_stack([delta * surv[:, :-1], surv[:, -1]])

def seq_loglik(theta, beta, X, y, F=lambda z: 1.0 / (1.0 + np.exp(-z))):
    P = seq_probs(theta, beta, X, F)
    return float(np.sum(np.log(P[np.arange(len(y)), y - 1])))

```

With cut-specific slopes the fit is [Theorem 36.4.1\(b\)](#): one logistic regression per stage, on the subjects still at risk.

```

# unrestricted sequential model: one binary logistic fit per stage, on those still
at risk
stage_beta, stage_ll = [], 0.0
for r in range(1, c):
    at_risk = y >= r
    Z = np.column_stack([np.ones(at_risk.sum()), -X[at_risk]])
    fit_r = sm.Logit((y[at_risk] == r).astype(float), Z).fit(dis=0)
    stage_beta.append(np.asarray(fit_r.params))
    stage_ll += fit_r.llf
    print(f"stage {r}: at risk {at_risk.sum():4d}, stop {int((y == r).sum()):4d}, "
          f"theta {fit_r.params[0]:7.4f}, beta {np.round(fit_r.params[1:], 4)}")

print(f"sum of the {c - 1} binary log-likelihoods: {stage_ll:.4f}")

```

With a common slope the fit is [Corollary 36.4.2](#): one logistic regression on the expanded data.

```

# common slope: one binary logistic regression on the expanded data set
rows_X, rows_y = [], []
for i in range(n):
    for r in range(1, min(y[i], c - 1) + 1): # stages this respondent reached
        stage = np.zeros(c - 1)
        stage[r - 1] = 1.0
        rows_X.append(np.concatenate([stage, -X[i]]))
        rows_y.append(float(y[i] == r))
Xe, ye = np.array(rows_X), np.array(rows_y)

fit_seq = sm.Logit(ye, Xe).fit(dis=0)
theta_seq, beta_seq = fit_seq.params[:c - 1], fit_seq.params[c - 1:]
se_seq = fit_seq.bse[c - 1:]
ll_seq = seq_loglik(theta_seq, beta_seq, X, y)

print(f"expanded data: {len(ye)} rows from {n} respondents")
print("cutpoints", np.round(theta_seq, 4))
print("slopes", np.round(beta_seq, 4), "se", np.round(se_seq, 4))
print(f"binary log-likelihood {fit_seq.llf:.4f} = multinomial log-likelihood {ll_seq:.4f}")

```

Changing the link to the complementary log-log turns the same expanded regression into a cumulative model, by [Proposition 36.4.3](#). The script computes the cumulative cutpoints from [Eq. 36.4.5](#) and confirms that the two ways of assembling the category probabilities agree to within 3×10^{-16} .

```

# Laara and Matthews: with a complementary log-log link the sequential model IS a
cumulative model

```

```

c11 = lambda z: 1.0 - np.exp(-np.exp(z))
fit_c11 = sm.GLM(ye, Xe, family=sm.families.Binomial(sm.families.links.CLogLog())).
    fit()
theta_t, beta_c = fit_c11.params[:c - 1], fit_c11.params[c - 1:]
theta_cum = np.log(np.cumsum(np.exp(theta_t)))           # the cumulative
    model's cutpoints

P_step = seq_probs(theta_t, beta_c, X, F=c11)             # built stage by
    stage
gamma_cum = c11(theta_cum[None, :] - (X @ beta_c)[: , None]) # built from
    cumulative probabilities
P_cum = np.diff(np.column_stack([np.zeros(n), gamma_cum, np.ones(n)]), axis=1)

print("sequential cutpoints ", np.round(theta_t, 4))
print("cumulative cutpoints ", np.round(theta_cum, 4))
print("largest difference between the two sets of fitted probabilities:",
    float(np.max(np.abs(P_step - P_cum))))

```

Example. (When the mechanism really is sequential)

Generate 4000 observations from a four-stage sequential logit model with one standard normal regressor, cutpoints $(-0.6, 0, 0.5)$ and slope $\beta = 1$; the category counts come out as 1487, 1094, 693 and 726. The sequential fit recovers the slope as 0.9761, standard error 0.0309. The proportional odds fit of the same data, with the same number of parameters, returns 1.1352, which is not estimating β at all, and Akaike's criterion is 9444.56 against 9515.66. A gap of seventy is not a close call.

The moral is not that one family is better — reverse the simulation and the verdict reverses with it — but that the choice is a modelling decision about *how the response came about*, on which the data have plenty to say.

```

# a mechanism that really is sequential, fitted by both models
def simulate_sequential(n, theta, beta, rng):
    X = rng.normal(size=(n, len(beta)))
    delta = 1.0 / (1.0 + np.exp(-(theta[None, :] - (X @ beta)[: , None])))
    stop = rng.random(delta.shape) < delta
    y = np.where(stop.any(axis=1), stop.argmax(axis=1) + 1, len(theta) + 1)
    return X, y

rng = np.random.default_rng(20360436)
theta0, beta0 = np.array([-0.6, 0.0, 0.5]), np.array([1.0])
Xs, ys = simulate_sequential(4000, theta0, beta0, rng)
print("simulated counts:", np.bincount(ys)[1:])

```

36.4.4 Choosing a family

Three families are now available: the cumulative model ([Definition 36.2.1](#)), the sequential model ([Definition 36.4.1](#)) and, through [Exercise \(C1\)](#), adjacent-category logits. They are non-nested, have the same dimension in their common-slope forms, and often fit real data about equally well, so a criterion such as AIC will decline to choose. The mechanism should choose.

- **Cumulative** when the categories are a graded measurement of something continuous: severity, agreement, quality. Its slope is invariant to how the scale was cut ([Theorem 36.3.1](#)), which makes results comparable across studies.
- **Sequential** when the categories are stages that must be passed through, especially for durations and attainments. Its coefficients describe one transition at a time, and [Theorem 36.4.1](#) makes cut-specific slopes cheap.
- **Adjacent-category** when local comparisons are the meaningful ones: category $r + 1$ rather than r , among those in one of the two.

None of them addresses overdispersion relative to the multinomial. [Chapter 38](#) treats quasi-likelihood and overdispersion, and [Chapter 40](#) the random-effects models that repeated categorical measurements need.

36.4.5 Exercises

36.4.5.1 A. Check your understanding

Exercise A1.

How many parameters has the sequential model with common slopes? With stage-specific slopes? How many rows has the expanded data set of [Corollary 36.4.2](#) when every subject falls in the last category?

Solution. Common slopes: $(c - 1) + p$. Stage-specific: $(c - 1)(1 + p)$. If every $y_i = c$ then each subject contributes $c - 1$ rows, giving $n(c - 1)$; every response in the expanded data is zero, and the fit does not exist — a separation of the kind in [Theorem 35.3.1](#).

Exercise A2.

Show by a three-category example that reversing the order of the categories changes the sequential model, but not the cumulative one ([Exercise \(A1\)](#)).

36.4.5.2 B. Practice

Exercise B1.

Interpret δ_{ir} as a discrete hazard and $\prod_{s \leq r} (1 - \delta_{is})$ as a survivor function. Show that under [Proposition 36.4.3](#) the model says $P(Y_i > r \mid \mathbf{x}_{(i)}) = S_0(r)^{\exp(-\mathbf{x}_{(i)}^\top \boldsymbol{\beta})}$ for a baseline survivor function S_0 , and identify S_0 .

Solution. From the proof of [Proposition 36.4.3](#), $P(Y_i > r) = \exp\{-H_r e^{-\mathbf{x}^\top \boldsymbol{\beta}}\}$, so with $S_0(r) = e^{-H_r}$ we get $P(Y_i > r) = S_0(r)^{\exp(-\mathbf{x}^\top \boldsymbol{\beta})}$. Here S_0 is the survivor function at $\mathbf{x} = \mathbf{0}$ and $H_r = \sum_{s \leq r} e^{\hat{\theta}_s}$ is the baseline cumulative hazard, which is exactly the grouped-data statement [Eq. 36.2.5](#).

36.4.5.3 C. Going deeper

Exercise C1.

Let T_i be a discrete survival time taking values $1, 2, \dots$, possibly right-censored at a known time c_i . Write the likelihood in terms of the discrete hazards $\lambda_{ir} = P(T_i = r \mid T_i \geq r)$, and show that it is again the expanded binary likelihood of [Corollary 36.4.2](#), now with subject-specific numbers of rows. What does censoring correspond to in [Theorem 36.4.1](#)?

Solution. The contribution of an uncensored subject is $\lambda_{i,t_i} \prod_{s < t_i} (1 - \lambda_{is})$ and of a censored one $\prod_{s \leq c_i} (1 - \lambda_{is})$. Both are products of Bernoulli terms over the periods the subject was at risk, so the expanded binary regression fits them, with a censored subject contributing only zero responses. In [Theorem 36.4.1](#) censoring is the case of a subject who is removed from the risk set without stopping: it reduces R_{ir} for later r without adding to any y_{ir} . This is why continuation-ratio models and discrete-time survival models are the same subject.

Exercise C2.

Does the sequential model have a collapsing invariance like [Theorem 36.3.1\(b\)](#)? Show that merging the *last* two categories leaves the model and the remaining parameters intact, but merging any other adjacent pair does not.

36.5 Summary and Notes

36.5.1 Summary

Idea.

1. The multinomial distribution is an exponential family with natural parameters the baseline-category logits, cumulant $b(\boldsymbol{\eta}) = \log(1 + \sum_s e^{\eta_s})$, mean $m\nabla b$ and covariance $m(\text{diag}(\boldsymbol{\pi}) - \boldsymbol{\pi}\boldsymbol{\pi}^\top)$ ([Lemma 36.1.1](#)). The chapter then chooses which $c - 1$ logits to make linear.
2. The baseline-category logit model ([Definition 36.1.1](#)) is the canonical-link generalized linear model for that family: score $\mathbf{X}^\top(\mathbf{y}_r - \boldsymbol{\mu}_r)$ per category, observed information equal to expected, and a log-likelihood strictly concave when $\text{rank}(\mathbf{X}) = p$, so the maximum is unique when it exists ([Theorem 36.1.2](#)).
3. Changing the baseline is a linear reparameterization, leaving estimates, fitted values, the maximized likelihood and the standard errors of contrasts unchanged ([Proposition 36.1.3](#)). A coefficient is a log odds ratio against the baseline, not a derivative of a probability ([Proposition 36.1.4](#)).
4. For an ordered response, modelling $P(Y \leq r)$ uses the ordering ([Definition 36.2.1](#)). Fitted probabilities are positive only where the linear predictors stay in order: automatic with common slopes, a real restriction without them ([Proposition 36.2.1](#)). Score and expected information are $\sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1}(\tilde{\mathbf{y}}_i - m_i \tilde{\boldsymbol{\pi}}_i)$ and $\sum_i m_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i$ ([Proposition 36.2.2](#)), and the log-likelihood is concave when the link density is log-concave.

5. The proportional odds model has a latent-variable derivation, slopes that survive any collapsing of adjacent categories, cutpoints that never need constraining, and one odds ratio applying at every cut ([Theorem 36.3.1](#)). The collapsing invariance is also how it is checked.
6. That restriction is tested by a score statistic computed from the restricted fit alone, on $(c - 2)|A|$ degrees of freedom, and diagnosed by plotting the slopes of the $c - 1$ dichotomized fits ([Proposition 36.3.2](#)). When it fails: partial proportional odds, a different link, a scale effect, a different family, or an honest table of slopes.
7. A sequential model ([Definition 36.4.1](#)) models the probability of stopping at each stage. Its likelihood factors into $c - 1$ binomial likelihoods, so with stage-specific slopes it is $c - 1$ separate binary regressions with asymptotically independent estimates ([Theorem 36.4.1](#)), and with a common slope one binary regression on expanded data ([Corollary 36.4.2](#)). No ordering constraint is needed.
8. With the complementary log-log link the two ordinal families coincide, cutpoints related by a cumulative sum on the exponential scale ([Proposition 36.4.3](#)): the grouped-data proportional hazards model. With the logit link they differ, and the data can tell them apart.

36.5.2 Notes and sources

Coverage. The topics follow Agresti (2015, chapter 6) and Fahrmeir, Kneib, Lang and Marx (2021, §6.2–6.3); the treatment, proofs, examples and exercises are our own.

Baseline-category logits. The model grew up independently in biostatistics and econometrics. McFadden (1974) derived it from random utility maximization, which is the source of the name *multinomial logit* and of the discrete-choice literature; the underlying axiom is Luce’s (1959), and the independence of irrelevant alternatives in [Exercise \(C2\)](#) is its most famous consequence and problem. McFadden’s conditional logit model, in which regressors vary by category, is the standard extension, not treated here. Existence of the maximum likelihood estimate is settled by Albert and Anderson (1984); [Theorem 35.3.1](#) is the binary case. The individualized fits of the remark in [Section 36.1](#) are analysed by Begg and Gray (1984).

Cumulative models. Modelling cumulative probabilities with a common slope goes back to Walker and Duncan (1967). McCullagh (1980) named the proportional odds model and gave the latent-variable derivation, the general cumulative link family and the invariance properties of [Theorem 36.3.1](#); McCullagh and Nelder (1989, chapter 5) is a compressed version. Anderson (1984) introduced a different ordinal family, the *stereotype* model, which estimates category scores rather than assuming them. That the log-likelihood of a cumulative link model is concave whenever the link density is log-concave was proved by Pratt (1981) and, for grouped data specifically, by Burrridge (1981); it is the reason Fisher scoring is as docile here as it is. The asymptotics of [Section 36.2](#) are imported rather than proved, this model not being a generalized linear model; the standard accounts are van der Vaart (1998) and Lehmann and Casella (1998). Agresti (2010) is the book-length treatment, and covers the scale-effect models of [Section 36.3](#) and the connection with rank statistics in [Exercise \(C2\)](#).

Checking proportional odds. The score test of [Proposition 36.3.2](#) is the one most software reports; Brant (1990) gave the Wald version based on the separate dichotomized fits, which is where the habit of plotting them comes from; it tests the same hypothesis as the score statistic but is a different statistic. Partial proportional odds models are due to Peterson and Harrell (1990), who also noted that such fits can produce negative probabilities — the failure of

Proposition 36.2.1.

Sequential models. Continuation-ratio logits go back to Fienberg (1980); the sequential formulation used here, with a link and a linear predictor at each stage, is Tutz’s (1991). Fahrmeir and Tutz (2001) and Tutz (2012) give the textbook treatments, the latter with a taxonomy of ordinal models built out of binary ones. The factorization of [Theorem 36.4.1](#) is the algebra that underlies discrete-time survival analysis, where the stages are time intervals and the continuation ratios are hazards; the continuous-time ancestor is Cox (1972), and [Proposition 36.4.3](#), due to Läärä and Matthews (1985), connects the two.

Data. Both examples use public-domain data shipped with statsmodels: the travel-mode data of [Example \(Choosing how to travel\)](#) come from the online archive of Greene’s econometrics text, and [Example \(A seven-point scale\)](#) uses an extract of the 1996 American National Election Study, whose education and income variables are ordered scales treated here as numerical scores. Treating them as factors changes the coefficients but no conclusion about proportional odds. Neither example is a causal statement, for the reasons in [Chapter 25](#).

What is missing. Responses clustered, repeated or overdispersed relative to [Lemma 36.1.1](#) need more than this chapter offers: [Chapter 38](#) takes up quasi-likelihood and overdispersion, [Chapter 40](#) random effects and estimating equations, and [Chapter 39](#) Bayesian fitting, where the latent variable of [Theorem 36.3.1\(a\)](#) becomes a data augmentation scheme.

Chapter 37

Counts

A count has no upper bound, cannot be negative, and is nearly always more variable when it is large than when it is small. The linear model fits none of these descriptions and no transformation repairs all of them at once. The generalized linear model does better: put the linear predictor on the log scale, so that the mean is multiplicative, and let the distribution supply a variance that grows with the mean. That is the Poisson log-linear model, the starting point of this chapter.

It is only a starting point. Real counts are almost always more variable than the Poisson allows, often have far more zeros, and are sometimes not a sample of independent events at all but a contingency table in disguise. Each complaint has a model attached to it: exposure and rates, the exact connection between Poisson counts and multinomial proportions, the negative binomial, and the two standard ways to model an excess of zeros.

What you need. [Chapter 34](#) (the generalized linear model: [Definition 34.2.1](#), the likelihood equations [Theorem 34.3.1](#), iteratively reweighted least squares [Theorem 34.4.1](#), the deviance [Definition 34.5.1](#) and [Theorem 34.5.5](#), and the three test statistics [Proposition 34.5.3](#)). [Chapter 35](#) supplies the separation theorem [Theorem 35.3.1](#), whose Poisson counterpart is [Proposition 37.1.3](#), and [Chapter 36](#) the baseline-category logit model [Definition 36.1.1](#), which [Section 37.3](#) shows is a log-linear model in disguise. From earlier parts: the two-way layout and its interaction ([Definition 16.2.1](#) and [Proposition 16.2.1](#)), variance-stabilizing transformations ([Theorem 22.4.1](#)), the sandwich covariance estimator ([Theorem 21.4.2](#)), the likelihood ratio test on the boundary of the parameter space ([Theorem 32.5.2](#)), and model selection by AIC and BIC ([Definition 29.2.2](#)).

37.0.1 Roadmap

- [Poisson regression](#)
- [Offsets and rates](#)
- [Poisson and multinomial](#)
- [Negative binomial models](#)
- [Zero inflation](#)
- [Summary and notes](#)

37.1 Poisson regression

Counts are nonnegative integers, their spread grows with their level, and a regressor acts on them multiplicatively. No transformation satisfies all three at once ([Chapter 22](#)): the square root of a Poisson count has nearly constant variance but a mean no longer linear in the regressors, the logarithm a nearly linear mean but a variance that still moves ([Exercise \(B2\)](#)), and neither is defined at zero. The generalized linear model separates the requirements: the link takes the mean, the distribution takes the variance, and nothing is done to the data.

37.1.1 The Poisson as an exponential dispersion family

Write the Poisson mass function in the form [Definition 34.1.1](#) asks for. For $y = 0, 1, 2, \dots$ and $\mu > 0$,

$$\Pr(Y = y) = \frac{e^{-\mu} \mu^y}{y!} = \exp\{y \log \mu - \mu - \log y!\},$$

so the natural parameter is $\theta = \log \mu$, the cumulant function is $b(\theta) = e^\theta$, the dispersion is $\phi = 1$ and the weight is $w = 1$. By [Proposition 34.1.2](#),

$$E(Y) = b'(\theta) = e^\theta = \mu, \quad \text{Var}(Y) = \phi b''(\theta) = e^\theta = \mu,$$

so the variance function is $V(\mu) = \mu$. The Poisson has no free dispersion parameter: once the mean is fixed, so is the variance. That is the most consequential fact in this chapter, and [Sections 37.4](#) and [37.5](#) are about what to do when the data disagree with it. The canonical link $\theta = \log \mu$ also makes the mean multiplicative and keeps it positive at every linear predictor: for once convenience and interpretation point the same way.

Definition 37.1.1 — The Poisson log-linear model

Let $Y_1, \dots, Y_n$ be independent, with Y_i Poisson distributed with mean $\mu_i > 0$, and let $\mathbf{x}_{(i)}$ be the i th row of a model matrix $\mathbf{X}$ of full column rank p . The **Poisson log-linear model** is the generalized linear model ([Definition 34.2.1](#)) with this random component, the log link and the linear predictor $\eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$:

$$\log \mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \quad \text{equivalently} \quad \mu_i = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}) = e^{\beta_1 x_{i1}} \dots e^{\beta_p x_{ip}}. \quad (37.1.1)$$

The second form carries the interpretation. Increasing the j th regressor by one unit, the others held anywhere, multiplies the mean by e^{β_j} , the **rate ratio** of that regressor. It does not depend on the levels of the others, which is the log-scale version of “no interaction”.

Remark (The identity link). Nothing forces the log link. The model $\mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ gives regressors additive effects on the count, which is sometimes the question asked: an intervention that prevents three events a year, not one that cuts events by ten per cent. The price is a constrained parameter space, since $\mathbf{x}_{(i)}^\top \boldsymbol{\beta} > 0$ is needed for every i and the constraint can bind at the maximum ([Exercise \(C1\)](#)).

37.1.2 The likelihood equations

Theorem 37.1.1 — The Poisson likelihood equations

In the model of [Definition 37.1.1](#) the log-likelihood is

$$\ell(\boldsymbol{\beta}) = \sum_{i=1}^n \{y_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta} - \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\} - \sum_{i=1}^n \log y_i!, \quad (37.1.2)$$

and, writing $\boldsymbol{\mu} = \boldsymbol{\mu}(\boldsymbol{\beta})$ for the vector of means and $\mathbf{W} = \text{diag}(\mu_1, \dots, \mu_n)$:

- (a) the score is $\partial\ell/\partial\boldsymbol{\beta} = \mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu})$, so the likelihood equations are $\mathbf{X}^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \mathbf{0}$;
- (b) the observed and expected information coincide and equal $\mathbf{X}^\top \mathbf{W} \mathbf{X}$;
- (c) ℓ is concave, and strictly concave when $\text{rank}(\mathbf{X}) = p$, so a stationary point is the unique maximum.

Proof. The Poisson has $\phi = 1$, $w_i = 1$, $V(\mu) = \mu$ and, under the canonical link, $\partial\mu_i/\partial\eta_i = \mu_i$. Substituting these in [Theorem 34.3.1](#)(d) gives the score $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu})$ and observed information equal to expected information $\mathbf{X}^\top \text{diag}\{w_i V(\mu_i)\} \mathbf{X} = \mathbf{X}^\top \mathbf{W} \mathbf{X}$, which are (a) and (b). For (c), that Hessian is nonnegative definite because $\mathbf{a}^\top \mathbf{X}^\top \mathbf{W} \mathbf{X} \mathbf{a} = \sum_i \mu_i (\mathbf{x}_{(i)}^\top \mathbf{a})^2 \geq 0$, and the sum vanishes only if $\mathbf{X} \mathbf{a} = \mathbf{0}$, since every $\mu_i > 0$. Under full column rank that forces $\mathbf{a} = \mathbf{0}$, so ℓ is strictly concave. ■

The general score of [Theorem 34.3.1](#) carries a factor $(\partial\mu_i/\partial\eta_i)/V(\mu_i)$, here $\mu_i/\mu_i = 1$; what is left has the form of the normal equations $\mathbf{X}^\top(\mathbf{y} - \hat{\mathbf{Y}}) = \mathbf{0}$, with the fitted mean vector in place of the projection $\mathbf{M}\mathbf{y}$. The residual $\mathbf{y} - \hat{\boldsymbol{\mu}}$ is orthogonal to every column of $\mathbf{X}$, although $\hat{\boldsymbol{\mu}}$ is not a linear function of $\mathbf{y}$ and there is no projection in sight ([Exercise \(B2\)](#)).

Theorem 37.1.2 — Fitted values reproduce observed margins

Let $\hat{\boldsymbol{\mu}}$ solve the likelihood equations of [Theorem 37.1.1](#). Then $\mathbf{x}_j^\top \hat{\boldsymbol{\mu}} = \mathbf{x}_j^\top \mathbf{y}$ for every column $\mathbf{x}_j$ of $\mathbf{X}$, and more generally $\mathbf{a}^\top \hat{\boldsymbol{\mu}} = \mathbf{a}^\top \mathbf{y}$ for every $\mathbf{a} \in \mathcal{C}(\mathbf{X})$. In particular:

- (a) if the model has an intercept, the fitted counts sum to the observed total, $\sum_i \hat{\mu}_i = \sum_i y_i$;
- (b) if $\mathbf{X}$ contains the indicator of a group G , the fitted counts of that group sum to its observed total, $\sum_{i \in G} \hat{\mu}_i = \sum_{i \in G} y_i$;
- (c) if $\mathbf{X}$ contains a quantitative regressor $\mathbf{x}_j$, the fitted counts reproduce the observed $\mathbf{x}_j$ -weighted total.

Proof. The column identities are [Corollary 34.3.2](#) with $w_i = 1$: the likelihood equations say $\mathbf{X}^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \mathbf{0}$, that is, $\mathbf{x}_j^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = 0$ for each j . The extension to $\mathcal{C}(\mathbf{X})$ is linearity: any $\mathbf{a} \in \mathcal{C}(\mathbf{X})$ is $\mathbf{X}\mathbf{c}$ for some $\mathbf{c}$, and $\mathbf{a}^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \mathbf{c}^\top \mathbf{X}^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = 0$. Parts (a), (b) and

(c) are this statement for $\mathbf{a} = \mathbf{1}$, for the group indicator, and for $\mathbf{x}_j$.

■

This is what makes log-linear models for contingency tables behave so tidily; [Section 37.3](#) uses it throughout.

37.1.3 When the maximum likelihood estimate exists

Strict concavity says that a maximum, if attained, is unique; not that one is attained. The log-likelihood [Eq. 37.1.2](#) can increase along a ray for ever, and then the fitting algorithm diverges. The condition below is the Poisson counterpart of separation in logistic regression ([Theorem 35.3.1](#)).

Proposition 37.1.3 — Existence of the maximum likelihood estimate

Let $\text{rank}(\mathbf{X}) = p$. The log-likelihood [Eq. 37.1.2](#) attains its maximum at a finite $\hat{\boldsymbol{\beta}}$ if and only if there is **no** vector $\mathbf{d} \neq \mathbf{0}$ with

$$\mathbf{x}_{(i)}^\top \mathbf{d} \leq 0 \text{ for every } i, \quad \text{and} \quad \mathbf{x}_{(i)}^\top \mathbf{d} = 0 \text{ whenever } y_i > 0. \quad (37.1.3)$$

Proof. Write $u_i = \mathbf{x}_{(i)}^\top \mathbf{d}$ and, for a fixed $\boldsymbol{\beta}_0$,

$$\ell(\boldsymbol{\beta}_0 + t\mathbf{d}) = \sum_i y_i \eta_i^0 + t \sum_i y_i u_i - \sum_i e^{\eta_i^0} e^{tu_i} - \sum_i \log y_i!,$$

where $\eta_i^0 = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_0$. Suppose such a $\mathbf{d}$ exists. Then $\sum_i y_i u_i = 0$, because every term with $y_i > 0$ has $u_i = 0$. Since every $u_i \leq 0$, each e^{tu_i} is nonincreasing in t , so $\ell(\boldsymbol{\beta}_0 + t\mathbf{d})$ is nondecreasing in t ; and it is strictly increasing unless every $u_i = 0$, which full column rank excludes. So the supremum is approached only as $t \rightarrow \infty$ and is not attained.

Conversely, suppose no such $\mathbf{d}$ exists, and fix a unit vector $\mathbf{d}$. Either some $u_i > 0$, and $\ell(\boldsymbol{\beta}_0 + t\mathbf{d}) \rightarrow -\infty$ because an exponential beats a linear term; or every $u_i \leq 0$, in which case some i with $y_i > 0$ has $u_i < 0$, so $\sum_i y_i u_i < 0$ while $-\sum_i e^{\eta_i^0} e^{tu_i} \leq 0$, and again $\ell \rightarrow -\infty$. So there is a $t_{\mathbf{d}}$ beyond which $\ell(\boldsymbol{\beta}_0 + t\mathbf{d}) < \ell(\boldsymbol{\beta}_0) - 1$. Continuity alone does not make that threshold uniform in $\mathbf{d}$; concavity does. By part (c) the difference quotient $\{\ell(\boldsymbol{\beta}_0 + t\mathbf{d}) - \ell(\boldsymbol{\beta}_0)\}/t$ is nonincreasing in t , so once it falls below $-1/t_{\mathbf{d}}$ it stays below, and by continuity it does so on a neighbourhood of $\mathbf{d}$. Finitely many such neighbourhoods cover the unit sphere, giving a single t^* outside whose ball $\ell < \ell(\boldsymbol{\beta}_0) - 1$; and a continuous function on that closed ball attains its maximum.

■

The condition fails when a regressor is the indicator of a set of observations whose counts are all zero: take $\mathbf{d}$ to be minus that coordinate direction. The coefficient runs to $-\infty$ and the algorithm reports a huge negative number with an enormous standard error. A ridge or lasso

Figure 37.1.1: The log-likelihood of a Poisson log-linear model with an intercept and one regressor, for the physician-visit data used below in this section, with the Fisher scoring path from the start $\beta = (\log \bar{y}, 0)^\top$. Contours are drawn at fixed drops below the maximum.

penalty (Chapter 27, Chapter 30) makes the penalized log-likelihood coercive and restores a finite maximizer.

37.1.4 Fitting

By Theorem 34.4.1, Fisher scoring is iteratively reweighted least squares: at the current β form the working response and weights

$$z_i = \eta_i + \frac{y_i - \mu_i}{\mu_i}, \quad w_i = \mu_i, \quad (37.1.4)$$

and set $\beta \leftarrow (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{z}$. Because the expected and observed information agree (Theorem 37.1.1(b)), Fisher scoring and Newton–Raphson coincide here, and by concavity the iteration converges from any start whenever a maximum exists. The same weighted least squares step appears in Proposition 20.6.1 and Theorem 21.3.1; only the weights differ. Figure 37.1.1 draws the log-likelihood surface of a two-regressor fit with the path from a poor start: the contours are closed and nested, as concavity requires, and the first step already lands near the maximum.

37.1.5 Interpretation and inference

The estimate $\hat{\beta}$ is consistent and asymptotically normal under the conditions of Theorem 34.5.1, with asymptotic covariance $(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$ at the estimate. Exponentiating the ends of the Wald interval $\hat{\beta}_j \pm z_{1-\alpha/2} \text{se}(\hat{\beta}_j)$ gives an interval for the rate ratio e^{β_j} , better than a delta method applied to $e^{\hat{\beta}_j}$: the log scale is where the normal approximation is accurate, and the transformed interval stays positive.

Example. (Physician visits in a health insurance experiment)

The RAND Health Insurance Experiment sample distributed with `statsmodels` records 20190 person-years. The response is the number of outpatient physician visits in the year, with mean 2.860 and a variance 7.093 times as large; [Example \(Physician visits are counts\)](#) used the same data to show how badly a normal linear model describes it.

Fit [Eq. 37.1.1](#) with an intercept, the logarithm of one plus the coinsurance rate (`lncoins`), an indicator of an individual-deductible plan (`idp`), a physical-limitation index, a chronic-disease score, and three indicators of self-rated health (good, fair, poor, against excellent). Fisher scoring converges in 7 steps. The coefficient of `lncoins` is -0.0712 , standard error 0.0022: a rate ratio of 0.9313 per unit, Wald interval (0.9272, 0.9354). Moving across its whole range of 4.615, from free care to the highest coinsurance plan, multiplies expected visits by 0.720. The disease score is not a count of diseases but a continuous index running to 58.6; each unit of it multiplies expected visits by 1.0353, so moving from its lower quartile 6.90 to its upper quartile 13.73 multiplies them by 1.267. Poor self-rated health multiplies them by 1.2441 against excellent health. The fitted counts sum to the observed total, and within each health group to that group's total, as [Theorem 37.1.2](#) requires.

```
import numpy as np
import statsmodels.api as sm

data = sm.datasets.randhie.load_pandas().data          # 20190 person-years, public
            domain
y = data["mdvis"].to_numpy(float)                      # outpatient physician visits
            in the year
names = ["intercept", "lncoins", "idp", "physlm", "disea", "hlthg", "hlthf", "hlthp"
        ]
X = np.column_stack([np.ones(len(y))] + [data[v].to_numpy(float) for v in names
            [1:]])

def poisson_fit(X, y, offset=0.0, tol=1e-11, maxit=50):
    """Fisher scoring for log mu = X beta + offset; returns beta and its iterates.
    """
    beta = np.zeros(X.shape[1])
    beta[0] = np.log(y.mean())
    path = [beta]
    for _ in range(maxit):
        mu = np.exp(X @ beta + offset)                # current fitted means
        z = X @ beta + (y - mu) / mu                  # working response
        XW = X * mu[:, None]                          # weights w_i = mu_i
        step = np.linalg.solve(X.T @ XW, XW.T @ z)
        converged = np.max(np.abs(step - beta)) < tol
        beta = step
        path.append(beta)
    if converged:
        break
    return beta, np.array(path)

beta, path = poisson_fit(X, y)
mu = np.exp(X @ beta)
se = np.sqrt(np.diag(np.linalg.inv(X.T @ (X * mu[:, None]))))
```

```
print("largest entry of X^T (y - mu):", np.abs(X.T @ (y - mu)).max())
for name, b, s in zip(names, beta, se):
    print(f"{name:10s} {b:8.4f} ({s:.4f})    rate ratio {np.exp(b):.4f}")
```

The deviance of the Poisson fit ([Definition 34.5.1](#)) is

$$D = 2 \sum_{i=1}^n \left\{ y_i \log \frac{y_i}{\hat{\mu}_i} - (y_i - \hat{\mu}_i) \right\}, \quad (37.1.5)$$

with the convention $0 \log 0 = 0$. If the model has an intercept the second term sums to zero by [Theorem 37.1.2\(a\)](#), and the deviance reduces to $2 \sum_i y_i \log(y_i/\hat{\mu}_i)$, the form usually written G^2 ; because $\phi = 1$ the deviance and the scaled deviance coincide.

Differences of deviances between nested models behave in the usual way: by [Theorem 34.5.5](#) the drop is asymptotically χ^2 on the difference in dimension, and it is the likelihood ratio statistic of [Proposition 34.5.3](#). The deviance of a *single* model is a different matter: its χ^2 calibration needs the fitted means to grow, which happens for grouped data with large cells and not for ungrouped records with small counts. In [Example \(Physician visits in a health insurance experiment\)](#) the deviance is 84569.7 on 20182 degrees of freedom and the Pearson statistic is 127526.5, ratios of 4.190 and 6.319. No formal test is available, but ratios of this size are a loud signal of misfit.

```
dev = 2 * np.sum(np.where(y > 0, y * np.log(np.where(y > 0, y, 1) / mu), 0.0) - (y -
    mu))
pearson = np.sum((y - mu) ** 2 / mu)
df = len(y) - X.shape[1]
print(f"deviance {dev:.1f} on {df} df    (ratio {dev / df:.3f})")
print(f"Pearson {pearson:.1f} on {df} df    (ratio {pearson / df:.3f})")
print("fitted total", mu.sum(), " observed total", y.sum())
```

Both statistics are sums of squared residuals: the Pearson residual $r_i^P = (y_i - \hat{\mu}_i)/\sqrt{\hat{\mu}_i}$ and the deviance residual $r_i^D = \text{sign}(y_i - \hat{\mu}_i)\sqrt{d_i}$, with d_i the i th term of [Eq. 37.1.5](#). These are the count analogues of [Definition 20.1.1](#); both are badly skewed when $\hat{\mu}_i$ is small ([Exercise \(B3\)](#)), so a normal probability plot of them tells one little. Leverage and influence transfer from [Chapter 20](#) through the weights: the hat matrix of the last weighted least squares step of [Proposition 20.6.1](#) plays the role of $\mathbf{M}$, and a one-step Cook's distance ([Definition 20.4.1](#)) built from it is the standard influence measure for a generalized linear model.

Idea. The Poisson log-linear model puts the linear predictor on the log scale, so its coefficients are log rate ratios, and it ties the variance to the mean, so it has no spare parameter for extra variability. The rest of the chapter follows from taking one or other of those decisions seriously. A deviance far larger than its degrees of freedom has three possible causes — a wrong mean model, a wrong variance function, or dependent observations — and reaching for an overdispersion parameter before checking the mean model is a common and expensive mistake, because an inflated variance hides exactly the lack of fit that would have told you what to add.

37.1.6 Exercises

37.1.6.1 A. Check your understanding

Exercise A1.

A Poisson log-linear model for the number of insurance claims has coefficient 0.182 on an indicator of urban residence. State the effect on the expected number of claims in words, and give the multiplicative effect of the indicator on the *odds* that a policy has at least one claim under the same model. Why is the second quantity not simply $e^{0.182}$?

Exercise A2.

Show directly from [Theorem 37.1.1](#) that in the model with an intercept only, the maximum likelihood estimate of the common mean is $\bar{y}$, and that the deviance equals $2 \sum_i y_i \log(y_i/\bar{y})$.

Solution. With $\mathbf{X} = \mathbf{1}$ the likelihood equation is $\sum_i (y_i - e^\beta) = 0$, so $e^{\hat{\beta}} = \bar{y}$. Substituting into [Eq. 37.1.5](#) and using $\sum_i (y_i - \bar{y}) = 0$ leaves $2 \sum_i y_i \log(y_i/\bar{y})$.

37.1.6.2 B. Practice**Exercise B1.**

Counts y_{ij} , $j = 1, \dots, n_i$, are observed in c groups, and the model is $\log \mu_{ij} = \beta_i$, one parameter per group. Show that $\hat{\mu}_{ij} = \bar{y}_i$, that $\widehat{\text{Var}}(\hat{\beta}_i) = 1/(n_i \bar{y}_i)$, and that a Wald interval for μ_h/μ_i is $\exp\{\hat{\beta}_h - \hat{\beta}_i \pm z\sqrt{1/(n_h \bar{y}_h) + 1/(n_i \bar{y}_i)}\}$.

Solution. [Theorem 37.1.2\(b\)](#) applied to the group indicators gives $n_i \hat{\mu}_i = \sum_j y_{ij}$. The information $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ is diagonal with entries $n_i \mu_i$, so the estimates are independent with variances $1/(n_i \mu_i)$; the variance of their difference is the sum, and exponentiating a Wald interval for $\beta_h - \beta_i$ gives the stated interval.

Exercise B2.

In the setting of [Exercise \(B1\)](#), show that the likelihood ratio statistic for $H_0 : \mu_1 = \dots = \mu_c$ is $2 \sum_i n_i \bar{y}_i \log(\bar{y}_i/\bar{y})$, where $\bar{y}$ is the overall mean, and state the conditions under which its $\chi^2(c-1)$ calibration is reasonable.

Exercise B3.

For a Poisson fit the Pearson residual is $r_i^P = (y_i - \hat{\mu}_i)/\sqrt{\hat{\mu}_i}$. Show that it is strongly skewed when μ_i is small, and that the Anscombe residual $\frac{3}{2}(y_i^{2/3} - \hat{\mu}_i^{2/3})/\hat{\mu}_i^{1/6}$ has variance about one, by applying the delta method to $Y^{2/3}$.

37.1.6.3 C. Going deeper**Exercise C1.**

Consider a Poisson model with the identity link, $\mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. Show that the log-likelihood

is concave on the open set where every $\mu_i > 0$, but that the maximum can occur on its boundary, where some $\hat{\mu}_i = 0$; what happens then to the standard errors an algorithm that ignores the constraint reports? Repeat for the additive *rate* model $\mu_i = t_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ of [Section 37.2](#), whose coefficients are rate *differences*: show that its likelihood equations are $\sum_i t_i (y_i - \mu_i) \mathbf{x}_{(i)} / \mu_i = \mathbf{0}$, and say why an epidemiologist asking how many events an intervention prevents wants it.

Exercise C2.

Give a data set with $n = 4$, $p = 2$ for which the condition of [Proposition 37.1.3](#) fails. Then add a ridge penalty $\lambda \|\boldsymbol{\beta}\|^2$ ([Definition 27.2.1](#)) and show that the penalized log-likelihood has a finite maximizer for every $\lambda > 0$.

Solution. Take $\mathbf{X}$ with intercept and a regressor $x = (0, 0, 1, 1)^\top$ and counts $\mathbf{y} = (3, 5, 0, 0)^\top$. Then $\mathbf{d} = (0, -1)^\top$ has $\mathbf{x}_{(i)}^\top \mathbf{d} \leq 0$ everywhere and $= 0$ at the two observations with $y_i > 0$, so the condition fails: the slope runs to $-\infty$ while the intercept converges to $\log 4$. Adding $-\lambda \|\boldsymbol{\beta}\|^2$ makes the objective tend to $-\infty$ in every direction, since the log-likelihood grows at most linearly along any ray on which it grows at all, so a finite maximizer exists; it is unique by strict concavity of the penalized objective.

37.2 Offsets and rates

A count on its own is rarely interesting. Twelve accidents mean one thing on a road carrying a thousand vehicles a day and another on one carrying a hundred thousand. What is comparable is the **rate**: the count divided by the exposure that produced it. The Poisson log-linear model handles rates without new machinery, by moving a known quantity into the linear predictor and refusing to give it a coefficient.

37.2.1 Exposure

Let $t_i > 0$ be the **exposure** of observation i : person-years of follow-up, vehicle-kilometres, population size, area surveyed. The natural assumption is that the expected count is proportional to exposure,

$$\mu_i = t_i \lambda_i,$$

where λ_i is the expected number of events per unit of exposure, the quantity of interest. Modelling λ_i log-linearly, $\log \lambda_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, gives

$$\log \mu_i = \log t_i + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \quad \mu_i = t_i \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}). \quad (37.2.1)$$

The term $\log t_i$ is an **offset**: a column of the linear predictor whose coefficient is known to be one rather than estimated. Coefficients are now log rate ratios, e^{β_j} multiplying the rate per unit of exposure rather than the raw count. This is *not* a regression of the observed rates y_i/t_i , which would throw away the information that a rate based on a thousand person-years is better determined than one based on five: the response stays the count and the exposure enters as a known constant.

Proposition 37.2.1 — Offsets

Consider the model Eq. 37.2.1 with $\text{rank}(\mathbf{X}) = p$, and write $\boldsymbol{\mu} = \boldsymbol{\mu}(\boldsymbol{\beta})$ for the mean vector it defines. Then:

- (a) the log-likelihood is $\ell(\boldsymbol{\beta}) = \sum_i \{y_i(\log t_i + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}) - t_i e^{\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}\} - \sum_i \log y_i!$; its score is $\mathbf{X}^\top (\mathbf{y} - \boldsymbol{\mu})$ and its information is $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{W} = \text{diag}(\mu_1, \dots, \mu_n)$, so Theorem 37.1.1 holds verbatim with the offset in place;
- (b) consequently Theorem 37.1.2 holds verbatim: the fitted counts, not the fitted rates, reproduce the observed margins of the model matrix, and with an intercept $\sum_i \hat{\mu}_i = \sum_i y_i$;
- (c) (**grouping**) suppose the rows of $\mathbf{X}$ take only G distinct values $\mathbf{x}_{(g)}$, with n_g rows equal to the g th, all with exposure $t_i = 1$. Let s_g be the total count of group g . Then fitting Eq. 37.1.1 to the n individual records and fitting Eq. 37.2.1 to the G totals s_g with exposures $t_g = n_g$ give the same $\hat{\boldsymbol{\beta}}$, the same information matrix and the same deviance differences between nested models;
- (d) (**a free exposure coefficient**) the model $\log \mu_i = \psi \log t_i + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ contains Eq. 37.2.1 as the submodel $\psi = 1$. Its fit coincides with the offset fit if and only if $\hat{\psi} = 1$, and the likelihood ratio statistic for $H_0 : \psi = 1$ is asymptotically $\chi^2(1)$.

Proof.

- (a) Substituting $\mu_i = t_i e^{\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}$ into the Poisson log-likelihood gives the stated expression, and $\partial \mu_i / \partial \boldsymbol{\beta} = \mu_i \mathbf{x}_{(i)}$ exactly as before, because the factor t_i is a constant. The derivative of $\sum_i y_i \log t_i$ in $\boldsymbol{\beta}$ is zero. Everything in the proof of Theorem 37.1.1 then goes through with the new μ_i , which is (a); and (b) follows from (a) as before.
- (b) Within group g all the means equal $\mu_g = e^{\mathbf{x}_{(g)}^\top \boldsymbol{\beta}}$, so

$$\ell_{\text{ind}}(\boldsymbol{\beta}) = \sum_{g=1}^G \{s_g \log \mu_g - n_g \mu_g\} - \sum_i \log y_i!$$

The grouped model has means $n_g \mu_g$, so its log-likelihood is

$$\ell_{\text{grp}}(\boldsymbol{\beta}) = \sum_{g=1}^G \{s_g (\log n_g + \log \mu_g) - n_g \mu_g\} - \sum_g \log s_g!$$

The two differ by a quantity free of $\boldsymbol{\beta}$. Log-likelihoods differing by a constant have the same maximizer and the same derivatives of every order, hence the same information; and differences of deviances are differences of log-likelihoods, so the constant cancels there too.

- (c) Setting $\psi = 1$ recovers Eq. 37.2.1, so the models are nested with one extra parameter. The larger model's log-likelihood is strictly concave in $(\boldsymbol{\beta}^\top, \psi)^\top$ whenever $[\mathbf{X}, \log \mathbf{t}]$ has full column rank, by Theorem 37.1.1(c) applied to that model matrix, so its maximizer is unique; it therefore agrees with the offset fit exactly when $\hat{\psi} = 1$. The distribution statement is Theorem 34.5.5 for one degree of freedom.

■

Part (c) says that grouping records with identical regressors and carrying the group size as an exposure is *exactly* a bookkeeping operation. It is a property of the Poisson, not of generalized linear models in general, and it comes from sums of independent Poissons being Poisson. The use is both practical — twenty thousand records collapse to a few dozen — and theoretical: the grouped cells may have large counts, so the deviance of a single fitted model is calibrated by [Theorem 34.5.5](#) even though it is not for the individual records.

Example. (Twenty thousand records in thirty-two rows)

Take the physician-visit data of [Example \(Physician visits in a health insurance experiment\)](#) and keep only categorical regressors: the individual-deductible indicator, the three self-rated health indicators, and the chronic-disease score banded into four groups. There are 32 distinct covariate patterns, holding between 9 and 3832 person-years. Collapse the 20190 records to these rows, recording the total visits and the number of person-years in each, and fit the rate model with offset the log of the person-years. The coefficients agree with the person-level fit to fourteen decimal places, as [Proposition 37.2.1\(c\)](#) promises.

Read as rates, a person-year in excellent health, in the lowest disease band and on a plan without an individual deductible, is expected to produce 1.9758 visits; an individual deductible multiplies that by 0.8247, poor self-rated health by 1.6875, and the highest disease band by 2.2621.

The grouped deviance is 665.60 on 24 degrees of freedom, and now the χ^2 calibration applies, since the smallest fitted cell mean is 24.7. The model is rejected. Where does the misfit sit? The fitted model has main effects only, so its 24 residual degrees of freedom are the interactions among the three factors; adding every two-factor interaction among them, 23 parameters in all, drops the deviance to 106.87 on 9 degrees of freedom, a fall of 558.7 on 15. Five sixths of the misfit is therefore mean model, not variance function. What survives the repair — 106.87 on nine degrees of freedom, still far beyond any plausible χ^2 — is the Poisson variance function, which [Section 37.4](#) takes up.

37.2.2 What a free exposure coefficient buys and costs

Why fix $\psi = 1$ instead of estimating it, as [Proposition 37.2.1\(d\)](#) allows? It depends on where the exposure came from.

When exposure is a bookkeeping device — the grouping of part (c), where the individual records are the real data — proportionality is a theorem, not an assumption, and a $\hat{\psi}$ far from one is a symptom of misspecification elsewhere, because $\log n_g$ is free to proxy for anything correlated with group size. In [Example \(Twenty thousand records in thirty-two rows\)](#) it is $\hat{\psi} = 1.2266$, standard error 0.0146, interval (1.1980, 1.2553), with likelihood ratio statistic 249.019 against $\psi = 1$. A person-year cannot contribute more than proportionally to its own visits; the statistic is detecting the same lack of fit as the deviance of 665.60.

When exposure genuinely varies across units — different follow-up times, different populations — proportionality is a substantive assumption, and there is a real trade-off, which a simulation makes concrete.

Example. (Three ways to handle an exposure)

Counts are generated for $m = 300$ units from $\log \mu_i = 0.4 + 0.5x_i + \psi \log t_i$, with x_i standard normal and the exposure t_i correlated with it. Three analyses are run on each of 2000 data sets — the correct offset, a free coefficient on $\log t$, and no exposure term — and [Figure 37.2.1](#) shows the sampling distributions of the estimated slope of x , whose

Figure 37.2.1: Sampling distributions of the estimated slope of x over 2000 simulated data sets, under three treatments of the exposure, when the true exposure exponent is (a) one and (b) 0.7. The dashed line marks the true slope.

true value is 0.5.

When the truth is $\psi = 1$, both the offset and the free-coefficient model are unbiased, with means 0.500 and 0.500, but the free coefficient has standard deviation 0.029 against 0.017, a loss of precision by a factor of 1.772: estimating a parameter you already know costs information. Dropping the exposure is a disaster, the slope averaging 1.096, because x is left to explain the variation in exposure as well as in the rate.

When the truth is $\psi = 0.7$, the free-coefficient model is still centred at 0.501, while the offset model, forcing a wrong proportionality, is centred at 0.322 — a bias of more than six of its own standard deviations. Fixing a coefficient you have got wrong costs more than estimating one you knew.

Warning. The third analysis fails by ordinary omitted variable bias: $\log t$ belongs in the linear predictor, and leaving it out loads its effect onto whatever is correlated with it. What is special about an offset is only that its coefficient is known, so it is not a variable to be selected and must never be dropped by a stepwise procedure or a lasso.

37.2.3 Rates elsewhere

Two further uses of the same device are worth naming.

Piecewise-constant hazards. Split each subject's follow-up into intervals on which the hazard is constant, and let d_{ik} be subject i 's events in interval k and t_{ik} the time at risk. Treating the d_{ik} as independent Poisson counts with means $t_{ik} \exp(\alpha_k + \mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ gives a proportional-hazards model with a step-function baseline, fitted as an ordinary Poisson regression with offset $\log t_{ik}$ and one parameter per interval ([Exercise \(B1\)](#)); the connection is due to Holford and to Laird and Olivier.

Standardization. A standardized morbidity ratio divides the observed count by an expected count E_i from external reference rates; taking $\log E_i$ as the offset makes $\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ the ratio itself.

Fixing the exposure coefficient is right when theory or bookkeeping says the count is proportional to the exposure, and costs nothing; estimating it is right when proportionality is in doubt, and costs precision. What is never right is leaving the exposure out.

37.2.4 Exercises

37.2.4.1 A. Check your understanding

Exercise A1.

A rate model uses person-years as the exposure. A colleague re-expresses exposure in person-months, multiplying every t_i by twelve. Which coefficients change and by how much? Which fitted values change?

Exercise A2.

Explain why regressing $\log(y_i/t_i)$ on $\mathbf{x}_{(i)}$ by least squares is not equivalent to fitting [Eq. 37.2.1](#), giving two distinct reasons.

37.2.4.2 B. Practice

Exercise B1.

Suppose subject i is followed until an event or censoring, with a hazard that is constant at $h_{ik} = \exp(\alpha_k + \mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ on interval k . Write $d_{ik} \in \{0, 1\}$ for the event indicator and t_{ik} for the time at risk in that interval. Show that the likelihood contribution of subject i is $\prod_k h_{ik}^{d_{ik}} e^{-h_{ik} t_{ik}}$, and hence that maximizing it is the same as fitting a Poisson log-linear model to the d_{ik} with offset $\log t_{ik}$.

Solution. With a constant hazard h on an interval, the probability of surviving a time t is e^{-ht} and the density of an event at the end is he^{-ht} , so the contribution of interval k is $h_{ik}^{d_{ik}} e^{-h_{ik} t_{ik}}$, and the contributions multiply. Its logarithm is $\sum_{i,k} \{d_{ik} \log h_{ik} - h_{ik} t_{ik}\}$. The Poisson log-likelihood for counts d_{ik} with means $t_{ik} h_{ik}$ differs from it by $\sum_{i,k} d_{ik} \log t_{ik}$, a constant in the parameters, so the maximizers agree. The d_{ik} need not actually be Poisson; only the likelihoods coincide.

Exercise B2.

In the setting of [Example \(Three ways to handle an exposure\)](#), suppose the analyst tests $H_0 : \psi = 1$ and uses the offset model if the test does not reject. Explain why the resulting estimator of the slope of x has a sampling distribution that is neither of the two shown in [Figure 37.2.1](#), and relate the phenomenon to the pre-test problem [Example \(Coverage after a pretest\)](#).

37.2.4.3 C. Going deeper

Exercise C1.

Extend [Proposition 37.2.1\(c\)](#) to the case where the individual records already carry exposures t_i that differ within a group. Show that the grouped fit with exposure $\sum_{i \in g} t_i$ reproduces the individual fit, and identify exactly what has to be constant within a group.

Solution. What must be constant within a group is the row $\mathbf{x}_{(i)}$, not the exposure. If $\mathbf{x}_{(i)} = \mathbf{x}_{(g)}$ for all $i \in g$ then $\mu_i = t_i \mu_g^*$ with $\mu_g^* = e^{\mathbf{x}_{(g)}^\top \boldsymbol{\beta}}$, so $\sum_{i \in g} \mu_i = (\sum_{i \in g} t_i) \mu_g^*$ and the log-likelihood is $\sum_g \{s_g \log \mu_g^* - (\sum_{i \in g} t_i) \mu_g^*\} + \sum_i y_i \log t_i$, whose last term is free of $\boldsymbol{\beta}$. Sums of independent Poissons are Poisson, so the grouped data have exactly the claimed distribution.

Exercise C2.

Let the truth be $\log \mu_i = \psi \log t_i + \beta_0 + \beta_1 x_i$ with $\psi \neq 1$, and suppose the offset model is fitted. Show that the limiting value of $\hat{\beta}_1$ solves $E\{\mathbf{x} t (t^{\psi-1} e^{\beta_0 + \beta_1 x} - e^{\beta_0^* + \beta_1^* x})\} = \mathbf{0}$, and argue that $\beta_1^* = \beta_1$ when $t^{\psi-1}$ is independent of x under the weighting by t .

37.3 Poisson and multinomial

A contingency table is a table of counts, so a Poisson log-linear model can be fitted to it. But the counts usually come from a survey with a fixed sample size, or from strata with fixed totals, and then they are not independent Poisson variables at all: they are multinomial. The two descriptions lead to the same fit. That is why software for Poisson regression is also software for contingency tables, and it is the bridge to the baseline-category logit models of [Chapter 36](#).

37.3.1 Conditioning on the total

Theorem 37.3.1 — Poisson counts conditioned on their total

- (a) Let $Y_1, \dots, Y_c$ be independent, Y_j Poisson with mean $\mu_j > 0$, and $N = \sum_j Y_j$. Then N is Poisson with mean $\mu_+ = \sum_j \mu_j$, and conditionally on $N = n$ the vector $(Y_1, \dots, Y_c)$ is multinomial with n trials and probabilities $\pi_j = \mu_j / \mu_+$.
- (b) Suppose the cells are indexed by a stratum $s = 1, \dots, S$ and a category $j = 1, \dots, c$, the counts Y_{sj} are independent Poisson with means μ_{sj} , and the log-linear model is

$$\log \mu_{sj} = \alpha_s + \mathbf{z}_{sj}^\top \boldsymbol{\gamma}, \quad (37.3.1)$$

with $\boldsymbol{\alpha} \in \mathbb{R}^S$ unrestricted: that is, the model contains a free parameter for every stratum. Then the Poisson log-likelihood splits as

$$\ell(\boldsymbol{\alpha}, \boldsymbol{\gamma}) = \ell_1(\mu_{1+}, \dots, \mu_{S+}) + \ell_2(\boldsymbol{\gamma}) + \text{constant},$$

where ℓ_1 is the log-likelihood of S independent Poisson totals and ℓ_2 is the log-likelihood of S independent multinomial samples with category probabilities

$$\pi_{sj}(\boldsymbol{\gamma}) = \frac{\exp(\mathbf{z}_{sj}^\top \boldsymbol{\gamma})}{\sum_{l=1}^c \exp(\mathbf{z}_{sl}^\top \boldsymbol{\gamma})}, \quad (37.3.2)$$

and the two pieces have no parameters in common.

- (c) Consequently the maximum likelihood estimate $\hat{\boldsymbol{\gamma}}$ from the Poisson fit is the maximum likelihood estimate from the multinomial fit; the fitted cell counts are $\hat{\mu}_{sj} = n_s \hat{\pi}_{sj}$ with $n_s = \sum_j y_{sj}$; the observed information for $\boldsymbol{\gamma}$ is the same in the two models; and deviance differences between models that all contain the stratum parameters agree. The stratum parameters $\hat{\alpha}_s$ themselves have no multinomial counterpart: they are determined by $\hat{\mu}_{s+} = n_s$.

Proof.

- (a) Sums of independent Poisson variables are Poisson with the sum of the means (convolve the mass functions, or multiply moment generating functions), so $\Pr(N = n) = e^{-\mu_+} \mu_+^n / n!$. For nonnegative integers y_j with $\sum_j y_j = n$,

$$\begin{aligned} \Pr(Y_1 = y_1, \dots, Y_c = y_c \mid N = n) &= \frac{\prod_j e^{-\mu_j} \mu_j^{y_j} / y_j!}{e^{-\mu_+} \mu_+^n / n!} \\ &= \frac{n!}{\prod_j y_j!} \prod_j \pi_j^{y_j}, \end{aligned}$$

because $\sum_j \mu_j = \mu_+$ makes the exponential factors cancel and $\prod_j \mu_j^{y_j} = \mu_+^n \prod_j \pi_j^{y_j}$. That is the multinomial mass function.

- (b) Write $\mu_{s+} = \sum_j \mu_{sj}$ and $\pi_{sj} = \mu_{sj} / \mu_{s+}$. Under Eq. 37.3.1, $\mu_{s+} = e^{\alpha_s} \sum_l \exp(\mathbf{z}_{sl}^\top \boldsymbol{\gamma})$, and the ratio π_{sj} is Eq. 37.3.2, free of $\boldsymbol{\alpha}$. Substituting $\mu_{sj} = \mu_{s+} \pi_{sj}$ in the Poisson log-likelihood,

$$\begin{aligned} \ell &= \sum_{s,j} \{y_{sj} \log \mu_{sj} - \mu_{sj}\} - \sum_{s,j} \log y_{sj}! \\ &= \sum_s \{n_s \log \mu_{s+} - \mu_{s+} - \log n_s!\} \\ &\quad + \sum_s \left\{ \log n_s! - \sum_j \log y_{sj}! + \sum_j y_{sj} \log \pi_{sj} \right\}, \end{aligned}$$

which is the stated split, the first sum being ℓ_1 and the second ℓ_2 plus the multinomial coefficients. For fixed $\boldsymbol{\gamma}$, the map $\boldsymbol{\alpha} \mapsto (\mu_{1+}, \dots, \mu_{S+})$ is a bijection from $\mathbb{R}^S$ onto $(0, \infty)^S$, so the parameters $(\mu_{1+}, \dots, \mu_{S+})$ and $\boldsymbol{\gamma}$ vary independently.

- (c) The two pieces share no parameters and their ranges are unconstrained, so the joint maximum is attained by maximizing each separately: ℓ_1 gives $\hat{\mu}_{s+} = n_s$ and ℓ_2 is the multinomial problem, giving $\hat{\boldsymbol{\gamma}}$ and $\hat{\mu}_{sj} = n_s \hat{\pi}_{sj}$. The information for $\boldsymbol{\gamma}$ is minus the second derivative of ℓ_2 , and differences of maximized log-likelihoods between models sharing the stratum parameters lose the common ℓ_1 .

■

Part (c) is the practical statement: *fit the table as independent Poisson counts, and provided the*

model contains a free parameter for every total the design fixed, you get the multinomial answer. The converse matters as much: if the design fixed the row totals and the model omits the row parameters, the two fits differ and the Poisson one answers a question the design cannot. The proof used s only to group cells, so any partition into blocks with fixed totals works the same way.

37.3.2 Independence in a two-way table

Take $S = r$ rows and c columns, and let $\mathbf{z}_{ij}$ consist of the column indicators alone, so that Eq. 37.3.1 reads

$$\log \mu_{ij} = \lambda + \lambda_i^R + \lambda_j^C, \quad (37.3.3)$$

the log-linear model with row and column main effects and no interaction. The parameters are redundant by two, and any of the usual side conditions removes the redundancy without changing the fit (Theorem 6.7.1).

Corollary 37.3.2 — The independence model

Under Eq. 37.3.3 the conditional distribution of the column given the row does not depend on the row, so the two classifications are independent. The maximum likelihood fitted values are

$$\hat{\mu}_{ij} = \frac{y_{i+} y_{+j}}{n}, \quad y_{i+} = \sum_j y_{ij}, \quad y_{+j} = \sum_i y_{ij}, \quad n = y_{++}, \quad (37.3.4)$$

the deviance is $G^2 = 2 \sum_{i,j} y_{ij} \log(y_{ij}/\hat{\mu}_{ij})$, the Pearson statistic is $X^2 = \sum_{i,j} (y_{ij} - \hat{\mu}_{ij})^2 / \hat{\mu}_{ij}$, and both have $(r-1)(c-1)$ residual degrees of freedom — and, when the expected counts are large, both are asymptotically χ^2 on that many degrees of freedom (Theorem 34.5.5).

Proof. With $\mathbf{z}_{ij}$ free of i , Eq. 37.3.2 gives $\pi_{ij} = \pi_j$, which is independence. By Theorem 37.1.2(b) applied to the row and to the column indicators, $\hat{\mu}_{i+} = y_{i+}$ and $\hat{\mu}_{+j} = y_{+j}$. Under Eq. 37.3.3, $\hat{\mu}_{ij} = \hat{\mu}_{i+} \hat{\mu}_{+j} / \hat{\mu}_{++}$, because $\hat{\mu}_{ij} = e^{\lambda} a_i b_j$ factorizes and summing gives $\hat{\mu}_{i+} \hat{\mu}_{+j} = e^{2\lambda} a_i b_j \sum_l b_l \sum_k a_k = \hat{\mu}_{ij} \hat{\mu}_{++}$. Substituting the matched margins gives the fit Eq. 37.3.4. The model has $1 + (r-1) + (c-1)$ free parameters against rc cells, leaving $rc - r - c + 1 = (r-1)(c-1)$. The deviance formula is Eq. 37.1.5 with the second term vanishing by Theorem 37.1.2(a). ■

The fitted values Eq. 37.3.4 are the expected counts of the elementary chi-squared test for independence, available since Pearson (1900); what the log-linear framework adds is everything around it.

37.3.3 Association is interaction on the log scale

Adding an interaction term to [Eq. 37.3.3](#) gives the saturated model

$$\log \mu_{ij} = \lambda + \lambda_i^R + \lambda_j^C + \lambda_{ij}^{RC}, \quad (37.3.5)$$

with rc free parameters and $\hat{\mu}_{ij} = y_{ij}$.

Proposition 37.3.3 — Interaction parameters are log odds ratios

In [Eq. 37.3.5](#), for any rows $i \neq k$ and columns $j \neq l$,

$$\lambda_{ij}^{RC} + \lambda_{kl}^{RC} - \lambda_{il}^{RC} - \lambda_{kj}^{RC} = \log \frac{\mu_{ij}\mu_{kl}}{\mu_{il}\mu_{kj}},$$

which does not depend on the side conditions ([Theorem 8.4.2](#)) used to identify the parameters. Under the multinomial reading of [Theorem 37.3.1](#) the right-hand side is the log odds ratio $\log\{\pi_{ij}\pi_{kl}/(\pi_{il}\pi_{kj})\}$. The model [Eq. 37.3.3](#) holds if and only if every such quantity is zero.

Proof. In the four terms of [Eq. 37.3.5](#) the constant, the row effects and the column effects each appear twice with a plus and twice with a minus sign, so they cancel, leaving the stated combination equal to $\log \mu_{ij} + \log \mu_{kl} - \log \mu_{il} - \log \mu_{kj}$. The cancellation uses nothing about the parameterization, so any two parameterizations of the same fitted means agree. Dividing every μ by μ_{++} leaves the ratio unchanged, giving the multinomial form; and all such quantities vanish exactly when $\log \mu_{ij}$ is additive in i and j , which is [Eq. 37.3.3](#). ■

The combination in [Proposition 37.3.3](#) is the tetrad difference of [Definition 16.2.1](#) applied to $\log \mu_{ij}$ instead of to a cell mean, so the apparatus of [Chapter 16](#) transfers: interaction contrasts survive reparameterization ([Proposition 16.2.1](#)) and main effects do not. The difference is that there the scale was chosen for convenience and could be changed by a transformation ([Proposition 16.2.2](#)), whereas here the log scale is forced by the link and “no interaction” means “independence”.

Example. (Education and party identification)

The 1996 American National Election Studies sample distributed with `statsmodels` records 944 respondents. Cross-classify them by education in four levels (no diploma, high school graduate, some college, degree) and by party identification collapsed to three, with column totals 380, 239 and 325.

Fitting the independence model [Corollary 37.3.2](#) gives $G^2 = 20.541$ and $X^2 = 19.338$ on six degrees of freedom. The smallest expected count is 16.46, so the χ^2 calibration is safe, and the p -value is 0.0022: independence is rejected. The largest Pearson residual $(y_{ij} - \hat{\mu}_{ij})/\sqrt{\hat{\mu}_{ij}}$ is -2.62 , at Republicans without a diploma, where 10 were observed against 22.38 expected; the largest positive one, 2.31 , is at Democrats in the same row.

The alternative need not be saturated. Education is ordered, so give it scores $u_i = 1, 2, 3, 4$ and fit $\log \mu_{ij} = \lambda + \lambda_i^R + \lambda_j^C + u_i \delta_j$, spending two parameters instead of six on the association. Its deviance is 7.367 on four degrees of freedom, p -value 0.1177: this model fits, and the drop from independence is 13.174 on two degrees of freedom, $p = 0.00138$.

Now read the same three fits as multinomial logit models for party given education (Definition 36.1.1), with Democrat as the baseline: independence becomes the intercept-only logit model, the score model a logit model linear in u_i , the saturated model a logit model with a free effect per education level. Each pair gives identical fitted counts, and the association parameters δ_j are exactly the education slopes of the logit model, 0.1513 for Independent against Democrat and 0.2748 for Republican against Democrat: each step up the education scale multiplies the odds of Republican rather than Democrat by 1.3163. In the saturated model the interaction contrast comparing the degree row with the no-diploma row and the Republican column with the Democrat column is 1.3658, so those odds are 3.919 times as large among respondents with a degree as among those without a diploma.

```

37.3.4 More than two classifications

With three classifications the same ideas give a family of models, one for each independence structure. Writing the saturated model as

$$\log \mu_{ijk} = \lambda + \lambda_i^A + \lambda_j^B + \lambda_k^C \\ + \lambda_{ij}^{AB} + \lambda_{ik}^{AC} + \lambda_{jk}^{BC} + \lambda_{ijk}^{ABC},$$

the standard submodels delete terms, always a higher-order term before any lower-order term it contains (a **hierarchical** model). Dropping all two-factor terms gives mutual independence; keeping λ^{AC} and λ^{BC} makes A and B conditionally independent given C ; dropping only λ^{ABC} gives **homogeneous association**, in which the AB odds ratios are the same at every level of C ([Exercise \(C2\)](#), [Exercise \(B2\)](#)).

[Theorem 37.1.2](#) makes the fitting transparent: the likelihood equations equate observed and fitted counts in exactly the margins spanned by the model's terms. For mutual independence those are the one-way margins and the fit is a product of proportions; for homogeneous association they are all three two-way margins, which has no closed form and is what iterative fitting is for.

Remark (Graphical models). Draw a vertex for each classification and an edge for each two-factor term the model retains. For the hierarchical models whose structure that graph captures, conditional independence given a separating set can be read off the picture: these are the **graphical log-linear models** of Darroch, Lauritzen and Speed (1980), the discrete ancestors of graphical models generally. They also say when collapsing over a variable leaves an association unchanged, which is never safe to assume: the AB association survives collapsing over C only when C is conditionally independent of A , or of B , given the other (Bishop, Fienberg and Holland, 1975). Otherwise marginal and conditional associations may differ in size or in sign, as [Section 14.5](#) found for partial correlations.

37.3.5 Exercises

37.3.5.1 A. Check your understanding

Exercise A1.

A three-way table is $3 \times 4 \times 2$. How many cells does it have, how many free parameters

does the homogeneous association model have, and what are the residual degrees of freedom?

Exercise A2.

Verify from [Theorem 37.3.1\(a\)](#) that the conditional distribution of Y_1 given $N = n$ is binomial with n trials and probability μ_1/μ_+ , and use it to explain why a Poisson model for two counts is the same as a binomial model for one of them given the total.

37.3.5.2 B. Practice

Exercise B1.

For the 2×2 table with entries $y_{11}, y_{12}, y_{21}, y_{22}$, compute the independence fit [Eq. 37.3.4](#) by hand and show that $y_{ij} - \hat{\mu}_{ij} = \pm(y_{11}y_{22} - y_{12}y_{21})/n$ with alternating signs. Deduce that $X^2 = n(y_{11}y_{22} - y_{12}y_{21})^2/(y_{1+}y_{2+}y_{+1}y_{+2})$.

Exercise B2.

For the conditional independence model $\log \mu_{ijk} = \lambda + \lambda_i^A + \lambda_j^B + \lambda_k^C + \lambda_{ik}^{AC} + \lambda_{jk}^{BC}$, show that the likelihood equations equate the AC and BC margins, that $\hat{\mu}_{ijk} = y_{i+k}y_{+jk}/y_{++k}$, and that the residual degrees of freedom are $(r-1)(c-1)\ell$ for an $r \times c \times \ell$ table.

Solution. The terms in the model span the indicators of the AC and BC cells, so [Theorem 37.1.2](#) equates those margins. The model says $\hat{\mu}_{ijk} = f_{ik}g_{jk}$, so within each level k it is the independence model of [Corollary 37.3.2](#) applied to the k th layer, whose fit is $y_{i+k}y_{+jk}/y_{++k}$. Each layer contributes $(r-1)(c-1)$ residual degrees of freedom, and there are ℓ layers.

Exercise B3.

In a $2 \times c \times \ell$ table with A binary, show that the homogeneous association model implies that the logit of $\Pr(A = 1 \mid B = j, C = k)$ is additive in j and k , and identify the logistic regression that corresponds to it. Which log-linear terms determine the logistic intercept, which the slopes, and which do not appear at all?

Solution. The logit is $\log(\mu_{1jk}/\mu_{2jk})$. Substituting the model, the terms $\lambda, \lambda_j^B, \lambda_k^C$ and λ_{jk}^{BC} cancel, leaving $(\lambda_1^A - \lambda_2^A) + (\lambda_{1j}^{AB} - \lambda_{2j}^{AB}) + (\lambda_{1k}^{AC} - \lambda_{2k}^{AC})$, which is additive: it is the main-effects logistic regression of A on B and C . The A main effect gives the intercept and the AB, AC terms the slopes; λ^{BC} , the association between the explanatory factors, does not appear.

37.3.5.3 C. Going deeper

Exercise C1.

The model of [Example \(Education and party identification\)](#) with row scores, $\log \mu_{ij} =$

$\lambda + \lambda_i^R + \lambda_j^C + u_i \delta_j$, is called a row-effects model. Show that its local log odds ratios $\log\{\mu_{ij}\mu_{i+1,j+1}/(\mu_{i,j+1}\mu_{i+1,j})\}$ equal $(u_{i+1} - u_i)(\delta_{j+1} - \delta_j)$. Then show that giving *both* classifications scores, with association term $\theta u_i v_j$, makes every local log odds ratio $\theta(u_{i+1} - u_i)(v_{j+1} - v_j)$ — the **uniform association** model — and count its parameters.

Exercise C2.

For a three-way table, show that the likelihood equations of the mutual independence model are $\hat{\mu}_{i++} = y_{i++}$, $\hat{\mu}_{+j+} = y_{+j+}$ and $\hat{\mu}_{++k} = y_{++k}$, and solve them to get $\hat{\mu}_{ijk} = y_{i++}y_{+j+}y_{++k}/n^2$. Explain why the homogeneous association model has no such closed form.

37.4 Negative binomial models

The Poisson model spends its parameters on the mean and none on the variance. Whether that is enough is an empirical question, and the answer is usually no.

37.4.1 Where overdispersion comes from

Call a count model **overdispersed** relative to the Poisson if $\text{Var}(Y_i) > \text{E}(Y_i)$. Leave aside the wrong mean model, which [Example \(Twenty thousand records in thirty-two rows\)](#) ruled out first and which no dispersion parameter repairs. Two mechanisms remain: **unobserved heterogeneity**, the units differing in ways the regressors do not capture, which the calculation below shows always inflates the variance; and **dependence between events**, one accident making the next more likely, so that the count is not Poisson even conditionally. This section models the first.

Lemma 37.4.1 — The negative binomial as a gamma mixture of Poissons

Let Λ have the gamma distribution with shape $\kappa > 0$ and rate κ/μ , so that $\text{E} \Lambda = \mu$ and $\text{Var} \Lambda = \mu^2/\kappa$, and let $Y \mid \Lambda = \lambda$ be Poisson with mean λ . Then:

- (a) more generally, for any mixing distribution with $\text{E} \Lambda = \mu$ and $\text{Var} \Lambda = \tau^2$, $\text{E} Y = \mu$ and $\text{Var} Y = \mu + \tau^2$;
- (b) with the gamma mixing distribution above, the marginal mass function of Y is

$$\Pr(Y = y) = \frac{\Gamma(y + \kappa)}{\Gamma(\kappa) y!} \left(\frac{\kappa}{\kappa + \mu} \right)^\kappa \left(\frac{\mu}{\kappa + \mu} \right)^y, \quad y = 0, 1, 2, \dots \quad (37.4.1)$$

with $\text{E} Y = \mu$ and $\text{Var} Y = \mu + \mu^2/\kappa$;

- (c) as $\kappa \rightarrow \infty$ with μ fixed, [Eq. 37.4.1](#) converges to the Poisson mass function with mean μ .

Proof.

- (a) $EY = E\Lambda = \mu$, and by the law of total variance, using $\text{Var}(Y | \Lambda) = \Lambda$, $\text{Var } Y = E\Lambda + \text{Var } \Lambda = \mu + \tau^2$.
- (b) The gamma density is $f(\lambda) = \{(\kappa/\mu)^\kappa / \Gamma(\kappa)\} \lambda^{\kappa-1} e^{-\kappa\lambda/\mu}$. Therefore

$$\begin{aligned} \Pr(Y = y) &= \int_0^\infty \frac{e^{-\lambda} \lambda^y}{y!} \frac{(\kappa/\mu)^\kappa}{\Gamma(\kappa)} \lambda^{\kappa-1} e^{-\kappa\lambda/\mu} d\lambda \\ &= \frac{(\kappa/\mu)^\kappa}{y! \Gamma(\kappa)} \int_0^\infty \lambda^{y+\kappa-1} e^{-\lambda(1+\kappa/\mu)} d\lambda. \end{aligned}$$

The integral is $\Gamma(y + \kappa)(1 + \kappa/\mu)^{-(y+\kappa)}$, so

$$\begin{aligned} \Pr(Y = y) &= \frac{\Gamma(y + \kappa)}{\Gamma(\kappa)y!} \left(\frac{\kappa}{\mu}\right)^\kappa \left(\frac{\mu}{\mu + \kappa}\right)^{y+\kappa} \\ &= \frac{\Gamma(y + \kappa)}{\Gamma(\kappa)y!} \left(\frac{\kappa}{\kappa + \mu}\right)^\kappa \left(\frac{\mu}{\kappa + \mu}\right)^y, \end{aligned}$$

which is [Eq. 37.4.1](#). The moments follow from (a) with $\tau^2 = \mu^2/\kappa$.

- (c) Write $\alpha = 1/\kappa$ and use $\Gamma(y + \kappa)/\Gamma(\kappa) = \prod_{k=0}^{y-1} (\kappa + k) = \kappa^y \prod_{k=0}^{y-1} (1 + \alpha k)$. Then [Eq. 37.4.1](#) becomes

$$\Pr(Y = y) = \frac{\mu^y}{y!} \left\{ \prod_{k=0}^{y-1} (1 + \alpha k) \right\} (1 + \alpha\mu)^{-1/\alpha-y}. \quad (37.4.2)$$

As $\alpha \downarrow 0$ the product tends to one and $(1 + \alpha\mu)^{-1/\alpha} \rightarrow e^{-\mu}$, leaving $e^{-\mu} \mu^y / y!$.

■

Part (a) says the inflation is unavoidable: *any* unmodelled variation in the mean adds to the variance, whatever its shape. The gamma is chosen in (b) for its closed form, not because heterogeneity is really gamma distributed; the log-normal gives no closed form, and is the natural choice once random effects enter the picture ([Chapter 40](#)).

Definition 37.4.1 — Negative binomial regression

Let $Y_1, \dots, Y_n$ be independent with the mass function [Eq. 37.4.1](#), means μ_i and shapes κ_i , and let $\log \mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$.

- (a) The **NB2** model takes $\kappa_i = \kappa$ constant, so that

$$\text{Var}(Y_i) = \mu_i + \frac{\mu_i^2}{\kappa}. \quad (37.4.3)$$

The variance is quadratic in the mean, and the coefficient of variation of Λ_i is the constant $\kappa^{-1/2}$.

- (b) The **NB1** model takes $\kappa_i = \alpha\mu_i$ proportional to the mean, so that

$$\text{Var}(Y_i) = \mu_i + \frac{\mu_i}{\alpha} = \phi \mu_i, \quad \phi = 1 + \alpha^{-1}. \quad (37.4.4)$$

The variance is linear in the mean, with a constant inflation factor.

The parameter $\alpha = 1/\kappa$ in the NB2 model is often called the **dispersion parameter**;

$\alpha = 0$ is the Poisson.

These are genuinely different models, not reparameterizations of one: NB2 says units differ multiplicatively by a fixed relative amount, NB1 that the excess variance is a fixed multiple of the mean.

37.4.2 Estimation and inference

Proposition 37.4.2 — Fitting the negative binomial

In the NB2 model of Definition 37.4.1 with κ treated as a parameter:

- (a) for fixed κ the distribution Eq. 37.4.1 is an exponential dispersion family (Definition 34.1.1) with natural parameter $\theta = \log\{\mu/(\mu + \kappa)\}$, cumulant function $b(\theta) = -\kappa \log(1 - e^\theta)$, dispersion $\phi = 1$ and variance function $V(\mu) = \mu + \mu^2/\kappa$;
- (b) with the log link, the score for β is

$$\frac{\partial \ell}{\partial \beta} = \sum_{i=1}^n \frac{y_i - \mu_i}{1 + \mu_i/\kappa} \mathbf{x}_{(i)}, \quad (37.4.5)$$

so that Fisher scoring is iteratively reweighted least squares with weights $w_i = \mu_i/(1 + \mu_i/\kappa)$, and the expected information for β is $\mathbf{X}^\top \mathbf{W} \mathbf{X}$;

- (c) β and κ are orthogonal: $E\{\partial^2 \ell / \partial \beta \partial \kappa\} = \mathbf{0}$. Hence the asymptotic distribution of $\hat{\beta}$ is the same whether κ is known or estimated, and the two can be updated alternately;
- (d) the score for κ is $\sum_i \{\psi(y_i + \kappa) - \psi(\kappa) + \log \frac{\kappa}{\kappa + \mu_i} + 1 - \frac{\kappa + y_i}{\kappa + \mu_i}\}$, where ψ is the digamma function; it has no closed-form root and is solved numerically;
- (e) the Poisson model is the boundary case $\alpha = 1/\kappa = 0$. The likelihood ratio statistic L for $H_0 : \alpha = 0$ is therefore *not* asymptotically $\chi^2(1)$; under the conditions of Self and Liang (1987) its limiting distribution is $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$, so the p -value is $\Pr\{N(0, 1) > \sqrt{L}\}$, half the naive one;
- (f) in the NB1 model of Definition 37.4.1(b), with $\kappa_i = \alpha \mu_i$ and a log link, the score for β at fixed α is

$$\frac{\partial \ell}{\partial \beta} = \alpha \sum_{i=1}^n \mu_i \left\{ \psi(y_i + \alpha \mu_i) - \psi(\alpha \mu_i) + \log \frac{\alpha}{1 + \alpha} \right\} \mathbf{x}_{(i)}. \quad (37.4.6)$$

The residual $y_i - \mu_i$ does not appear, so this is not a weighted least squares equation at all. The quasi-Poisson model of Chapter 38 shares the NB1 variance function $V(\mu) = \phi \mu$ but has the Poisson estimating equation $\mathbf{X}^\top (\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$, so the two give different $\hat{\beta}$ from the same data (Exercise (B3)): a variance function does not determine a fit. Overdispersion is the rule rather than the exception, and modelling it changes the coefficients little and the standard errors a great deal; which of the three devices to use turns on whether a likelihood is needed, as it is for AIC and for Section 37.5.

Proof.

- (a) Take logarithms in [Eq. 37.4.1](#):

$$\log \Pr(Y = y) = y \log \frac{\mu}{\mu + \kappa} + \kappa \log \frac{\kappa}{\kappa + \mu} + \log \frac{\Gamma(y + \kappa)}{\Gamma(\kappa) y!}.$$

With $\theta = \log\{\mu/(\mu + \kappa)\}$, which is a strictly increasing bijection from $(0, \infty)$ onto $(-\infty, 0)$, we have $\mu = \kappa e^\theta / (1 - e^\theta)$ and $\kappa/(\kappa + \mu) = 1 - e^\theta$, so the second term is $\kappa \log(1 - e^\theta) = -b(\theta)$. The last term does not involve μ . Then $b'(\theta) = \kappa e^\theta / (1 - e^\theta) = \mu$ and $b''(\theta) = \kappa e^\theta / (1 - e^\theta)^2 = \mu(1 + \mu/\kappa)$, which by [Proposition 34.1.2](#) are the mean and the variance.

- (b) By [Theorem 34.3.1](#) the score is $\sum_i \mathbf{x}_{(i)}(y_i - \mu_i)(\partial \mu_i / \partial \eta_i) / V(\mu_i)$. With the log link $\partial \mu_i / \partial \eta_i = \mu_i$, and $\mu_i / V(\mu_i) = \mu_i / \{\mu_i(1 + \mu_i/\kappa)\} = 1/(1 + \mu_i/\kappa)$, giving the score [Eq. 37.4.5](#). The general IRLS weight of [Theorem 34.4.1](#) is $(\partial \mu_i / \partial \eta_i)^2 / V(\mu_i) = \mu_i / (1 + \mu_i/\kappa)$.
- (c) Differentiating [Eq. 37.4.5](#), written as $\sum_i \mathbf{x}_{(i)} \kappa (y_i - \mu_i) / (\mu_i + \kappa)$, with respect to κ at fixed $\boldsymbol{\beta}$ (so that μ_i is fixed) gives

$$\begin{aligned} \frac{\partial^2 \ell}{\partial \boldsymbol{\beta} \partial \kappa} &= \sum_i \mathbf{x}_{(i)}(y_i - \mu_i) \frac{\partial}{\partial \kappa} \frac{\kappa}{\mu_i + \kappa} \\ &= \sum_i \mathbf{x}_{(i)}(y_i - \mu_i) \frac{\mu_i}{(\mu_i + \kappa)^2}. \end{aligned}$$

Every term is a constant times $y_i - \mu_i$, which has mean zero, so the expectation vanishes. The information matrix is therefore block diagonal, and the leading block of its inverse is the inverse of the $\boldsymbol{\beta}$ block.

- (d) Differentiate the logarithm of [Eq. 37.4.1](#) in κ at fixed μ , using $d \log \Gamma(x) / dx = \psi(x)$, and collect terms.
- (e) With $\kappa_i = \alpha \mu_i$ the two ratios in [Eq. 37.4.1](#) become constants, $\kappa_i / (\kappa_i + \mu_i) = \alpha / (1 + \alpha)$ and $\mu_i / (\mu_i + \kappa_i) = 1 / (1 + \alpha)$, so

$$\ell = \sum_i \left\{ \log \frac{\Gamma(y_i + \alpha \mu_i)}{\Gamma(\alpha \mu_i) y_i!} + \alpha \mu_i \log \frac{\alpha}{1 + \alpha} - y_i \log(1 + \alpha) \right\}.$$

Only $\alpha \mu_i$ depends on $\boldsymbol{\beta}$; differentiating with $\partial \mu_i / \partial \boldsymbol{\beta} = \mu_i \mathbf{x}_{(i)}$ gives [Eq. 37.4.6](#).

- (f) By [Lemma 37.4.1\(c\)](#) the Poisson is the limit $\alpha \downarrow 0$, and $\alpha \geq 0$ is required for [Eq. 37.4.1](#) to be a distribution, so the null value is on the boundary. The expansion behind the $\chi^2(1)$ limit assumes an interior maximum; here the unconstrained maximizer of the profile likelihood falls below zero about half the time, and $L = 0$ on that event. [Theorem 32.5.2](#) computes the analogous mixture exactly in a balanced variance-components problem; the general statement is Self and Liang's. The upper tail of $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$ at L is $\frac{1}{2} \Pr\{\chi^2(1) > L\} = \Pr\{N(0, 1) > \sqrt{L}\}$.

■

Part (c) makes the alternating algorithm honest as well as convenient: iterate the weighted least squares step of (b) at the current κ , then solve (d) at the current $\boldsymbol{\beta}$, and the standard errors computed as though κ were known are asymptotically correct.

37.4.3 A score test for overdispersion

The likelihood ratio test in [Proposition 37.4.2\(e\)](#) needs the negative binomial fit. A score test needs only the Poisson fit, which makes it the natural diagnostic to compute alongside any Poisson regression.

Theorem 37.4.3 — Score test against NB2 alternatives

Let $\hat{\mu}_i$ be the fitted means of a Poisson log-linear model with $\text{rank}(\mathbf{X}) = p$, and consider the NB2 family [Eq. 37.4.2](#) indexed by $\alpha \geq 0$. Then the score for α at $\alpha = 0$ is

$$\left. \frac{\partial \ell}{\partial \alpha} \right|_{\alpha=0} = \frac{1}{2} \sum_{i=1}^n \{(y_i - \mu_i)^2 - y_i\}, \quad (37.4.7)$$

its variance under the Poisson model is $\frac{1}{2} \sum_i \mu_i^2$, and its covariance with the score for $\boldsymbol{\beta}$ is zero. Suppose in addition that, as $n \rightarrow \infty$ with p fixed, the true means stay in a fixed compact interval inside $(0, \infty)$ and no observation dominates, in the sense that

$$\frac{\sum_{i=1}^n \mu_i^4}{(\sum_{i=1}^n \mu_i^2)^2} \rightarrow 0. \quad (37.4.8)$$

Then

$$S = \frac{\sum_{i=1}^n \{(y_i - \hat{\mu}_i)^2 - y_i\}}{\sqrt{2 \sum_{i=1}^n \hat{\mu}_i^2}} \quad (37.4.9)$$

is asymptotically standard normal under the Poisson model, and the test rejects for large positive S .

Proof. Take logarithms in [Eq. 37.4.2](#):

$$\ell_i(\alpha) = y_i \log \mu_i - \log y_i! + \sum_{k=0}^{y_i-1} \log(1 + \alpha k) - \left(\frac{1}{\alpha} + y_i \right) \log(1 + \alpha \mu_i).$$

Expand in α . The sum contributes $\alpha \sum_{k=0}^{y_i-1} k + O(\alpha^2) = \alpha y_i(y_i - 1)/2 + O(\alpha^2)$. For the last term, $\log(1 + \alpha \mu_i) = \alpha \mu_i - \alpha^2 \mu_i^2/2 + O(\alpha^3)$, so

$$\left(\frac{1}{\alpha} + y_i \right) \log(1 + \alpha \mu_i) = \mu_i + \alpha \left(y_i \mu_i - \frac{\mu_i^2}{2} \right) + O(\alpha^2).$$

Hence

$$\begin{aligned} \ell_i(\alpha) &= y_i \log \mu_i - \mu_i - \log y_i! \\ &\quad + \alpha \{y_i(y_i - 1)/2 - y_i \mu_i + \mu_i^2/2\} + O(\alpha^2). \end{aligned}$$

The leading term is the Poisson log-likelihood and the coefficient of α is $\frac{1}{2} \{y_i^2 - y_i - 2y_i \mu_i + \mu_i^2\} = \frac{1}{2} \{(y_i - \mu_i)^2 - y_i\}$, which gives [Eq. 37.4.7](#).

For the variance, put $Z_i = Y_i - \mu_i$ and $A_i = (Y_i - \mu_i)^2 - Y_i = Z_i^2 - Z_i - \mu_i$. For a Poisson variable, $E Z_i = 0$, $E Z_i^2 = \mu_i$, $E Z_i^3 = \mu_i$ and $E Z_i^4 = \mu_i + 3\mu_i^2$. Therefore $E A_i = \mu_i - 0 - \mu_i = 0$ and

$$\begin{aligned} \text{Var } A_i &= E(Z_i^2 - Z_i - \mu_i)^2 \\ &= E Z_i^4 - 2 E Z_i^3 - 2\mu_i E Z_i^2 + E Z_i^2 + 2\mu_i E Z_i + \mu_i^2 \\ &= 2\mu_i^2. \end{aligned}$$

The A_i are independent, so the variance of Eq. 37.4.7 is $\frac{1}{4} \sum_i 2\mu_i^2 = \frac{1}{2} \sum_i \mu_i^2$.

For the covariance, differentiate Eq. 37.4.7 in β , using $\partial\mu_i/\partial\beta = \mu_i \mathbf{x}_{(i)}$:

$$\frac{\partial}{\partial\beta} \frac{1}{2} \{(y_i - \mu_i)^2 - y_i\} = -\mu_i(y_i - \mu_i) \mathbf{x}_{(i)},$$

whose expectation is zero. The information between α and β therefore vanishes at $\alpha = 0$, so the usual adjustment for an estimated nuisance parameter is zero and replacing β by $\hat{\beta}$ does not change the asymptotic variance of the score to first order. Dividing by the standard deviation, with $\hat{\mu}_i$ for μ_i , gives Eq. 37.4.9. For the limit, the A_i are independent with mean zero and $E A_i^4 = O(\max(\mu_i, 1)^4)$, a fourth-moment calculation like the one above. Under the two hypotheses of the statement — means in a fixed compact interval inside $(0, \infty)$ and Eq. 37.4.8 — Lyapunov's condition holds with $\delta = 2$ and the standardized sum is asymptotically standard normal. Dean and Lawless (1989) treat designs in which the means are not so confined. ■

The statistic is one-sided by construction: a count *less* variable than the Poisson is possible but not negative binomial, so a large negative S points somewhere else (Exercise (C1)).

37.4.4 The physician visits again

Example. (Negative binomial fits to the visit counts)

Refit the model of Example (Physician visits in a health insurance experiment) with the NB2 distribution, alternating the weighted least squares step of Proposition 37.4.2(b) with a one-dimensional solve for κ . The fit gives $\hat{\kappa} = 0.7637$, that is $\hat{\alpha} = 1.3094$; at the overall mean of 2.860 visits the model's variance is 13.574 against the Poisson's 2.860. The maximized log-likelihood rises from -62737.33 to -43468.52 , so the likelihood ratio statistic for $H_0 : \alpha = 0$ is 38537.6; the boundary correction of Proposition 37.4.2(e) halves a p -value whose logarithm is about -19275 . The score statistic Eq. 37.4.9, from the Poisson fit alone, is 523.0.

What changes is inference. For the individual-deductible indicator the point estimate moves only from -0.2648 to -0.2475 , but its standard error moves from 0.0102 to 0.0218, a factor of 2.125. Two other repairs agree: scaling the Poisson standard errors by $\sqrt{\hat{\phi}}$, with $\hat{\phi} = 6.319$ the Pearson statistic over its degrees of freedom, gives 0.0257, and the sandwich estimator of Theorem 21.4.2 gives 0.0268. A Poisson analysis would have declared effects significant on the strength of a variance assumption the data reject.

Fitting NB1 instead gives log-likelihood -43380.59 with $\hat{\phi} = 4.766$, a better fit than

Figure 37.4.1: Sample variances of the physician-visit counts within twenty-five bins of the fitted Poisson mean, against the three fitted variance functions. The Poisson line is far below every bin.

NB2 by AIC: 86779.2 against 86955.0, with the Poisson far behind at 125490.7. [Figure 37.4.1](#) shows why the comparison is close. Sorting the person-years by fitted mean into twenty-five bins, the bin variances follow the NB2 curve at the high end, while in the crowded low range, where most of the data and most of the likelihood sit, NB1 is closer. AIC weighs the whole likelihood and the figure the upper tail; when they disagree, choose by the use the model will be put to.

37.4.5 Exercises

37.4.5.1 A. Check your understanding

Exercise A1.

A negative binomial NB2 fit reports $\hat{\kappa} = 2$. By what factor does the model inflate the variance over the Poisson at a fitted mean of 1, of 10, and of 100? Repeat for an NB1

fit with $\hat{\phi} = 3$, and comment.

Exercise A2.

A colleague reports a likelihood ratio statistic of 2.9 for Poisson against NB2 and, comparing with $\chi^2(1)$, obtains $p = 0.089$ and concludes there is no overdispersion. What is the correct p -value, and does the conclusion change at the five per cent level?

37.4.5.2 B. Practice

Exercise B1.

For an intercept-only Poisson model, $\hat{\mu}_i = \bar{y}$ for every i . Show that the score statistic [Eq. 37.4.9](#) reduces to $\sqrt{n/2} \{s_n^2/\bar{y} - 1\}$ with $s_n^2 = n^{-1} \sum_i (y_i - \bar{y})^2$, so that it compares the sample variance with the sample mean. Evaluate it for $n = 100$, $\bar{y} = 3$, $s_n^2 = 5$.

Solution. With $\hat{\mu}_i = \bar{y}$ the numerator is $\sum_i (y_i - \bar{y})^2 - n\bar{y} = n(s_n^2 - \bar{y})$ and the denominator is $\sqrt{2n\bar{y}^2} = \bar{y}\sqrt{2n}$, so the ratio is $\sqrt{n/2}(s_n^2 - \bar{y})/\bar{y}$. For the numbers given this is $\sqrt{50} \times (5 - 3)/3$, about 4.7: strong evidence of overdispersion.

Exercise B2.

Show that if Y is NB2 with mean μ and shape κ , then $\Pr(Y = 0) = (1 + \mu/\kappa)^{-\kappa}$, that this exceeds $e^{-\mu}$ for every finite κ , and that it tends to one as $\kappa \rightarrow 0$ with μ fixed. Interpret the last statement.

Solution. Setting $y = 0$ in [Eq. 37.4.1](#) leaves $\{\kappa/(\kappa + \mu)\}^\kappa$, which is $(1 + \mu/\kappa)^{-\kappa}$. Since $\log(1 + x) < x$ for $x > 0$, $\kappa \log(1 + \mu/\kappa) < \mu$, so the probability exceeds $e^{-\mu}$. As $\kappa \rightarrow 0$, $\kappa \log(1 + \mu/\kappa) \rightarrow 0$ and the probability tends to one: extreme heterogeneity concentrates the distribution on zero with occasional very large counts, which is why the negative binomial can on its own account for a great many zeros.

Exercise B3.

Show that the quasi-Poisson estimating equation for β is the *same* as the Poisson one, so that $\hat{\beta}$ is unchanged, while the NB2 equation [Eq. 37.4.5](#) downweights observations with large fitted means. Which model would you expect to be more affected by a single very large count?

Exercise B4.

Show that the deviance ([Definition 34.5.1](#)) of the NB2 model with κ known is

$$D = 2 \sum_{i=1}^n \left\{ y_i \log \frac{y_i}{\hat{\mu}_i} - (y_i + \kappa) \log \frac{y_i + \kappa}{\hat{\mu}_i + \kappa} \right\},$$

and that it tends to the Poisson deviance [Eq. 37.1.5](#) as $\kappa \rightarrow \infty$. Why does an analysis

of deviance based on it need κ to be held fixed across the models compared?

Solution. Dropping the terms free of μ , the log-likelihood contribution of observation i is $y_i \log\{\mu_i/(\mu_i + \kappa)\} + \kappa \log\{\kappa/(\mu_i + \kappa)\}$. The saturated model puts $\mu_i = y_i$, so twice the difference is

$$2\left\{y_i \log \frac{y_i}{\hat{\mu}_i} + (y_i + \kappa) \log \frac{\hat{\mu}_i + \kappa}{y_i + \kappa}\right\},$$

which is the stated formula. For the limit write $(y_i + \kappa) \log\{1 + (y_i - \hat{\mu}_i)/(\hat{\mu}_i + \kappa)\} = (y_i - \hat{\mu}_i) + O(\kappa^{-1})$. The deviance depends on κ , so two models fitted with different $\hat{\kappa}$ have deviances on different scales and their difference is not a likelihood ratio statistic; compare their maximized log-likelihoods instead.

37.4.5.3 C. Going deeper

Exercise C1.

Construct a count distribution with mean μ and variance strictly less than μ , and explain why no member of the negative binomial family has this property. What mechanisms produce underdispersed counts in practice, and what would you fit?

Solution. The binomial with m trials and probability π has mean $m\pi$ and variance $m\pi(1 - \pi) < m\pi$, while by [Lemma 37.4.1\(a\)](#) every Poisson mixture has variance at least its mean. Underdispersion arises when events are regular rather than random — inspections on a schedule, quotas — and the natural models are the binomial, or a Conway–Maxwell–Poisson family with a dispersion parameter free on both sides of one.

Exercise C2.

[Proposition 37.4.2\(a\)](#) identifies the canonical link of the NB2 family as $\theta = \log\{\mu/(\mu + \kappa)\}$. Work out the likelihood equations under this link, show that they take the form $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$, and explain why the log link is nevertheless the standard choice.

37.5 Zero inflation

Many count data sets have far more zeros than a Poisson or negative binomial model with the right mean can produce. The usual explanation is that zeros come from two places: some units are not at risk at all — they do not smoke, do not drive, are not eligible — and contribute a zero with certainty, while the rest contribute one only when the count happens to be zero. This section writes that story down as a model, does the same for its rival, and asks how the two can be told apart.

37.5.1 Two ways to make extra zeros

Definition 37.5.1 — Zero-inflated and hurdle models

Let $f(y; \lambda)$ be a count distribution with parameter λ , such as the Poisson or the NB2 family of [Definition 37.4.1](#), and let $\mathbf{z}_{(i)}$ and $\mathbf{x}_{(i)}$ be rows of two model matrices, which may be equal, overlapping or disjoint.

(a) The **zero-inflated** model gives Y_i the mass function

$$\Pr(Y_i = y) = \begin{cases} \pi_i + (1 - \pi_i)f(0; \lambda_i), & y = 0, \\ (1 - \pi_i)f(y; \lambda_i), & y = 1, 2, \dots, \end{cases} \quad (37.5.1)$$

with $\text{logit } \pi_i = \mathbf{z}_{(i)}^\top \boldsymbol{\gamma}$ and $\log \lambda_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$. Equivalently, a latent indicator Z_i is one with probability π_i , and $Y_i = 0$ when $Z_i = 1$ while $Y_i \sim f(\cdot; \lambda_i)$ when $Z_i = 0$. Taking f Poisson gives the **zero-inflated Poisson** (ZIP), and f negative binomial the **zero-inflated negative binomial** (ZINB).

(b) The **hurdle** model gives Y_i the mass function

$$\Pr(Y_i = y) = \begin{cases} 1 - \rho_i, & y = 0, \\ \rho_i \frac{f(y; \lambda_i)}{1 - f(0; \lambda_i)}, & y = 1, 2, \dots, \end{cases} \quad (37.5.2)$$

with $\text{logit } \rho_i = \mathbf{z}_{(i)}^\top \boldsymbol{\gamma}$ and $\log \lambda_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$: a binary model decides whether the count is positive, and a **zero-truncated** version of f decides how large it is.

These are different stories. The zero-inflated model says there are two kinds of unit and a zero does not reveal which; the hurdle model says there is one kind of unit and two decisions, whether to cross the threshold and how far to go once across. Which is right is a subject-matter question, and the data distinguish them only indirectly.

Proposition 37.5.1 — Properties of the two models

In the notation of [Definition 37.5.1](#), write $\mu_i = E(Y_i)$ and $\mathbf{1}_i = \mathbf{1}\{y_i > 0\}$. The zero-inflated log-likelihood is

$$\begin{aligned} & \sum_{i: y_i=0} \log\{\pi_i + (1 - \pi_i)f(0; \lambda_i)\} \\ & + \sum_{i: y_i>0} [\log(1 - \pi_i) + \log f(y_i; \lambda_i)], \end{aligned}$$

and the hurdle one is

$$\begin{aligned} & \sum_i [\mathbf{1}_i \log \rho_i + (1 - \mathbf{1}_i) \log(1 - \rho_i)] \\ & + \sum_{i: y_i>0} [\log f(y_i; \lambda_i) - \log\{1 - f(0; \lambda_i)\}]. \end{aligned}$$

Then:

(a) for the zero-inflated model with f Poisson,

$$\mu_i = (1 - \pi_i)\lambda_i, \quad \text{Var}(Y_i) = \mu_i(1 + \pi_i\lambda_i), \quad (37.5.3)$$

so a zero-inflated Poisson is always overdispersed relative to its own mean unless $\pi_i = 0$;

- (b) the hurdle log-likelihood separates, $\ell(\boldsymbol{\gamma}, \boldsymbol{\beta}, \cdot) = \ell_{\text{binary}}(\boldsymbol{\gamma}) + \ell_{\text{positive}}(\boldsymbol{\beta}, \cdot)$, so the two parts can be fitted independently, and their estimates are asymptotically independent; the zero-inflated log-likelihood does not separate;
- (c) the hurdle model can represent **zero deflation**, $\rho_i > 1 - f(0; \lambda_i)$, while [Eq. 37.5.1](#) needs $\pi_i \geq 0$ and can only add zeros; and, for the hurdle model, if $\mathbf{z}_{(i)}$ contains an intercept then its fitted probabilities of a zero average to the observed proportion of zeros, whatever else is in the binary part. The zero-inflated model satisfies no such identity;
- (d) the zero-inflated model contains f itself as the limiting case $\pi_i \equiv 0$, which lies outside the range where the usual expansion is valid, so a likelihood ratio test of f against its zero-inflated version is *not* asymptotically χ^2 ; nor is the Vuong statistic of [Eq. 37.5.5](#) valid for such a comparison.

Proof.

- (a) With the latent representation, $E(Y_i) = E\{E(Y_i | Z_i)\} = (1 - \pi_i)\lambda_i = \mu_i$. Since $E(Y_i | Z_i) = \lambda_i(1 - Z_i)$ has variance $\lambda_i^2\pi_i(1 - \pi_i)$, the law of total variance gives

$$\begin{aligned}\text{Var}(Y_i) &= E\{\text{Var}(Y_i | Z_i)\} + \text{Var}\{E(Y_i | Z_i)\} \\ &= (1 - \pi_i)\lambda_i + \lambda_i^2\pi_i(1 - \pi_i).\end{aligned}$$

Factoring out $(1 - \pi_i)\lambda_i = \mu_i$ gives $\text{Var}(Y_i) = \mu_i(1 + \pi_i\lambda_i)$, which exceeds μ_i whenever $\pi_i > 0$.

- (b) With $\mathbf{1}_i = \mathbf{1}\{y_i > 0\}$, [Eq. 37.5.2](#) gives

$$\begin{aligned}\ell &= \sum_i \left[\mathbf{1}_i \log \rho_i + (1 - \mathbf{1}_i) \log(1 - \rho_i) \right] \\ &\quad + \sum_{i: y_i > 0} \left[\log f(y_i; \lambda_i) - \log\{1 - f(0; \lambda_i)\} \right].\end{aligned}$$

The first sum involves only $\boldsymbol{\gamma}$ and the second only $\boldsymbol{\beta}$ and any shape parameter of f , with unconstrained parameter spaces, so the joint maximum is the pair of separate maxima and the information is block diagonal. For [Eq. 37.5.1](#) the contribution of a zero is $\log\{\pi_i + (1 - \pi_i)f(0; \lambda_i)\}$, which involves both parameter vectors inside one logarithm and does not separate.

- (c) In [Eq. 37.5.2](#), ρ_i is a free probability, so $\Pr(Y_i = 0) = 1 - \rho_i$ can take any value in $(0, 1)$; in [Eq. 37.5.1](#), $\Pr(Y_i = 0) = \pi_i + (1 - \pi_i)f(0; \lambda_i) \geq f(0; \lambda_i)$ for $\pi_i \in [0, 1]$. The first sum in the display in (b) is the log-likelihood of a logistic regression of $\mathbf{1}_i$ on $\mathbf{z}_{(i)}$, whose likelihood equations are $\sum_i (\mathbf{1}_i - \hat{\rho}_i) \mathbf{z}_{(i)} = \mathbf{0}$ by [Theorem 34.3.1](#) with the canonical link. If $\mathbf{z}_{(i)}$ contains an intercept, one of those equations reads $\sum_i \hat{\rho}_i = \sum_i \mathbf{1}_i$, so $n^{-1} \sum_i (1 - \hat{\rho}_i)$ is the observed proportion of zeros. The zero-inflated likelihood equation for the inflation intercept is instead $\sum_i \hat{\pi}_i = \sum_i \hat{w}_i$, with $\hat{w}_i$ the posterior weights [Eq. 37.5.4](#), which says nothing about $\sum_i \widehat{\Pr}(Y_i = 0)$.
- (d) Setting $\pi_i \equiv 0$ in [Eq. 37.5.1](#) recovers f , but how the χ^2 argument fails depends on the parameterization. If inflation is a single probability π , the null sits on the boundary of $[0, 1]$ and [Proposition 37.4.2\(e\)](#) applies verbatim. If $\text{logit } \pi_i = \mathbf{z}_{(i)}^\top \boldsymbol{\gamma}$, the null is reached only as the intercept tends to $-\infty$, and under it the remaining coefficients of $\boldsymbol{\gamma}$ are unidentified — a harder non-regularity, where no fixed mixture

of χ^2 laws is the limit. Either way the calibration fails. The Vuong statistic assumes strictly non-nested models, so that the mean of its summands is nonzero under the null; when they are nested that mean is zero and the limit is not normal. ■

Part (a) matters when choosing among the four combinations. A zero-inflated Poisson is already overdispersed, so excess zeros with no other anomaly can be described either by a ZIP or by a negative binomial; what a ZIP cannot do is produce a long right tail without also producing extra zeros. Zero inflation on a negative binomial addresses zeros and tail separately, which is why ZINB is the workhorse.

37.5.2 Fitting

The hurdle model needs no new machinery: fit a logistic regression to $\mathbf{1}\{y_i > 0\}$, then maximize $\sum_{y_i > 0} [\log f(y_i; \lambda_i) - \log\{1 - f(0; \lambda_i)\}]$ numerically over the positive observations. The zero-inflated model does not separate, but its latent representation invites the EM algorithm, which is what Lambert used. The E step computes the posterior probability that observation i came from the degenerate component,

$$w_i = \Pr(Z_i = 1 \mid Y_i = y_i) = \begin{cases} \frac{\pi_i}{\pi_i + (1 - \pi_i)f(0; \lambda_i)}, & y_i = 0, \\ 0, & y_i > 0, \end{cases} \quad (37.5.4)$$

by Bayes's rule. The M step maximizes the expected complete-data log-likelihood, which *does* separate: a logistic regression of the fractional response w_i on $\mathbf{Z}$, and a count regression of y_i on $\mathbf{X}$ with prior weights $1 - w_i$. Both are weighted fits already in hand. The M step need only *increase* that expected log-likelihood, not maximize it, so a single weighted least squares step for β and a single Newton step for the shape suffice; either way the observed-data log-likelihood increases at every iteration ([Exercise \(B4\)](#)).

37.5.3 An example

Example. (Five models for the physician visits)

A proportion 0.3124 of the 20190 person-years record no physician visit; the Poisson model of [Example \(Physician visits in a health insurance experiment\)](#) predicts 0.0809.

Table 37.5.1. Five count models for the physician-visit data, all with the same eight regressors; the zero-inflated models use them in both parts. The observed proportion of zeros is 0.3124.

model	parameters	log-likelihood	AIC	BIC	fitted $\Pr(Y = 0)$
Poisson	8	−62737.3	125490.7	125554.0	0.0809
NB2	9	−43468.5	86955.0	87026.3	0.3200
ZIP	16	−54978.6	109989.1	110115.8	0.3125
ZINB	17	−43391.8	86817.5	86952.0	0.3255

Figure 37.5.1: Observed distribution of physician visits (bars) and the fitted marginal distributions $n^{-1} \sum_i \Pr(Y_i = k)$ under four models. The Poisson is hopeless at zero and too heavy in the middle; the other three are close to each other and to the data.

hurdle NB	17	-43244.6	86523.2	86657.7	0.3124
-----------	----	----------	---------	---------	--------

Three things stand out. First, zero inflation alone does not save the Poisson: the ZIP reproduces the zeros almost exactly, at 0.3125, and still trails the plain negative binomial by more than eleven thousand in log-likelihood, because the trouble here is the whole shape of the distribution and not only its zeros. Second, the negative binomial *already* matches the zeros, at 0.3200 against 0.3124, as [Exercise \(B2\)](#) predicts: heterogeneity in the rate produces excess zeros as a by-product, and adding zero inflation gains 153.5 in twice the log-likelihood for eight parameters while slightly *overshooting*, at 0.3255. Third, the hurdle model wins on both AIC and BIC, and by construction reproduces the zero proportion exactly.

The hurdle model wins because of the positive counts, not the zeros. Splitting each log-likelihood at $y = 0$ shows it: on the zeros the hurdle model scores -6966.1 against the ZINB's -6757.5, a loss of 208.6; on the positive counts -36278.5 against -36634.2, a gain of 355.7, for a net 147.2. Above two visits the two are indistinguishable in [Figure 37.5.1](#); the difference is in how mass is arranged over the small positive counts, and the hurdle model buys that freedom by giving the truncated component its own shape, $\hat{\kappa} = 0.557$ against 0.838 in the ZINB. Estimated zero inflation in the ZINB averages only 0.0475: it too spends its extra parameters re-shaping the low counts, which is what a hurdle model does directly.

37.5.4 Telling them apart

Table 37.5.1 compares fits, not mechanisms, and settles no question about which story is right. It is worth being clear about what the data can and cannot decide.

Identification. When $\mathbf{z}_{(i)}$ and $\mathbf{x}_{(i)}$ are the same, the two parts compete to explain the same zeros and the likelihood is often very flat: a larger π_i with a larger λ_i fits almost as well as a smaller π_i with a smaller one. The parameters are identified in principle, since the positive counts pin down λ_i , but standard errors can be large, the two parts' coefficients strongly correlated, and the fit sensitive to the start. Restricting $\mathbf{z}_{(i)}$ to a few variables, or to an intercept, helps and is easier to defend.

The Vuong test. For two non-nested models fitted to the same data, Vuong (1989) proposed comparing the pointwise log-likelihood ratios $m_i = \log f_1(y_i; \hat{\theta}_1) - \log f_2(y_i; \hat{\theta}_2)$ with

$$V = \frac{\sqrt{n} \bar{m}}{s_m}, \quad s_m^2 = \frac{1}{n-1} \sum_{i=1}^n (m_i - \bar{m})^2, \quad (37.5.5)$$

which is asymptotically standard normal when the two models are equally close to the truth, so that large $|V|$ favours one or the other by its sign. For the physician visits, ZINB against the hurdle model gives $V = -7.23$: taken at face value it prefers the hurdle model, agreeing with AIC.

The test is often misused, routinely applied to compare a count model with its own zero-inflated version — exactly the nested case the theory excludes. Under the null $\bar{m}$ and s_m both tend to zero, the ratio has no normal limit, and the reported p -value is meaningless. In [Example \(Five models for the physician visits\)](#) that comparison gives $V = 5.90$, a number with no calibration; Wilson (2015) documents the practice. A further difficulty, quantified by Schennach and Wilhelm (2017), is poor size even in the non-nested case when the two models are close.

```
mu_p, mu_nb = np.exp(X @ beta_pois), np.exp(X @ beta_nb)
pi_zinb = 1 / (1 + np.exp(-X @ gamma_zinb))
mu_zinb = np.exp(X @ beta_zinb)
pi_h = 1 / (1 + np.exp(-X @ gamma_h))
mu_h = np.exp(X @ beta_h)
p0_h = np.exp(kappa_h * np.log(kappa_h / (kappa_h + mu_h)))

def vuong(log_f1, log_f2):
    """Vuong's statistic for model 1 against model 2 (not valid for nested models).
    """
    m = log_f1 - log_f2
    return np.sqrt(len(m)) * m.mean() / m.std(ddof=1)

log_zinb = np.where(y == 0, np.log(pi_zinb + (1 - pi_zinb) * np.exp(nb_logpmf(0.0,
    mu_zinb, kappa_zinb))),
    np.log1p(-pi_zinb) + nb_logpmf(y, mu_zinb, kappa_zinb))
log_hurdle = np.where(y == 0, np.log1p(-pi_h),
    np.log(pi_h) + nb_logpmf(y, mu_h, kappa_h) - np.log1p(-p0_h))
log_nb = nb_logpmf(y, mu_nb, kappa_nb)

print(f"ZINB against NB2 (nested, so not valid): V = {vuong(log_zinb, log_nb):6.2f}")
print(f"ZINB against the hurdle model: V = {vuong(log_zinb, log_hurdle):6.2f}")
```

What does distinguish them. By [Proposition 37.5.1\(c\)](#) the two differ in what they can say about the positive counts and about zero deflation, and those are where to look: comparing fitted and observed frequencies at $y = 1, 2, 3$, as in [Figure 37.5.1](#), is more informative than any single statistic.

Warning. Excess zeros are a symptom, not a diagnosis. Before reaching for a two-part model, check that the mean model is right, that the overdispersion is not heterogeneity a negative binomial would absorb, and that the zeros are not an artefact of the recording process: a question never asked, a period of non-observation, a value truncated on entry. The physician-visit data make the point. Of the two models, the hurdle likelihood factorizes and the zero-inflated one does not, which makes the hurdle easier to fit and to interpret; the zero-inflated model has the better story when there really are two kinds

of unit.

37.5.5 Exercises

37.5.5.1 A. Check your understanding

Exercise A1.

A ZIP model has $\pi = 0.3$ and $\lambda = 4$. Compute EY , $\text{Var } Y$, $\Pr(Y = 0)$ and the ratio of variance to mean, and compare with a Poisson having the same mean.

37.5.5.2 B. Practice

Exercise B1.

Let Y be Poisson with mean λ , truncated to $\{1, 2, \dots\}$. Show that $EY = \lambda/(1 - e^{-\lambda})$ and $\text{Var } Y = EY\{1 + \lambda - EY\}$, and deduce that the truncated distribution is underdispersed relative to its own mean.

Solution. Write $c = 1 - e^{-\lambda}$. The $y = 0$ term contributes nothing to either moment, so $EY = \lambda/c$ and $E\{Y(Y-1)\} = \lambda^2/c$, giving $\text{Var } Y = \lambda^2/c + \lambda/c - \lambda^2/c^2 = EY(1 + \lambda - EY)$. Since $EY = \lambda/c > \lambda$, the bracket is less than one.

Exercise B2.

Derive the mean and variance of a ZINB with inflation probability π , count mean λ and shape κ . Show that for a given mean and variance there is a curve of (π, λ, κ) values giving the same first two moments, and explain what this implies for the precision of the estimates.

Solution. $EY = (1 - \pi)\lambda$ and, by the law of total variance, $\text{Var } Y = (1 - \pi)(\lambda + \lambda^2/\kappa) + \pi(1 - \pi)\lambda^2 = EY\{1 + \lambda(\pi + 1/\kappa)\}$. The mean fixes $(1 - \pi)\lambda$ and the variance $\lambda(\pi + 1/\kappa)$: two equations in three unknowns, so a one-dimensional family shares the first two moments. Only higher moments separate them, so the likelihood is flat along it and the estimates are strongly correlated with large standard errors.

Exercise B3.

Fit a ZINB to the physician-visit data using only an intercept in the inflation part, and compare its AIC with the model of [Example \(Five models for the physician visits\)](#) that uses all the regressors in both parts. Which does AIC prefer, and what does the comparison say about the eight inflation coefficients?

Exercise B4.

Show that the EM step described around [Eq. 37.5.4](#) increases the observed-data log-likelihood at every iteration, by writing the observed-data log-likelihood as the expected

complete-data log-likelihood minus an entropy term and using Jensen's inequality.

37.5.5.3 C. Going deeper

Exercise C1.

Take f Poisson, $\mathbf{z}_{(i)} = \mathbf{x}_{(i)}$, and a hurdle model whose binary part uses the complementary log-log link, $\log\{-\log(1 - \rho_i)\} = \mathbf{z}_{(i)}^\top \boldsymbol{\gamma}$, in place of the logit of Definition 37.5.1(b). Show that this model contains the plain Poisson as the submodel $\boldsymbol{\gamma} = \boldsymbol{\beta}$, so that a likelihood ratio test of the Poisson against it is a standard interior test on p restrictions, unlike the zero-inflated comparison of Proposition 37.5.1(d). Then show that the same is not true if the binary part uses the logit.

Solution. The hurdle model reduces to f when $\rho_i = 1 - f(0; \lambda_i)$ for every i . For the Poisson that is $1 - e^{-\lambda_i}$, so $-\log(1 - \rho_i) = \lambda_i$ and the complementary log-log link makes the constraint read $\mathbf{z}_{(i)}^\top \boldsymbol{\gamma} = \log \lambda_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, that is $\boldsymbol{\gamma} = \boldsymbol{\beta}$: a linear restriction of p dimensions in the interior of $\mathbb{R}^{2p}$, so the usual $\chi^2(p)$ limit applies. With the logit the constraint is $\mathbf{x}_{(i)}^\top \boldsymbol{\gamma} = \log(e^{\lambda_i} - 1)$, and since $t \mapsto \log(e^t - 1)$ is not affine, the vector on the right lies in $\mathcal{C}(\mathbf{X})$ only in degenerate cases such as $\mathbf{X}\boldsymbol{\beta}$ constant. The Poisson is then not a smooth submodel at all and no likelihood ratio test of one against the other exists: a model “containing” another is not the same as nesting it.

Exercise C2.

In a zero-inflated model β_j is a log rate ratio for the count component, not for the response. Derive $\partial \log E(Y_i) / \partial x_{ij}$ when x_j appears in both parts, and explain why reporting $e^{\hat{\beta}_j}$ as “the effect on the expected count” is wrong.

Solution. $E(Y_i) = (1 - \pi_i)\lambda_i$, so $\log E(Y_i) = \log(1 - \pi_i) + \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ and

$$\frac{\partial \log E(Y_i)}{\partial x_{ij}} = \beta_j - \frac{1}{1 - \pi_i} \frac{\partial \pi_i}{\partial x_{ij}} = \beta_j - \pi_i \gamma_j,$$

using $\partial \pi_i / \partial x_{ij} = \pi_i(1 - \pi_i)\gamma_j$ for the logit link. The effect on the expected response therefore mixes the two parts and depends on π_i , hence on all the covariates; $e^{\hat{\beta}_j}$ is the rate ratio only within the non-degenerate component, a conditional statement about a latent class nobody observes.

37.6 Summary and Notes

37.6.1 Summary

Idea.

1. The Poisson is the exponential dispersion family with $V(\mu) = \mu$ and no free dispersion; its canonical link is the logarithm, so coefficients are log rate ratios (Def-

- initiation 37.1.1).
2. The likelihood equations are $\mathbf{X}^\top(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \mathbf{0}$, the information is $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{W} = \text{diag}(\hat{\mu}_i)$, and the log-likelihood is strictly concave at full column rank ([Theorem 37.1.1](#)). Fitted counts reproduce the observed margins spanned by the model matrix ([Theorem 37.1.2](#)).
 3. The maximum likelihood estimate exists exactly when no direction $\mathbf{d}$ satisfies [Eq. 37.1.3](#) ([Proposition 37.1.3](#)); a ridge penalty always restores one.
 4. Exposure enters as an offset, a column with coefficient fixed at one. Grouping records with identical regressors and carrying group size as exposure leaves the fit unchanged; estimating the exposure coefficient costs precision, fixing a wrong one costs bias ([Proposition 37.2.1](#)).
 5. Independent Poisson counts conditioned on their total are multinomial, and the two fits agree whenever the model has a free parameter for every total the design fixed ([Theorem 37.3.1](#)). Independence is the no-interaction model ([Corollary 37.3.2](#)), and interaction parameters are log odds ratios ([Proposition 37.3.3](#)).
 6. A gamma mixture of Poissons is negative binomial, with variance $\mu + \mu^2/\kappa$ ([Lemma 37.4.1](#), [Definition 37.4.1](#)); any mixing distribution inflates the variance. At fixed κ the NB2 model is a generalized linear model, $\boldsymbol{\beta}$ and κ are orthogonal, and the test of $\alpha = 1/\kappa = 0$ is on the boundary, so its null distribution is $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$; part (f) gives the NB1 score and its relation to quasi-Poisson ([Proposition 37.4.2](#)). The score test [Eq. 37.4.9](#) needs only the Poisson fit ([Theorem 37.4.3](#)).
 7. Zero-inflated models add a mass at zero; hurdle models cut the distribution at zero and fit the two pieces separately, which factorizes the likelihood ([Definition 37.5.1](#), [Proposition 37.5.1](#)). The Vuong statistic [Eq. 37.5.5](#) is not valid for the nested comparison it is usually applied to.

37.6.2 Notes and sources

Poisson regression. The log-linear model for counts predates the generalized linear model, but Nelder and Wedderburn (1972) put it in its modern setting, and McCullagh and Nelder (1989) is the standard reference for the deviance, residuals and fitting algorithm. Agresti (2015, chapter 7) and Fahrmeir et al. (2021, section 5.2) are the sources against which this chapter's coverage was checked; Cameron and Trivedi (2013) and Winkelmann (2008) are book-length econometric treatments. The existence condition [Proposition 37.1.3](#) is the Poisson analogue of the separation conditions of [Chapter 35](#), proved here from scratch. The Anscombe residual of [Exercise \(B3\)](#) is from Anscombe (1948).

Rates. Treating survival data with piecewise-constant hazards as Poisson counts with an offset is due to Holford (1980) and Laird and Olivier (1981); it is the reason that much of the early software for survival analysis was software for log-linear models.

Contingency tables. The Poisson–multinomial correspondence and the maximum likelihood theory of hierarchical log-linear models are in Birch (1963) and, comprehensively, Bishop, Fienberg and Holland (1975). Graphical log-linear models are due to Darroch, Lauritzen and Speed (1980). The chi-squared test for independence is Pearson (1900); [Corollary 37.3.2](#) is its likelihood-based restatement.

The negative binomial. The gamma mixture derivation goes back to Greenwood and Yule (1920), who used it for accident proneness. The NB1 and NB2 parameterizations and their

different estimating equations are discussed by Cameron and Trivedi (2013, section 3.3) and Hilbe (2011). The score test [Eq. 37.4.9](#) is due to Dean and Lawless (1989); the derivation here, by expanding the log-likelihood in α , is the usual one. The boundary problem is the setting of Self and Liang (1987), invoked by [Proposition 37.4.2\(e\)](#); [Theorem 32.5.2](#) computes a comparable case exactly.

Zeros. The zero-inflated Poisson model and its EM algorithm are Lambert (1992), written for defect counts in manufacturing; hurdle models are Mullahy (1986). Vuong (1989) introduced the model-selection statistic, for strictly non-nested models; Wilson (2015) documents its misuse for zero-inflation testing, and Schennach and Wilhelm (2017) analyse its size and propose a repair. The definitions and likelihoods of the two model families are [Definition 37.5.1](#) and the preamble to [Proposition 37.5.1](#). [Chapter 38](#) returns to overdispersion without a likelihood, and [Chapter 40](#) to counts that are not independent.

Chapter 38

Quasi-Likelihood and Overdispersion

A generalized linear model asks for a great deal and gives a great deal back. Naming the family fixes the whole distribution of the response, and with it the exact relation between its mean and its variance — the part of the bargain the data most often refuse. Counts of accidents, litters of affected pups, votes in households, durations of strikes are nearly always more variable than the Poisson or the binomial allows, and no choice of link repairs it. This chapter takes the least drastic way out. The likelihood equations of [Chapter 34](#) use the density only through the mean and the variance function, so one may write down those two and estimate from the equations alone. The estimate is unchanged, its consistency survives a wrong variance function, and its standard errors can be read off the data rather than the model. What is given up is the likelihood, and with it the likelihood ratio test, the Akaike criterion, and every statement about a probability.

What you need. [Chapter 34](#) throughout: the model ([Definition 34.2.1](#)), the variance function ([Definition 34.1.2](#)), the score and the information ([Theorem 34.3.1](#)), iteratively reweighted least squares ([Theorem 34.4.1](#)), the deviance ([Definition 34.5.1](#), [Theorem 34.5.5](#)) and the asymptotics ([Theorem 34.5.1](#), [Proposition 34.5.2](#)). [Section 21.4](#) for the sandwich estimators ([Definition 21.4.1](#), [Theorem 21.4.2](#)) and [Section 21.3](#) for weighted least squares ([Theorem 21.3.1](#)). - [Quasi-likelihood estimating equations](#)
- [Sandwich covariance estimation](#)
- [Overdispersion](#)
- [Summary and notes](#)

38.1 Variance functions

Fitting a generalized linear model needs a family, a link and a linear predictor. [Section 34.3](#) noticed that the family enters the likelihood equations

$$\sum_{i=1}^n x_{ij} \frac{w_i h'(\eta_i)}{V(\mu_i)} (y_i - \mu_i) = 0, \quad j = 1, \dots, p, \quad (38.1.1)$$

only through the variance function V : two densities with the same V produce the same estimate. The apparatus of [Definition 34.1.1](#) — a natural parameter, a cumulant function, a density that integrates to one — *derives* [Eq. 38.1.1](#) and then disappears from it. This section puts the variance function first, and the model becomes a mean and a variance and nothing else.

38.1.1 Specifying the second moment only

Definition 38.1.1 — A variance specification

Let $Y_1, \dots, Y_n$ be independent, let $w_1, \dots, w_n > 0$ be known weights, let g be a strictly monotone differentiable link with inverse h , and let V be a positive, continuously differentiable function on an open interval $\mathcal{M} \subseteq \mathbb{R}$. A **variance specification** is the pair of assumptions

$$\mathbb{E}(Y_i) = \mu_i = h(\mathbf{x}_i^\top \boldsymbol{\beta}), \quad \text{Var}(Y_i) = \frac{\phi V(\mu_i)}{w_i}, \quad (38.1.2)$$

with $\boldsymbol{\beta} \in \mathbb{R}^p$ and $\phi > 0$ unknown. The function V is the **variance function** and ϕ the **dispersion**. No distribution is assumed for Y_i beyond these two moments.

The definition is weaker than [Definition 34.2.1](#) in saying nothing about higher moments, the support, or whether any distribution with these moments exists, and stronger in leaving ϕ free even for a V that came from a family in which it was fixed. The specifications in constant use are

name	$V(\mu)$	w_i	ϕ	$\mathcal{M}$
quasi-normal	1	1	free	$\mathbb{R}$
quasi-Poisson	μ	1	free	$(0, \infty)$
quasi-binomial	$\mu(1 - \mu)$	m_i	free	$(0, 1)$
quasi-gamma	μ^2	1	free	$(0, \infty)$
power	μ^ξ	1	free	$(0, \infty)$
NB2	$\mu + \mu^2/\kappa$	1	1	$(0, \infty)$

where y_i is a group proportion in the quasi-binomial row and m_i the number of trials behind it. A value $\phi > 1$ is **overdispersion** relative to the family that supplied V , and $\phi < 1$ **underdispersion**. The first four rows are variance functions of [Definition 34.1.2](#) with the dispersion set free; the last is that of [Definition 37.4.1\(a\)](#), for which a genuine likelihood exists.

Remark (When is a variance specification a distribution?). For ϕ free and $V(\mu) = \mu^\xi$, Jorgensen's classification of the Tweedie families ([Exercise \(C2\)](#)) settles whether some exponential dispersion family has exactly these moments: one exists for $\xi \leq 0$ and for $\xi \geq 1$, and for no ξ strictly between. Existence is not usefulness. At $\xi = 1$ the Tweedie family with dispersion ϕ is ϕW with W Poisson of mean μ/ϕ : the right two moments, but on the multiples of ϕ rather than the integers. So no *exponential dispersion family* on the counts has mean μ and variance $\phi\mu$ for one ϕ and all μ . A family of counts with exactly those two moments does exist — the NB1 model of [Definition 37.4.1\(b\)](#) — but it is not an exponential dispersion family, and its likelihood equations are not [Eq. 38.1.1](#); that is the point of the third subsection of this section.

Warning. The quasi-binomial specification is empty when $m_i = 1$. An ungrouped binary response has $Y_i^2 = Y_i$, so $\text{Var}(Y_i) = \mu_i(1 - \mu_i)$ exactly for every distribution on $\{0, 1\}$ with mean μ_i , and there is no room for a ϕ . A dispersion estimate far from 1 in an ungrouped logistic fit is a statement about the mean model — an omitted term, a wrong link, a few gross outliers — never about the variance, the second-moment counterpart of [Theorem 34.5.5\(c\)](#).

38.1.2 Two ways to inflate a binomial

Where a dispersion is available it can take more than one shape, and the shapes are distinguishable. Suppose observation i averages m_i dependent binary trials.

Lemma 38.1.1 — Exchangeable trials

Let $Z_1, \dots, Z_m$ be binary variables with common mean π and $\text{Cov}(Z_s, Z_t) = \rho\pi(1 - \pi)$ for all $s \neq t$, so that ρ is their common correlation, and let $\bar{Z} = m^{-1} \sum_t Z_t$. Then

$$\mathbb{E}(\bar{Z}) = \pi, \quad \text{Var}(\bar{Z}) = \left\{1 + \rho(m - 1)\right\} \frac{\pi(1 - \pi)}{m}, \quad (38.1.3)$$

and $\rho \geq -1/(m - 1)$, with $\rho \geq 0$ whenever the trials are conditionally independent and identically distributed given some unobserved variable.

Proof. Each Z_t has variance $\pi(1 - \pi)$, so the stated covariance is ρ times it and $\text{Var}(\bar{Z}) = m^{-2}\{m\pi(1 - \pi) + m(m - 1)\rho\pi(1 - \pi)\}$, which is [Eq. 38.1.3](#); nonnegativity gives $1 + \rho(m - 1) \geq 0$. If the Z_t are independent given U with $\Pr(Z_t = 1 \mid U) = \Pi$ the same for each t , the law of total covariance gives $\text{Cov}(Z_s, Z_t) = \text{Var}(\Pi) \geq 0$. ■

The variance specification suggested by [Eq. 38.1.3](#) is

$$V_\rho(\mu) = \left\{1 + \rho(m_i - 1)\right\} \mu(1 - \mu), \quad w_i = m_i, \quad \phi = 1,$$

in which the inflation grows with the group size, against the quasi-binomial $V(\mu) = \mu(1 - \mu)$ with $w_i = m_i$ and a constant ϕ . The two agree at one group size and nowhere else ([Figure 38.1.1](#)): at $\phi = 1.8$ and $\rho = 0.05$ they cross at $m = 17.0$ and differ by a factor 1.639 at $m = 40$.

Figure 38.1.1: Two variance functions for a proportion from m trials, as multiples of $\pi(1 - \pi)/m$. A constant dispersion inflates every group equally; exchangeable trials inflate large groups more, by Eq. 38.1.3.

Spread-out group sizes separate them, by a plot of squared Pearson residuals against m_i ; equal ones do not.

```
import numpy as np

m_grid = np.arange(1, 41)
phi, rho = 1.8, 0.05
inflated = np.full_like(m_grid, phi, dtype=float)      # V(pi) = phi pi(1-pi)/m
exchangeable = 1 + rho * (m_grid - 1)                  # V(pi) = {1+rho(m-1)} pi(1-
    pi)/m
crossing = 1 + (phi - 1) / rho                          # the one group size where
    they agree
print(f"the two variance functions agree at m = {crossing:.1f}")
print(f"at m = 40 they differ by a factor {exchangeable[-1] / phi:.3f}")
```

The second specification is not an invention of the quasi-likelihood literature: the **beta-binomial** distribution, a binomial mixed over a beta success probability, has exactly this variance (Exercise (B1)), so a mixture and a correlation leave the same trace in the second moment.

38.1.3 A variance function does not determine a fit

A variance function settles the estimating equations, which is less than settling the fit: two models can share a variance function and disagree about $\hat{\beta}$, because the second model's likelihood equations need not be Eq. 38.1.1. The NB1 model of Definition 37.4.1(b) has variance $\phi\mu_i$ with $\phi = 1 + \alpha^{-1}$, the quasi-Poisson variance function exactly; but its score Eq. 37.4.6 does not contain the residual $y_i - \mu_i$ at all, and the two estimates differ in general (Exercise (B3)), as Section 38.4 shows in numbers. A *model* is a set of distributions; a *variance specification* is two moment assumptions plus the rule Eq. 38.1.1 for turning them into an estimate.

38.1.4 What the missing density costs

Dropping the density is not free. There is no maximized likelihood, so [Proposition 34.5.3](#) loses one of its three members and [Section 38.3](#) must supply substitutes; no Akaike or Bayesian criterion, since both are $-2\ell(\hat{\beta})$ plus a penalty ([Definition 29.2.2](#)), though cross-validation ([Definition 29.3.1](#)) survives; and no predictive distribution, so a fitted quasi-Poisson model cannot say what fraction of units will record zero, simulate a data set, or be checked by a predictive comparison, where a negative binomial or beta-binomial model does all three. What survives is the estimate, its consistency, its asymptotic normality, and a covariance estimate that does not need the variance function to be right — the subject of the next two sections.

38.1.5 Exercises

38.1.5.1 A. Check your understanding

Exercise A1.

For each of the following, say whether a dispersion parameter $\phi \neq 1$ is meaningful, and why: (a) counts of insurance claims per policy; (b) the proportion of a litter of 12 pups showing a defect; (c) an indicator of whether a patient survived; (d) the proportion of 500 sampled voters supporting a candidate, the voters sampled in clusters of 10 households.

Solution.

- (a) Yes: nothing ties a count's variance to its mean, and heterogeneity between policies inflates it ([Lemma 37.4.1\(a\)](#)). (b) Yes, with $w_i = 12$: correlation between littermates, or variation between litters, inflates the variance by [Lemma 38.1.1](#). (c) No: a binary response has variance $\mu(1 - \mu)$ whatever else is true. (d) Yes, but the group size is the cluster, not 500; using $m = 500$ in [Eq. 38.1.3](#) would overstate the inflation.

Exercise A2.

Two analysts fit grouped binomial data with group sizes between 5 and 60, one using a constant dispersion ϕ and one using the exchangeable form [Eq. 38.1.3](#) with correlation ρ . They report $\hat{\phi} = 2.5$ and $\hat{\rho} = 0.04$. At which group size do the two fitted variances agree? For which groups does the first analyst's model claim the larger variance?

Solution. Setting $1 + \rho(m - 1) = \phi$ gives $m = 1 + (\phi - 1)/\rho = 1 + 1.5/0.04 = 38.5$; below it the constant-dispersion model claims the larger variance, above it the smaller.

38.1.5.2 B. Practice

Exercise B1.

Let Π have a beta distribution with parameters $a, b > 0$, so that $E\Pi = \mu = a/(a + b)$ and $\text{Var } \Pi = \mu(1 - \mu)/(a + b + 1)$, and let $m\bar{Y}$ be binomial (m, Π) given Π . Show that

$E\bar{Y} = \mu$ and

$$\text{Var}(\bar{Y}) = \{1 + \rho(m-1)\} \frac{\mu(1-\mu)}{m}, \quad \rho = \frac{1}{a+b+1},$$

so the beta-binomial has the variance function of [Eq. 38.1.3](#). Deduce that the beta-binomial and an exchangeable-trials model with the same ρ cannot be told apart by first and second moments.

Solution. The conditional mean is Π and the conditional variance $\Pi(1-\Pi)/m$, so $E\bar{Y} = \mu$ and, by the law of total variance and $E\Pi^2 = \text{Var}\Pi + \mu^2$,

$$\text{Var}(\bar{Y}) = \frac{E\{\Pi(1-\Pi)\}}{m} + \text{Var}\Pi = \frac{\mu(1-\mu) - \text{Var}\Pi}{m} + \text{Var}\Pi = \frac{\mu(1-\mu)}{m} \{1 + (m-1)\rho\}$$

with $\rho = \text{Var}\Pi / \{\mu(1-\mu)\} = 1/(a+b+1)$. The two specifications therefore give identical first and second moments for every m .

Exercise B2.

Under the power specification $\text{Var}(Y) = \phi\mu^\xi$, find the coefficient of variation $\sqrt{\text{Var}(Y)}/E(Y)$ as a function of μ . For which ξ is it constant? Which of the specifications in the table of this section have the property that a multiplicative change of units, $Y \mapsto cY$, leaves the specification in the same family with a new ϕ ?

38.1.5.3 C. Going deeper

Exercise C1.

Let $Y \mid \Lambda$ have mean Λ and variance $a\Lambda^\xi$, and let Λ have mean μ and finite variance τ^2 . Show that the marginal variance is $a E(\Lambda^\xi) + \tau^2$, equal to $a\mu + \tau^2$ when $\xi = 1$. For $\xi = 2$, use Jensen's inequality to show that it is at least $a\mu^2 + \tau^2$, so a mixture of quasi-gamma responses is overdispersed relative to the quasi-gamma specification with the same a .

38.2 Quasi-likelihood estimating equations

Estimation here starts from [Eq. 38.1.1](#) and not from a density. There are two useful ways to read it: as the derivative of a function that is not quite a log-likelihood but close enough to carry the usual arguments, and as the best member of a large family of estimating equations. This section develops both, and they meet in the middle.

38.2.1 The quasi-likelihood function

Definition 38.2.1 — Quasi-likelihood

Under [Definition 38.1.1](#), the **quasi-likelihood** of a mean $\mu \in \mathcal{M}$ given a response y in

the closure of $\mathcal{M}$, with weight w , is

$$Q(\mu; y) = \frac{w}{\phi} \int_y^\mu \frac{y-t}{V(t)} dt, \quad (38.2.1)$$

assumed finite, the integral being read as a limit at an endpoint of $\mathcal{M}$ where it converges — as it does at $y = 0$ for $V(t) = t$ and at $y \in \{0, 1\}$ for $V(t) = t(1-t)$. The quasi-likelihood of the model is $Q(\boldsymbol{\beta}) = \sum_{i=1}^n Q(\mu_i; y_i)$ with $\mu_i = h(\mathbf{x}_i^\top \boldsymbol{\beta})$ and weight w_i .

The definition is designed to make one identity true by construction, and everything else follows from it.

Proposition 38.2.1 — What the quasi-likelihood does and does not share with a log-likelihood

Write $Q' = \partial Q / \partial \mu$. Then, for every variance specification:

- (a) $Q'(\mu; y) = w(y - \mu) / \{\phi V(\mu)\}$, and $Q(\mu; y) \leq 0$ with equality only at $\mu = y$: the quasi-likelihood is maximized at the observation, as a saturated fit would be;
- (b) $E\{Q'(\mu; Y)\} = 0$ and $\text{Var}\{Q'(\mu; Y)\} = -E\{\partial^2 Q / \partial \mu^2\} = w / \{\phi V(\mu)\}$, the two Bartlett identities;
- (c) if (V, ϕ, w) are those of an exponential dispersion family (Definition 34.1.1), then $Q(\mu; y) = \ell(\mu; y) - \ell(y; y)$, so Q is the log-likelihood measured from its saturated value, and $-2\phi Q(\boldsymbol{\beta}) = D(\mathbf{y}, \boldsymbol{\mu})$ is the deviance of Eq. 34.5.4.

Proof.

- (a) Differentiating Eq. 38.2.1 in its upper limit gives the stated Q' . Because $V > 0$, the integrand $(y-t)/V(t)$ is positive for $t < y$ and negative for $t > y$, so for $\mu > y$ the integral is of a negative function and for $\mu < y$ it is minus the integral of a positive one: both give $Q \leq 0$, with equality only for an empty interval.
- (b) $E(Y - \mu) = 0$ gives the first identity, and $\text{Var}(Y) = \phi V(\mu)/w$ gives $\text{Var}(Q') = w / \{\phi V(\mu)\}$. Differentiating Q' again,

$$\frac{\partial^2 Q}{\partial \mu^2} = -\frac{w}{\phi} \cdot \frac{V(\mu) + (y - \mu)V'(\mu)}{V(\mu)^2},$$

whose expectation is $-w / \{\phi V(\mu)\}$, since the term carrying $y - \mu$ has mean zero.

- (c) For an exponential dispersion family the chain rule used in the proof of Theorem 34.3.1 gives $\partial \ell / \partial \mu = w(y - \mu) / \{\phi V(\mu)\}$, which is Q' ; two functions of μ with the same derivative differ by a constant, and both sides vanish at $\mu = y$. Comparing with Eq. 34.5.4 gives $D = -2\phi Q$. ■

The converse of (c) fails: $\exp Q$ is in general not a density in y (Exercise (C1)). Part (c) is nevertheless why the objects here look familiar — everything the exponential family contributed to Definition 34.5.1 is already in the integral Eq. 38.2.1 — and for a variance function from no family Eq. 38.2.1 still measures the discrepancy between a fit and an observation, the **quasi-**

Figure 38.2.1: One term of the quasi-deviance Eq. 38.2.2 at $y = 2$, $w = 1$, against the fitted mean, for four power variance functions. Only the constant one penalizes symmetrically.

deviance

$$D(\mathbf{y}, \boldsymbol{\mu}) = -2\phi Q(\boldsymbol{\beta}) = 2 \sum_{i=1}^n w_i \int_{\mu_i}^{y_i} \frac{y_i - t}{V(t)} dt \geq 0, \quad (38.2.2)$$

which does not involve ϕ and vanishes only at $\boldsymbol{\mu} = \mathbf{y}$. Figure 38.2.1 draws one term for four power variance functions: only $V \equiv 1$ penalizes symmetrically, and under $V(\mu) = \mu$ a fitted mean one unit too small costs 2.043 times as much as one unit too large, against 4.254 for $V(\mu) = \mu^2$ and 9.000 for $V(\mu) = \mu^3$. A variance function that grows with the mean is a statement about which errors matter.

```
import numpy as np
from scipy import integrate

def quasi_deviance_term(y, mu, V):
    """2 * integral from mu to y of (y - t)/V(t) dt: one observation's quasi-
    deviance."""
    value, _ = integrate.quad(lambda t: (y - t) / V(t), mu, y)
    return 2 * value

y0 = 2.0
closed_form = {
    "V = 1": (lambda m: (y0 - m) ** 2, lambda t: 1.0),
    "V = mu": (lambda m: 2 * (y0 * np.log(y0 / m) - (y0 - m)), lambda t: t),
    "V = mu^2": (lambda m: 2 * (-np.log(y0 / m) + (y0 - m) / m), lambda t: t ** 2),
    "V = mu^3": (lambda m: (y0 - m) ** 2 / (y0 * m ** 2), lambda t: t ** 3),
}
for name, (formula, V) in closed_form.items():
    print(f"{name:9s} at mu = 0.8: {quasi_deviance_term(y0, 0.8, V):.6f}"
          f" closed form {formula(0.8):.6f}")
```

38.2.2 The quasi-score

Theorem 38.2.2 — The quasi-score

Let $\mathbf{U}(\boldsymbol{\beta}) = \partial Q / \partial \boldsymbol{\beta}$ be the **quasi-score**, and keep the notation $\mathbf{W} = \text{diag}\{w_i h'(\eta_i)^2 / V(\mu_i)\}$ and $\mathbf{D} = \text{diag}\{h'(\eta_i)\}$ of [Theorem 34.3.1](#). Write $\mathbf{A}_n = \phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$. Then:

- (a) $\mathbf{U}(\boldsymbol{\beta}) = \phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu})$, which is [Eq. 34.3.1](#) exactly. The estimating equations $\mathbf{U}(\hat{\boldsymbol{\beta}}) = \mathbf{0}$ are [Eq. 38.1.1](#), they do not involve ϕ , and they are solved by the iteratively reweighted least squares of [Theorem 34.4.1](#);
- (b) if the mean model is correct then $E \mathbf{U}(\boldsymbol{\beta}^0) = \mathbf{0}$, whatever the true variances are: the quasi-score is an unbiased estimating function;
- (c) $-E\{\partial \mathbf{U} / \partial \boldsymbol{\beta}^\top\} = \mathbf{A}_n$, again whatever the true variances are;
- (d) if in addition the variance specification [Eq. 38.1.2](#) is correct, then $\text{Cov}\{\mathbf{U}(\boldsymbol{\beta}^0)\} = \mathbf{A}_n$ as well: sensitivity and variability agree, which is the second Bartlett identity for Q ;
- (e) if instead $\text{Var}(Y_i) = \sigma_i^2$ for arbitrary σ_i^2 , then

$$\text{Cov}\{\mathbf{U}(\boldsymbol{\beta}^0)\} = \mathbf{B}_n = \frac{1}{\phi^2} \sum_{i=1}^n \left\{ \frac{w_i h'(\eta_i)}{V(\mu_i)} \right\}^2 \sigma_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top, \quad (38.2.3)$$

which equals $\mathbf{A}_n$ if and only if $\sum_i \{w_i h'_i / V_i\}^2 \{\sigma_i^2 - \phi V_i / w_i\} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top = \mathbf{0}$.

Proof.

- (a) By [Proposition 38.2.1\(a\)](#) and the chain rule,

$$\frac{\partial Q}{\partial \beta_j} = \sum_{i=1}^n Q'(\mu_i; y_i) \frac{d\mu_i}{d\eta_i} x_{ij} = \frac{1}{\phi} \sum_{i=1}^n x_{ij} \frac{w_i h'(\eta_i)}{V(\mu_i)} (y_i - \mu_i),$$

which is the coordinate form of [Eq. 34.3.1](#). The map from $(V, h, \mathbf{w}, \phi)$ to it is the one computed in [Theorem 34.3.1\(a\)](#), so the matrix form, the absence of ϕ and the iteration of [Theorem 34.4.1](#) transfer unchanged; none of the three used the density.

- (b) Every term carries the factor $y_i - \mu_i$, which has mean zero when $\mu_i = h(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^0)$. No assumption about $\text{Var}(Y_i)$ is used.
- (c) Write $a(\eta) = h'(\eta) / V\{h(\eta)\}$, so that $\mathbf{U} = \phi^{-1} \sum_i w_i a(\eta_i) (y_i - \mu_i) \mathbf{x}_{(i)}$. Differentiating,

$$\frac{\partial \mathbf{U}}{\partial \boldsymbol{\beta}^\top} = \frac{1}{\phi} \sum_{i=1}^n w_i \{a'(\eta_i) (y_i - \mu_i) - a(\eta_i) h'(\eta_i)\} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top,$$

the computation of [Theorem 34.3.1\(c\)](#). Expectation annihilates the first term whatever the variances, and $w_i a(\eta_i) h'(\eta_i) = \mathbf{W}_{ii}$ leaves $-\mathbf{A}_n$.

- (d) and (e). The summands of $\mathbf{U}$ are independent with mean zero, so $\text{Cov}(\mathbf{U}) = \phi^{-2} \sum_i w_i^2 a(\eta_i)^2 \text{Var}(Y_i) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$, which is [Eq. 38.2.3](#). Substituting $\sigma_i^2 = \phi V(\mu_i) / w_i$ turns the i th coefficient into $\phi^{-2} w_i^2 \{h'_i / V_i\}^2 \phi V_i / w_i = \phi^{-1} w_i h_i'^2 / V_i$, giving $\mathbf{A}_n$. The stated condition is the difference of the two sums.

■

Remark (Existence and uniqueness). Nothing above guarantees that [Eq. 38.1.1](#) has a solution, or only one. Under the canonical link of the variance function, $g'(\mu) = 1/V(\mu)$,

the proof of (c) has $a \equiv 1$ and $a' \equiv 0$, so the Jacobian is $-\mathbf{A}_n$, negative definite whenever $\text{rank}(\mathbf{X}) = p$; Q is then strictly concave and a root, if one exists, is the unique maximizer, by [Theorem 34.3.3](#) with b'' replaced by V . For other links Q can have several stationary points, as the warning after [Theorem 34.3.3](#) showed.

Example. (Strike durations)

Kennan's data record the length in days of 62 strikes in US manufacturing, with a measure of unanticipated industrial production at the time each strike began. Take a log link and $V(\mu) = \mu$. The production coefficient is -7.680 ; replacing $V(\mu) = \mu$ by $V(\mu) = 7.5\mu$ returns the same number to ten decimal places, since ϕ cancels from [Eq. 38.1.1](#), while $V(\mu) = \mu^2$ moves it to -9.353 , a quadratic variance function downweighting the long strikes.

The mean duration is 42.66 days and the sample variance 2102.7, nearly fifty times as large: a Poisson likelihood is no serious description of these data, and the question is how much of the Poisson machinery survives anyway.

```
import numpy as np
import statsmodels.api as sm

data = sm.datasets.strikes.load_pandas().data
y = data["duration"].to_numpy(float)      # length of the strike, in days
x = data["iprod"].to_numpy(float)         # unanticipated industrial production
X = np.column_stack([np.ones(len(y)), x])
n, p = X.shape

def quasi_irls(X, y, V, steps=60):
    """Solve the quasi-score equations for a log link and variance function V."""
    beta = np.zeros(X.shape[1])
    beta[0] = np.log(y.mean())
    for _ in range(steps):
        eta = X @ beta
        mu = np.exp(eta)
        W = mu ** 2 / V(mu)                # working weight (dmu/deta)^2 / V(mu)
        z = eta + (y - mu) / mu             # working response
        beta = np.linalg.solve((X.T * W) @ X, (X.T * W) @ z)
    return beta

beta_scaled = quasi_irls(X, y, lambda m: 7.5 * m) # V(mu) = phi mu: same
equations
beta_sq = quasi_irls(X, y, lambda m: m ** 2) # V(mu) = mu^2: different
equations
print(f"V = mu      {beta_lin}")
print(f"V = 7.5 mu   {beta_scaled}")
print(f"V = mu^2     {beta_sq}")
```

38.2.3 Optimality among linear estimating functions

The second view asks what else might have been used. Any function of the data and the parameter with mean zero at β^0 is an **unbiased estimating function**, and setting it to zero defines an estimator; the quasi-score is the best of a natural class.

Proposition 38.2.3 — Godambe optimality

Assume Eq. 38.1.2, and consider **linear estimating functions**

$$\mathbf{g}(\beta) = \sum_{i=1}^n \mathbf{a}_i(\beta) \{y_i - \mu_i(\beta)\} = \mathbf{C}(\beta) (\mathbf{y} - \boldsymbol{\mu}),$$

where $\mathbf{C} = [\mathbf{a}_1, \dots, \mathbf{a}_n]$ is $p \times n$, differentiable in β , and does not depend on $\mathbf{y}$. Let $\mathbf{S} = -E\{\partial \mathbf{g} / \partial \beta^\top\}$ and suppose $\mathbf{S}$ is nonsingular. Define the **Godambe information**

$$\mathcal{J}(\mathbf{g}) = \mathbf{S}^\top \text{Cov}\{\mathbf{g}(\beta^0)\}^{-1} \mathbf{S}.$$

- (a) Every such $\mathbf{g}$ is unbiased, and $\mathbf{S} = \mathbf{C} \mathbf{D} \mathbf{X}$.
- (b) $\mathcal{J}(\mathbf{g}) \preceq \phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X} = \mathcal{J}(\mathbf{U})$ in the order of nonnegative definiteness, for every linear estimating function $\mathbf{g}$.
- (c) Equality holds if and only if $\mathbf{C}^\top = \boldsymbol{\Sigma}^{-1} \mathbf{D} \mathbf{X} \mathbf{N}$ for a nonsingular $p \times p$ matrix $\mathbf{N}$, with $\boldsymbol{\Sigma} = \text{Cov}(\mathbf{Y})$: the coefficients are those of the quasi-score up to one common nonsingular transformation, and $\mathbf{g}$ then has the same roots as $\mathbf{U}$.

Proof.

- (a) Unbiasedness follows from $E(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$. Differentiating,

$$\frac{\partial \mathbf{g}}{\partial \beta^\top} = \sum_{i=1}^n \frac{\partial \mathbf{a}_i}{\partial \beta^\top} (y_i - \mu_i) - \mathbf{C} \frac{\partial \boldsymbol{\mu}}{\partial \beta^\top},$$

read entry by entry. Its expectation vanishes because $\mathbf{a}_i$ does not depend on $\mathbf{y}$, and $\partial \boldsymbol{\mu} / \partial \beta^\top = \mathbf{D} \mathbf{X}$, so $\mathbf{S} = \mathbf{C} \mathbf{D} \mathbf{X}$.

- (b) and (c). Under Eq. 38.1.2, $\boldsymbol{\Sigma} = \text{diag}\{\phi V(\mu_i)/w_i\}$ is positive definite. Set

$$\mathbf{F} = \boldsymbol{\Sigma}^{1/2} \mathbf{C}^\top, \quad \mathbf{K} = \boldsymbol{\Sigma}^{-1/2} \mathbf{D} \mathbf{X},$$

both $n \times p$. Then $\text{Cov}(\mathbf{g}) = \mathbf{C} \boldsymbol{\Sigma} \mathbf{C}^\top = \mathbf{F}^\top \mathbf{F}$ and $\mathbf{S} = \mathbf{C} \mathbf{D} \mathbf{X} = \mathbf{F}^\top \mathbf{K}$, so

$$\mathcal{J}(\mathbf{g}) = \mathbf{K}^\top \mathbf{F} (\mathbf{F}^\top \mathbf{F})^{-1} \mathbf{F}^\top \mathbf{K} = \mathbf{K}^\top \mathbf{P} \mathbf{K},$$

where $\mathbf{P} = \mathbf{F} (\mathbf{F}^\top \mathbf{F})^{-1} \mathbf{F}^\top$ is the orthogonal projection onto $\mathcal{C}(\mathbf{F})$ (Theorem 6.3.6), and $\mathbf{F}^\top \mathbf{F}$ is nonsingular because $\mathbf{S}$ is. As $\mathbf{I} - \mathbf{P}$ is symmetric idempotent, $\mathbf{v}^\top (\mathbf{I} - \mathbf{P}) \mathbf{v} = \|(\mathbf{I} - \mathbf{P}) \mathbf{v}\|^2 \geq 0$, so $\mathbf{P} \preceq \mathbf{I}$ and $\mathcal{J}(\mathbf{g}) \preceq \mathbf{K}^\top \mathbf{K}$. Finally

$$\mathbf{K}^\top \mathbf{K} = \mathbf{X}^\top \mathbf{D} \boldsymbol{\Sigma}^{-1} \mathbf{D} \mathbf{X} = \sum_{i=1}^n \frac{w_i h'(\eta_i)^2}{\phi V(\mu_i)} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top = \frac{1}{\phi} \mathbf{X}^\top \mathbf{W} \mathbf{X},$$

and [Theorem 38.2.2\(a\),\(d\)](#) identify this as $\mathcal{J}(\mathbf{U})$, since for the quasi-score sensitivity and variability are both $\mathbf{A}_n$.

Equality in (b) means $\mathbf{K}^\top(\mathbf{I} - \mathbf{P})\mathbf{K} = \mathbf{0}$, that is $\mathcal{C}(\mathbf{K}) \subseteq \mathcal{C}(\mathbf{F})$. Both matrices have p columns and, because $\mathbf{F}^\top\mathbf{K}$ is nonsingular, rank p ; so their column spaces coincide and $\mathbf{K} = \mathbf{F}\mathbf{N}$ for a nonsingular $\mathbf{N}$. Written out this is $\mathbf{C}^\top = \boldsymbol{\Sigma}^{-1}\mathbf{D}\mathbf{X}\mathbf{N}^{-1}$, whose i th row is a fixed multiple of $w_i h'(\eta_i) \mathbf{x}_{(i)}^\top / V(\mu_i)$. Then $\mathbf{g} = \mathbf{N}^{-\top} \mathbf{U}$, because $\mathbf{X}^\top \mathbf{D} \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \boldsymbol{\mu})$ already carries the factor ϕ^{-1} that $\mathbf{U}$ has; so $\mathbf{g}$ vanishes exactly where $\mathbf{U}$ does. ■

Warning. The optimality is *within the class of linear estimating functions*. A known true density would have a score nonlinear in $\mathbf{y}$ with a larger Godambe information — the NB1 score [Eq. 37.4.6](#) is an instance — so “best linear” is the honest reading, as in [Theorem 7.2.1](#). Optimality also assumes [Eq. 38.1.2](#); under a wrong variance function the quasi-score stays unbiased but is no longer optimal, and [Section 38.3](#) prices the loss.

38.2.4 Exercises

38.2.4.1 A. Check your understanding

Exercise A1.

Compute $\phi w^{-1} Q(\mu; y)$ from [Eq. 38.2.1](#) for $V(\mu) = 1$, $V(\mu) = \mu$, $V(\mu) = \mu(1 - \mu)$ and $V(\mu) = \mu^2$, and check that in each case it is the log-likelihood kernel of the corresponding family, up to a function of y alone.

Solution. For $V = 1$, $\int_y^\mu (y - t) dt = -(y - \mu)^2/2$. For $V(t) = t$ the integrand is $y/t - 1$, giving the Poisson kernel $y \log \mu - \mu$. For $V(t) = t(1 - t)$, partial fractions give $y/t - (1 - y)/(1 - t)$, whose integral is the binomial kernel $y \log \mu + (1 - y) \log(1 - \mu)$. For $V(t) = t^2$ the integrand is $y/t^2 - 1/t$, giving the gamma kernel $-y/\mu - \log \mu$.

Exercise A2.

Show that the NB2 variance function $V(\mu) = \mu + \mu^2/\kappa$ with κ known gives $\phi w^{-1} Q(\mu; y) = y \log\{\mu/(\mu + \kappa)\} + \kappa \log\{\kappa/(\mu + \kappa)\}$ up to a function of y , which is the negative binomial log-likelihood kernel of [Eq. 37.4.1](#). NB2 with κ known is an exponential dispersion family, so [Proposition 38.2.1\(c\)](#) applies; explain why the *quasi-Poisson* specification $V(\mu) = \mu$ with ϕ free does not enjoy the same conclusion, and relate this to the remark of [Section 38.1](#).

38.2.4.2 B. Practice

Exercise B1.

Take n independent responses with $E Y_i = \mu$ (one unknown parameter, no regressors) and $\text{Var } Y_i = \phi V(\mu)/w_i$. Show that the quasi-score estimate of [Theorem 38.2.2](#) is the weighted mean $\sum_i w_i y_i / \sum_i w_i$, and verify [Proposition 38.2.3](#) directly: among estimating

functions $\sum_i a_i(y_i - \mu)$ with constants a_i , the Godambe information is maximized by $a_i \propto w_i$.

Solution. Parameterizing by μ makes $h' \equiv 1$, so Eq. 38.1.1 reads $\sum_i w_i(y_i - \mu)/V(\mu) = 0$ and $\hat{\mu} = \sum_i w_i y_i / \sum_i w_i$. For a general $\mathbf{a}$ the sensitivity is $S = \sum_i a_i$ and the variability is $\phi V(\mu) \sum_i a_i^2 / w_i$, so

$$J = \frac{(\sum_i a_i)^2}{\phi V(\mu) \sum_i a_i^2 / w_i} \leq \frac{\sum_i w_i}{\phi V(\mu)}$$

by the Cauchy–Schwarz inequality applied to $\sum_i a_i = \sum_i (a_i / \sqrt{w_i}) \sqrt{w_i}$, with equality if and only if $a_i \propto w_i$. The bound is $\phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{X} = \mathbf{1}$.

Exercise B2.

Suppose the link satisfies $g'(\mu) = 1/V(\mu)$, the canonical link of the variance function. Show that Eq. 38.1.1 becomes $\sum_i w_i x_{ij}(y_i - \hat{\mu}_i) = 0$ for every j , so that the fit reproduces the weighted column totals of $\mathbf{X}$ exactly, as in Corollary 34.3.2. Check the condition for $V(\mu) = \mu$ with a log link and for $V(\mu) = \mu(1 - \mu)$ with a logit link, and find the canonical link of $V(\mu) = \mu^2$.

Solution. Since h is the inverse of g , $h'(\eta) = 1/g'(\mu) = V(\mu)$, so the coefficient $w_i h'(\eta_i)/V(\mu_i)$ in Eq. 38.1.1 is w_i . For $V(\mu) = \mu$ the log link has $g'(\mu) = 1/\mu$; for $V(\mu) = \mu(1 - \mu)$ the logit link has $g'(\mu) = 1/\{\mu(1 - \mu)\}$; for $V(\mu) = \mu^2$ the condition $g'(\mu) = \mu^{-2}$ gives $g(\mu) = -1/\mu$, the canonical link of the gamma family. The conclusion is the quasi-likelihood form of Corollary 34.3.2, proved there for exponential dispersion families but needing only Eq. 38.1.1.

38.2.4.3 C. Going deeper

Exercise C1.

Take the quasi-binomial specification $V(t) = t(1 - t)$ on $(0, 1)$ with $w = 1$ and any $\phi > 0$. (a) Show that $y \mapsto \exp\{Q(\mu; y)\}$ is integrable over $(0, 1)$, so normalizes to a density f . (b) Show that a distribution on $[0, 1]$ with mean m has variance at most $m(1 - m)$, with equality only on $\{0, 1\}$; deduce that f has variance strictly below $m(1 - m)$ at its own mean m , never $\phi m(1 - m)$ with $\phi \geq 1$. (c) Show that f is symmetric about $1/2$ when $\mu = 1/2$, and check numerically that at $\mu = 0.3$, $\phi = 1$ it has mean 0.4408 and variance 0.0687, against $\mu = 0.3$ and $\phi\mu(1 - \mu) = 0.21$. Conclude that integrability of $\exp Q$ does not make a variance specification a family.

Solution.

- (a) $Q \leq 0$ by Proposition 38.2.1(a), so $\exp Q \leq 1$ on a bounded interval.
- (b) For $Y \in [0, 1]$, $E\{Y(1 - Y)\} \geq 0$ gives $EY^2 \leq m$ and hence $\text{Var } Y \leq m - m^2$; equality forces $Y(1 - Y) = 0$ almost surely, which a density on the open interval excludes.
- (c) By Exercise (A1) the exponent is $\phi^{-1}\{y \log \mu + (1 - y) \log(1 - \mu) - y \log y - (1 - y) \log(1 - y)\}$, unchanged by $y \mapsto 1 - y$ when $\mu = 1/2$. Elsewhere neither moment is reproduced: $\exp Q$ normalizes without the result being a distribution with the

moments of [Eq. 38.1.2](#).

38.3 Sandwich covariance estimation

[Theorem 38.2.2](#) left an asymmetry: the estimating equations are unbiased as soon as the mean model is right, while the identity that turns $\mathbf{A}_n = \phi^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$ into a covariance needs the variance model too. When the latter fails, the covariance of $\hat{\boldsymbol{\beta}}$ becomes a product of three matrices instead of one, and the middle factor can be estimated from the residuals even though its n ingredients cannot.

38.3.1 The asymptotic distribution

Throughout $\boldsymbol{\beta}^0$ is the true parameter, $\eta_i^0 = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}^0$, $\mu_i^0 = h(\eta_i^0)$, and $\sigma_i^2 = \text{Var}(Y_i)$ is *not* assumed equal to $\phi V(\mu_i^0)/w_i$. Write

$$a(\eta) = \frac{h'(\eta)}{V\{h(\eta)\}}, \quad \mathbf{A}_n = \frac{1}{\phi} \mathbf{X}^\top \mathbf{W} \mathbf{X} = \frac{1}{\phi} \sum_{i=1}^n w_i a(\eta_i^0) h'(\eta_i^0) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top,$$

and let $\mathbf{B}_n$ be the matrix [Eq. 38.2.3](#). The conditions are

- (Q1) the Y_i are independent with $E Y_i = \mu_i^0$ for a $\boldsymbol{\beta}^0$ interior to the admissible set, p is fixed and $\text{rank}(\mathbf{X}) = p$;
- (Q2) $\|\mathbf{x}_{(i)}\| \leq C$ and $0 < w_{\min} \leq w_i \leq w_{\max} < \infty$;
- (Q3) on a neighbourhood $\mathcal{N}$ of $\boldsymbol{\beta}^0$, h and a are continuously differentiable with h' , a , a' bounded and h' , a bounded away from zero, uniformly in i and n ;
- (Q4) $\sigma_i^2 \geq \sigma_{\min}^2 > 0$, $E(Y_i - \mu_i^0)^4 \leq K$, and $n^{-1} \mathbf{A}_n \rightarrow \bar{\mathbf{A}}$, $n^{-1} \mathbf{B}_n \rightarrow \bar{\mathbf{B}}$ with both limits positive definite;
- (Q5) with probability tending to one [Eq. 38.1.1](#) has a root $\hat{\boldsymbol{\beta}} \in \mathcal{N}$ with $\hat{\boldsymbol{\beta}} \rightarrow \boldsymbol{\beta}^0$ in probability.

Theorem 38.3.1 — Consistency, normality and the sandwich

Assume (Q1)–(Q5). Then:

(a)

$$\mathbf{B}_n^{-1/2} \mathbf{A}_n (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0) \xrightarrow{d} N_p(\mathbf{0}, \mathbf{I}), \quad (38.3.1)$$

so that $\hat{\boldsymbol{\beta}}$ behaves as if its covariance were the **sandwich** $\mathbf{A}_n^{-1} \mathbf{B}_n \mathbf{A}_n^{-1}$, which involves the distribution of $\mathbf{Y}$ only through its first two moments.

- (b) If the variance specification [Eq. 38.1.2](#) is correct, then $\mathbf{B}_n = \mathbf{A}_n$ by [Theorem 38.2.2\(d\)](#), and [Eq. 38.3.1](#) becomes $\mathbf{A}_n^{1/2} (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0) \rightarrow N_p(\mathbf{0}, \mathbf{I})$: the **model-based** covariance $\mathbf{A}_n^{-1} = \phi (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$ is correct, and by [Proposition 38.2.3](#) no linear estimating function has a larger Godambe information — hence, whenever (Q1)–(Q5) hold for that estimating function too, none has a smaller asymptotic covariance.

- (c) Let $\hat{c}_i = w_i h'(\hat{\eta}_i) / V(\hat{\mu}_i)$ and define the **empirical sandwich**

$$\hat{\Sigma}_{\text{rob}} = (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \left\{ \sum_{i=1}^n \hat{c}_i^2 (y_i - \hat{\mu}_i)^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right\} (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}, \quad (38.3.2)$$

in which ϕ cancels. Then $n\hat{\Sigma}_{\text{rob}} - n\mathbf{A}_n^{-1}\mathbf{B}_n\mathbf{A}_n^{-1} \rightarrow \mathbf{0}$ in probability, and Eq. 38.3.1 holds with $\hat{\Sigma}_{\text{rob}}^{-1/2}(\hat{\beta} - \beta^0)$ in place of the left-hand side.

Proof. Step 1: the quasi-score is asymptotically normal. By Theorem 38.2.2(a) and (e), $\mathbf{U}_n(\beta^0) = \phi^{-1} \sum_i w_i a(\eta_i^0) \xi_i \mathbf{x}_{(i)}$ with $\xi_i = Y_i - \mu_i^0$ independent and mean zero and $\text{Cov}\{\mathbf{U}_n(\beta^0)\} = \mathbf{B}_n$. Fix a unit vector $\mathbf{v}$ and write $\mathbf{v}^\top \mathbf{B}_n^{-1/2} \mathbf{U}_n = \sum_i d_{ni} \xi_i$ with $d_{ni} = \phi^{-1} w_i a(\eta_i^0) \mathbf{v}^\top \mathbf{B}_n^{-1/2} \mathbf{x}_{(i)}$, so that $\sum_i d_{ni}^2 \sigma_i^2 = 1$. By (Q4), $\sigma_i^2 \leq K^{1/2}$ and hence $\sum_i d_{ni}^2 \geq K^{-1/2}$, while (Q2)–(Q4) give $d_{ni}^2 \leq \phi^{-2} w_{\max}^2 a_{\max}^2 C^2 \lambda_{\max}(\mathbf{B}_n^{-1}) = O(n^{-1})$, because $\lambda_{\min}(n^{-1}\mathbf{B}_n) \rightarrow \lambda_{\min}(\mathbf{B}) > 0$. So $\max_i d_{ni}^2 / \sum_i d_{ni}^2 \rightarrow 0$, which is Eq. 21.2.2, and the fourth moments are bounded: Lemma 21.2.1(b) with $\delta = 2$ and the Cramér–Wold device give $\mathbf{B}_n^{-1/2} \mathbf{U}_n(\beta^0) \rightarrow N_p(\mathbf{0}, \mathbf{I})$.

Step 2: the expansion. By (Q3), $\beta \mapsto \mathbf{U}_n(\beta)$ is continuously differentiable on $\mathcal{N}$, so on $\{\hat{\beta} \in \mathcal{N}\}$,

$$\mathbf{0} = \mathbf{U}_n(\hat{\beta}) = \mathbf{U}_n(\beta^0) + \bar{\mathbf{J}}_n (\hat{\beta} - \beta^0),$$

where

$$\bar{\mathbf{J}}_n = \int_0^1 \frac{\partial \mathbf{U}_n}{\partial \beta^\top} (\beta^0 + t(\hat{\beta} - \beta^0)) dt.$$

Step 3: the Jacobian. By the proof of Theorem 38.2.2(c),

$$\frac{\partial \mathbf{U}_n}{\partial \beta^\top}(\beta) = \frac{1}{\phi} \sum_{i=1}^n w_i \{a'(\eta_i) \{y_i - \mu_i(\beta)\} - a(\eta_i) h'(\eta_i)\} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top,$$

with $\eta_i = \mathbf{x}_{(i)}^\top \beta$; take $\|\beta - \beta^0\| \leq \delta$, so that every η_i moves by at most $C\delta$. The second term is nonrandom and equals $-\mathbf{A}_n$ at β^0 , and since ah' is uniformly continuous by (Q3) the two differ, after division by n , by at most $\phi^{-1} w_{\max} C^2 \omega(C\delta)$ with ω the modulus of continuity. In the first term write $y_i - \mu_i(\beta) = \xi_i + \{\mu_i^0 - \mu_i(\beta)\}$: the displacement is at most $h'_{\max} C\delta$, contributing $O(\delta)$ to n^{-1} times the norm, while $n^{-1} \phi^{-1} \sum_i w_i a'(\eta_i) \xi_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ has entries that average independent mean-zero variables of bounded variance, hence $o_p(1)$ by Chebyshev. By (Q5) δ may tend to zero, so $-n^{-1} \bar{\mathbf{J}}_n \rightarrow \bar{\mathbf{A}}$ in probability, with $\bar{\mathbf{A}}$ nonsingular.

Step 4: assembling. With probability tending to one $\bar{\mathbf{J}}_n$ is invertible and $\hat{\beta} - \beta^0 = (-\bar{\mathbf{J}}_n)^{-1} \mathbf{U}_n(\beta^0)$, so

$$\mathbf{B}_n^{-1/2} \mathbf{A}_n (\hat{\beta} - \beta^0) = \left(\mathbf{B}_n^{-1/2} \mathbf{A}_n (-\bar{\mathbf{J}}_n)^{-1} \mathbf{A}_n^{-1} \mathbf{B}_n^{1/2} \right) \mathbf{B}_n^{-1/2} \mathbf{U}_n(\beta^0).$$

By (Q4) and Step 3 the bracket tends in probability to $\mathbf{I}$, since $n^{-1} \mathbf{A}_n$, $n^{-1} \mathbf{B}_n$, their square roots and inverses all converge to fixed nonsingular limits. Slutsky and Step 1 give Eq. 38.3.1, and (b) is the substitution $\mathbf{B}_n = \mathbf{A}_n$.

Step 5: the empirical middle. Write $c_i = w_i a(\eta_i^0)$, so the middle of Eq. 38.3.2 at the true parameter is $\sum_i c_i^2 \xi_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ and $\phi^2 \mathbf{B}_n = \sum_i c_i^2 \sigma_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$. Each entry of $n^{-1} \sum_i c_i^2 (\xi_i^2 - \sigma_i^2) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ is an average of independent mean-zero variables whose variances are bounded by $c_{\max}^4 C^4 K$, so it is $o_p(1)$ by Chebyshev; this is Step 2 of the proof of Theorem 21.4.2.

Replacing ξ_i by $y_i - \hat{\mu}_i$ and c_i by $\hat{c}_i$ costs a further $o_p(1)$, both displacements being bounded uniformly in i by a constant times $\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0\|$, so Step 3 of that proof applies verbatim. The same reasoning gives $n^{-1}\mathbf{X}^\top \hat{\mathbf{W}}\mathbf{X} \rightarrow \phi \mathbf{A}$, and combining the three factors proves (c). ■

Remark (What (Q5) hides, and when it is free). Assuming a consistent root assumes something real: the equations can have no solution, or several. Under the canonical link of the variance function Q is strictly concave, and the argument for [Theorem 34.5.1](#) gives existence and consistency without (Q5) as soon as $\lambda_{\min}(\mathbf{A}_n) \rightarrow \infty$; for a general link the conditions of Fahrmeir and Kaufmann (1985), quoted in [Proposition 34.5.2](#), do the same and need only unbiasedness. Conditions (Q2)–(Q4) are the quasi-likelihood forms of the bounded-leverage and moment conditions of [Theorem 21.4.2](#), and fail in the same places.

38.3.2 Model-based or robust

The two covariance estimates answer different questions. Under the log link with $V(\mu) = \mu$ and $w_i = 1$, where $\mathbf{W}_{ii} = \mu_i$ and $a(\eta_i) = 1$,

$$\mathbf{A}_n^{-1} \mathbf{B}_n \mathbf{A}_n^{-1} = \left(\sum_i \mu_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right)^{-1} \left(\sum_i \sigma_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right) \left(\sum_i \mu_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right)^{-1},$$

against the model-based $\phi(\sum_i \mu_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top)^{-1}$. Only the *shape* of the dependence on μ matters, since a constant factor is absorbed into ϕ : a quasi-Poisson analysis is right about the standard errors whenever the true variance is proportional to the mean, whatever the constant, and wrong for any other shape.

Example. (Coverage when the variance function is right and when it is wrong)

A quasi-Poisson model $\log \mu_i = \beta_0 + \beta_1 x_i$ was fitted to data simulated with the same mean and two true variances, $\text{Var}(Y_i) = \mu_i + 2\mu_i^2$ (quadratic) and $\text{Var}(Y_i) = 9\mu_i$ (linear), over 3000 replicates at each of seven sample sizes. [Figure 38.3.1](#) records the coverage of nominal 95% intervals for β_1 from four standard errors: Poisson with $\phi = 1$, model-based scaled by $\hat{\phi}$, the empirical sandwich [Eq. 38.3.2](#), and a leverage-corrected sandwich described below.

Ignoring the dispersion is fatal in both panels and does not improve with n : 0.334 at $n = 20$ and 0.323 at $n = 1280$ in the quadratic case, 0.513 and 0.482 in the linear case. A linear true variance makes the specification correct and the $\hat{\phi}$ -scaled interval already good at $n = 20$, covering 0.919 against the sandwich's 0.880; a quadratic one stops it improving, at 0.914 for $n = 1280$, while the sandwich climbs to 0.941, buying correctness in the limit at the price of noise in small samples, as in [Example \(Coverage in a skewed design\)](#).

```
import numpy as np

BETA = np.array([1.5, 1.0])
```

Figure 38.3.1: Coverage of nominal 95% intervals for the slope of a quasi-Poisson fit with a correct mean model. In (a) the true variance is quadratic in the mean, so the working variance function has the wrong shape; in (b) it is proportional to the mean.

```

38.3.3 The dispersion, the quasi-deviance and tests

The model-based covariance needs ϕ , and so does any F test; neither $\hat{\beta}$ nor the sandwich Eq. 38.3.2 does. Since ϕ cancels from Eq. 38.1.1 and scales $\mathbf{A}_n$ by ϕ^{-1} , it is orthogonal to β : estimating it multiplies the asymptotic covariance of $\hat{\beta}$ by a consistent factor rather than inflating it.

Proposition 38.3.2 — Estimating the dispersion, and quasi-deviance tests

Assume Eq. 38.1.2 with the mean model correct.

- (a) $E[w_i(Y_i - \mu_i^0)^2 / V(\mu_i^0)] = \phi$ for every i , so the **Pearson estimator** $\hat{\phi}_P = X^2 / (n - p)$ with $X^2 = \sum_i w_i(y_i - \hat{\mu}_i)^2 / V(\hat{\mu}_i)$ — the statistic Eq. 34.5.5 — is consistent for ϕ under (Q1)–(Q5). The divisor $n - p$ is an analogy with s^2 (Theorem 5.6.1), exact only in the normal linear model.
- (b) The **deviance estimator** $\hat{\phi}_D = D(\mathbf{y}, \hat{\mu}) / (n - p)$, with D the quasi-deviance Eq. 38.2.2, is *not* in general consistent for ϕ . The two agree only so far as a third-order remainder is negligible: large binomial groups and large Poisson means, not small counts. Only $\hat{\phi}_P$ has expectation exactly ϕ at the true mean.
- (c) For nested mean models $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\text{rank}(\mathbf{X}) - \text{rank}(\mathbf{X}_0) = q$, fitted with the same V , the **quasi- F statistic** is

$$F = \frac{\{D(\mathbf{y}, \tilde{\mu}) - D(\mathbf{y}, \hat{\mu})\} / q}{\hat{\phi}_P}. \quad (38.3.3)$$

Under the reduced model and (Q1)–(Q5), $qF \rightarrow \chi^2(q)$, so referring F to $F(q, n - p)$ is asymptotically correct and is the usual small-sample convention. If the variance specification is wrong the limit fails and the Wald statistic built from Eq. 38.3.2 should be used instead.

- (d) No convention makes $-2Q(\hat{\beta})$ a log-likelihood, so Definition 29.2.2 does not apply. The criterion QAIC = $D(\mathbf{y}, \hat{\mu}) / \hat{\phi} + 2p$, with $\hat{\phi}$ fixed at its value in the largest model, is in common use, but it is a convention, not a theorem. Cross-validation (Definition 29.3.1) needs no likelihood, and the analogue for correlated responses, the QIC of Chapter 40, rests on the same convention.

Proof.

- (a) Under Eq. 38.1.2, $E(Y_i - \mu_i^0)^2 = \phi V(\mu_i^0)/w_i$, which is the identity. The $T_i = w_i(Y_i - \mu_i^0)^2/V(\mu_i^0)$ are independent with mean ϕ and bounded variances, so $n^{-1} \sum_i T_i \rightarrow \phi$ by Chebyshev; replacing μ_i^0 by $\hat{\mu}_i$ costs $o_p(1)$, by Step 5 of the proof of Theorem 38.3.1 with $\mathbf{x}_{(i)}\mathbf{x}_{(i)}^\top$ replaced by 1, and $n/(n-p) \rightarrow 1$.
- (b) Each term of Eq. 38.2.2 is $2w_i \int_{\hat{\mu}_i}^{y_i} (y_i - t)V(t)^{-1} dt$. Expanding $1/V(t)$ about $t = y_i$ and integrating gives $w_i(y_i - \hat{\mu}_i)^2/V(y_i) + O(w_i|y_i - \hat{\mu}_i|^3)$, the calculation recorded after Eq. 34.5.5: a Pearson term with $V(y_i)$ in place of $V(\hat{\mu}_i)$. The two estimators therefore differ by the remainder and by the gap between those denominators, both negligible when $|y_i - \hat{\mu}_i|$ is small relative to μ_i and neither otherwise; there is no exact unbiasedness to appeal to, since $E d_i \neq \phi$ in general.
- (c) By Eq. 38.2.2 the difference is $2\phi\{Q(\hat{\beta}) - Q(\tilde{\beta})\}$. The proof of Proposition 34.5.3 used the log-likelihood only through the quadratic expansion Eq. 34.5.3, whose ingredients are asymptotic normality of the score and the identity between its variance and minus the expected Hessian. Under Eq. 38.1.2, Step 1 of the proof of Theorem 38.3.1 supplies the first and Theorem 38.2.2(d) the second, with $\mathbf{A}_n$ in both roles, so that argument goes through word for word with Q in place of ℓ . Hence $\{D(\mathbf{y}, \tilde{\mu}) - D(\mathbf{y}, \hat{\mu})\}/\phi \rightarrow \chi^2(q)$; part (a) lets $\hat{\phi}_P$ replace ϕ , and $qF(q, n-p) \rightarrow \chi^2(q)$ makes the F reference asymptotically equivalent.
- (d) is a definition and a warning, not a claim.

■

Example. (Four standard errors for the strike data)

Continue Example (Strike durations). The Pearson statistic is 2393.5 on 60 degrees of freedom, so $\hat{\phi}_P = 39.89$, against $\hat{\phi}_D = 37.22$ from the quasi-deviance. The four standard errors for the production coefficient -7.680 are

covariance	standard error	t
Poisson, $\phi = 1$	0.406	-18.92
model-based, $\hat{\phi}_P$	2.564	-3.00
empirical sandwich	2.573	-2.98
leverage-corrected sandwich	2.896	-2.65

The Poisson standard error is too small by a factor of about six. More interesting are the second and third rows: the sandwich exceeds the model-based value by a factor of only 1.004, which is evidence *for* the quasi-Poisson variance function, so the model-based standard error is valid and slightly more efficient. The fourth row divides each squared residual by $(1 - h_{ii})^2$, with h_{ii} the leverages of the weighted hat matrix of Definition 34.5.2; the largest is 0.192, enough to matter at $n = 62$.

```
import numpy as np
import statsmodels.api as sm

data = sm.datasets.strikes.load_pandas().data
y = data["duration"].to_numpy(float)           # length of the strike, in days
```

```

x = data["iproduct"].to_numpy(float)          # unanticipated industrial production
X = np.column_stack([np.ones(len(y)), x])
n, p = X.shape

def quasi_irls(X, y, V, steps=60):
    """Solve the quasi-score equations for a log link and variance function V."""

print(f"largest leverage {hat.max():.4f}, sum {hat.sum():.4f}")

```

38.3.4 Corrections, clusters and resampling

Three qualifications finish the section.

Small samples. The empirical sandwich is biased downwards, for the reason [Proposition 21.4.1\(a\)](#) identified in the linear model, and the remedy is the same: divide the i th squared residual by $1 - h_{ii}$ or by $(1 - h_{ii})^2$, with h_{ii} the diagonal of $\hat{\mathbf{W}}^{1/2} \mathbf{X} (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \mathbf{X}^\top \hat{\mathbf{W}}^{1/2}$, giving the analogues of HC2 and HC3 of [Definition 21.4.1](#). The second is the “corrected” line of [Example \(Coverage when the variance function is right and when it is wrong\)](#), better than the plain sandwich at $n = 80$ in the quadratic panel, 0.906 against 0.891; Kauermann and Carroll (2001) give the leading bias term. The middle of [Eq. 38.3.2](#) is itself an average with very unequal weights, so it behaves like a variance estimate on far fewer than $n - p$ degrees of freedom ([Example \(One household carries the standard error\)](#)).

Clusters. If the observations come in G independent groups with arbitrary within-group de-

pendence, the middle of Eq. 38.3.2 becomes

$$\sum_{g=1}^G \left(\sum_{i \in g} \hat{c}_i (y_i - \hat{\mu}_i) \mathbf{x}_{(i)} \right) \left(\sum_{i \in g} \hat{c}_i (y_i - \hat{\mu}_i) \mathbf{x}_{(i)} \right)^\top,$$

the cluster-robust form Eq. 33.2.3 with the quasi-score's coefficients in place of the rows of $\mathbf{X}$. Its consistency needs $G \rightarrow \infty$, by Step 5 above with the cluster in place of the observation. The quasi-score is then no longer optimal, because the within-group correlations are ignored; Chapter 40 puts a generalized estimating equation in its place.

Resampling. The bootstrap of Chapter 23 applies unchanged: whole observations (Proposition 23.1.5), the wild bootstrap (Definition 23.2.1), or whole clusters (Exercise (C1)) for small G .

38.3.5 Exercises

38.3.5.1 A. Check your understanding

Exercise A1.

Under a log link and $V(\mu) = \mu$ with $w_i \equiv 1$, suppose the true variances are $\sigma_i^2 = \tau \mu_i$ for an unknown $\tau > 0$. Show that the sandwich and the model-based covariance have the same probability limit, and identify what $\hat{\phi}_P$ estimates. Repeat for $\sigma_i^2 = \tau \mu_i^2$ and show that the two then differ unless all μ_i are equal.

Exercise A2.

Verify from Eq. 38.3.2 that the empirical sandwich does not change if V is replaced by cV for a constant $c > 0$, and explain why this is to be expected.

38.3.5.2 B. Practice

Exercise B1.

Take an intercept-only quasi-Poisson model, $\log \mu_i = \beta$ for all i . Show that $\hat{\mu}_i = \bar{y}$, that the model-based variance of $\hat{\beta}$ is $\hat{\phi}_P / (n\bar{y})$, and that the sandwich variance is $\sum_i (y_i - \bar{y})^2 / (n\bar{y})^2$. Show that the two agree exactly when $\hat{\phi}_P$ is computed with divisor n rather than $n - p$.

Exercise B2.

Let $\text{Var}(Y_i) = \sigma_i^2$ and consider the quasi-score built from a working variance function V . Using Proposition 38.2.3 with the *true* variances, show that $\mathbf{A}_n^{-1} \mathbf{B}_n \mathbf{A}_n^{-1}$ — the asymptotic covariance of Theorem 38.3.1(a) — is never smaller, in the nonnegative definite order, than the inverse Godambe information $(\sum_i h'(\eta_i)^2 \sigma_i^{-2} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top)^{-1}$ of the best linear estimating function, and that the two agree exactly when $\sigma_i^2 \propto V(\mu_i)/w_i$.

Solution. Repeat the proof of [Proposition 38.2.3](#) with $\Sigma = \text{diag}(\sigma_i^2)$ in place of $\text{diag}\{\phi V(\mu_i)/w_i\}$; only its last display used the specification. The quasi-score built from V is a linear estimating function with $\mathbf{a}_i = w_i h'(\eta_i) \mathbf{x}_{(i)} / \{\phi V(\mu_i)\}$, so by [Theorem 38.2.2\(c\),\(e\)](#) its Godambe information is $\mathbf{A}_n \mathbf{B}_n^{-1} \mathbf{A}_n$, at most the maximum $\mathbf{K}^\top \mathbf{K} = \sum_i h'(\eta_i)^2 \sigma_i^{-2} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$; inverting reverses the order. Equality needs coefficients proportional to $h'(\eta_i) \mathbf{x}_{(i)} / \sigma_i^2$, that is $w_i / V(\mu_i) \propto 1 / \sigma_i^2$.

38.3.5.3 C. Going deeper

Exercise C1.

A large discrepancy between $\hat{\phi}_P(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$ and [Eq. 38.3.2](#) is evidence that the variance specification is wrong. Propose a test statistic from the difference of the two matrices, say $\text{tr}\{(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X}) \hat{\Sigma}_{\text{rob}}\} - p \hat{\phi}_P$, argue informally that its mean is about zero when the specification is correct, and say what stands in the way of a usable null distribution. (This is White's information matrix test; compare [Exercise \(B3\)](#).)

38.4 Overdispersion

The word has been used loosely so far. This section says where the extra variability comes from, how to see it, what ignoring it costs, and which repair to make.

38.4.1 Where it comes from

Proposition 38.4.1 — Sources of overdispersion, and the price of ignoring it

- (a) *Unobserved heterogeneity.* Let $Y \mid \Lambda$ have mean Λ and variance $V^*(\Lambda)$, and let Λ have mean μ and variance τ^2 , with $0 < \tau^2 < \infty$ and $E\{V^*(\Lambda)\} < \infty$. Then $EY = \mu$ and $\text{Var } Y = E\{V^*(\Lambda)\} + \tau^2$, which for a Poisson kernel $V^*(\lambda) = \lambda$ is $\mu + \tau^2 > \mu$: any unmodelled variation in the mean overdisperses.
- (b) *Clustering.* If the response is an average of m units with pairwise correlation $\rho > 0$, its variance is inflated by $1 + \rho(m-1)$, by [Lemma 38.1.1](#); the same factor applies to a sum of m correlated indicators.
- (c) *Contagion.* Let $Y = \sum_{j=1}^N S_j$, where N is Poisson with mean ν and the S_j are independent copies of a positive integer-valued S with $ES^2 < \infty$, independent of N : events arrive in clusters. Then $EY = \nu ES$ and $\text{Var } Y = \nu ES^2$, so

$$\frac{\text{Var } Y}{EY} = \frac{ES^2}{ES} \geq ES \geq 1, \quad (38.4.1)$$

with equality throughout if and only if $S \equiv 1$, that is unless the events arrive singly.

- (d) *Neither of the above.* A wrong mean model, an omitted interaction or a few gross outliers all inflate X^2 , and no dispersion parameter repairs them; for ungrouped

binary data a large X^2 is always a statement about the mean model.

- (e) *The price.* Suppose the mean model is correct and the true variances are $\sigma_i^2 = \phi_0 V(\mu_i^0)/w_i$ with $\phi_0 \geq 1$ unknown, while inference uses $\phi = 1$. Then under (Q1)–(Q5) any statistic of [Proposition 34.5.3](#) for a q -dimensional hypothesis converges to $\phi_0 \chi^2(q)$, so a nominal level- α test has asymptotic size

$$\Pr\{\chi^2(q) > \chi_{1-\alpha}^2(q)/\phi_0\} \geq \alpha, \quad (38.4.2)$$

increasing in ϕ_0 , and tending to 1 as $q \rightarrow \infty$ for every fixed $\phi_0 > 1$. Standard errors are too small by the factor $\phi_0^{1/2}$.

Proof.

- (a) The law of total variance gives $\text{Var } Y = E\{V^*(\Lambda)\} + \tau^2$, and $E \Lambda = \mu$; this is [Lemma 37.4.1](#)(a) with the mixing distribution left arbitrary.
 (b) is [Lemma 38.1.1](#).
 (c) Conditioning on N gives $E(Y | N) = N E S$ and $\text{Var}(Y | N) = N \text{Var } S$, so $E Y = \nu E S$ and

$$\begin{aligned} \text{Var } Y &= E(N) \text{Var } S + \text{Var}(N)(E S)^2 \\ &= \nu \{\text{Var } S + (E S)^2\} = \nu E S^2, \end{aligned}$$

using $\text{Var } N = E N = \nu$. Dividing gives $\text{Var } Y / E Y = E S^2 / E S$; the first inequality in [Eq. 38.4.1](#) is $E S^2 \geq (E S)^2$, equality only for degenerate S , and the second is $E S \geq 1$. Equality in both forces $S \equiv 1$, and then $Y = N$ is Poisson.

- (d) The binary claim is the warning of [Section 38.1](#); the rest records what X^2 measures and is not a mathematical assertion.
 (e) By [Theorem 38.3.1](#)(a) with $\mathbf{B}_n = \phi_0 \mathbf{A}_n$ — which is [Theorem 38.2.2](#)(e) at $\sigma_i^2 = \phi_0 V_i/w_i$ with the working $\phi = 1$ — $\mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0) \rightarrow N_p(\mathbf{0}, \phi_0 \mathbf{I})$. The Wald statistic computed as though the covariance were $\mathbf{A}_n^{-1}$ is $\|(\mathbf{I} - \mathbf{P}_n)\mathbf{A}_n^{1/2}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}^0)\|^2$ for a projection $\mathbf{P}_n$ of rank $p - q$, as in the proof of [Proposition 34.5.3](#), hence converges to ϕ_0 times a $\chi^2(q)$ variable; the other two differ from it by $o_p(1)$ by the same proof, since [Proposition 38.3.2](#)(c) extends the expansion to Q . The size [Eq. 38.4.2](#) follows and exceeds α because $\phi_0 > 1$ lowers the threshold; the limit as $q \rightarrow \infty$ is [Exercise \(A1\)](#).

■

These sizes are worse than intuition suggests. At $\phi_0 = 2$ a nominal 5% test of one coefficient rejects with probability 0.166 and of six coefficients with probability 0.391; at $\phi_0 = 5$ the figures are 0.381 and 0.866. A dispersion of five is not unusual — the strike data of [Example \(Strike durations\)](#) have $\hat{\phi}_P = 39.89$.

```
import numpy as np
from scipy import stats

def naive_size(phi, q):
    """Size of a nominal 5% chi-squared test when the statistic is inflated by phi.
    """
    return stats.chi2.sf(stats.chi2.ppf(0.95, q) / phi, q)

print("phi    q = 1    q = 3    q = 6")
```

Figure 38.4.1: Simulated null distributions of the drop in deviance for one coefficient, on data whose variance is four times their mean: (a) the raw statistic against $\chi^2(1)$; (b) the statistic divided by the Pearson dispersion, against $F(1, 98)$. The dashed line is the upper 5% point.

```
for phi in (1.5, 2.0, 3.0, 5.0, 10.0):
    print(f"{phi:4.1f} " + " ".join(f"{naive_size(phi,q):7.3f}" for q in (1, 3, 6)
    ))
```

Example. (A test that rejects six times too often)

Counts were simulated with a constant mean 6.0, a variance 4.0 times the mean and a true slope of zero, and a Poisson log-linear model was fitted to each of 5000 data sets of size 100. Referring the drop in deviance to $\chi^2(1)$ rejects at the nominal 5% level in 0.322 of the replicates — Eq. 38.4.2 predicts 0.327 at $\phi_0 = 4$ — with the statistic averaging 3.90 against a $\chi^2(1)$ mean of one. Dividing by $\hat{\phi}_P$ and referring to $F(1, 98)$ rejects in 0.051, and the sandwich Wald test Eq. 38.3.2 in 0.058 (Figure 38.4.1).

```
def poisson_fit(X, y, steps=20):
    beta = np.zeros(X.shape[1])
    beta[0] = np.log(max(y.mean(), 0.5))
    for _ in range(steps):

print(f"rejection rates at the 5% level: naive {rates[0]:.3f},"
      f" quasi-F {rates[1]:.3f}, sandwich Wald {rates[2]:.3f}")

```

38.4.2 Seeing it

Four diagnostics, in the order in which they should be used. **Check the mean model first:** an omitted term can remove an apparent dispersion entirely, as [Example \(Twenty thousand records in thirty-two rows\)](#) showed, and only a mean model that has survived [Definition 34.5.2](#) and the plots of [Chapter 20](#) makes a dispersion parameter mean what it says. **Compare $\hat{\phi}_P = X^2/(n-p)$ with one,** remembering that it is calibrated only where [Theorem 34.5.5\(b\)](#) applies, noisy for ungrouped counts with small means, and meaningless for ungrouped binary data. **Use a score test:** for counts, [Theorem 37.4.3](#) tests the Poisson against NB2 alternatives from the Poisson fit alone, with a one-sided alternative. **Compare the two covariances:** a large discrepancy between $\hat{\phi}_P(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1}$ and the sandwich [Eq. 38.3.2](#) says the *shape* of the variance function is wrong and not merely its scale, while a small one, as in [Example \(Four standard errors for the strike data\)](#), is evidence that the shape is right ([Exercise \(C1\)](#)). A plot of squared Pearson residuals against fitted means, and against group sizes where they vary, shows the same in more detail.

38.4.3 Choosing a repair

Four devices are in use, differing in what they assume and what they give.

device	assumes	gives	does not give
quasi model with $\hat{\phi}$	mean and variance shape	$\hat{\beta}$, F tests, model-based errors	likelihood, AIC, predictions
quasi model with the sandwich	mean model only	$\hat{\beta}$, Wald tests	efficiency, small samples
NB2, NB1 or beta-binomial	a full distribution	likelihood, AIC, predictions	robustness to that choice
random effect	a full distribution and a mixing law	conditional coefficients, prediction of units	the marginal coefficients

Putting a dispersion parameter into a quasi model changes the standard errors and leaves $\hat{\beta}$ exactly where it was ([Theorem 38.2.2\(a\)](#)); changing to a different likelihood with the same variance function can move it by more than a standard error ([Example \(Four analyses of the strike data\)](#)). The fourth device changes the estimand rather than the estimate: a coefficient conditional on a unit's own random effect answers a different question from one describing a population average, a distinction [Chapter 40](#) takes up and does not treat as small.

Example. (Four analyses of the strike data)

Continuing [Example \(Strike durations\)](#) and [Example \(Four standard errors for the strike data\)](#), the production coefficient under four treatments of the extra variability is

fit	coefficient	standard error
Poisson, $\phi = 1$	-7.680	0.406
quasi-Poisson, $V = \phi\mu$	-7.680	2.564
NB1, $\text{Var} = \phi\mu$	-4.934	1.983
NB2, $\text{Var} = \mu + \mu^2/\kappa$	-9.327	2.931

The NB1 fit has $\hat{\phi} = 42.78$, close to the quasi-Poisson $\hat{\phi}_P = 39.89$, and *the same variance function*; yet its coefficient differs by more than a standard error, because its estimating equation [Eq. 37.4.6](#) is not [Eq. 38.1.1](#) — the warning of [Section 38.1](#) in numbers. The NB2 fit, with $\hat{\alpha} = 1/\hat{\kappa} = 0.954$, gives -9.327 against the -9.353 of the quasi model with $V(\mu) = \mu^2$: at these fitted means the quadratic term of the NB2 variance dominates, so the two nearly coincide.

The tests agree on the conclusion and not on its strength. The drop in deviance is 350.9, overwhelming as $\chi^2(1)$; the quasi- F statistic [Eq. 38.3.3](#) is 8.80 on (1, 60) degrees of freedom, $p = 0.0043$, and the score test for overdispersion [Eq. 37.4.9](#) is 224.5. Unanticipated production predicts shorter strikes, at about the evidence a t statistic of three provides; the Poisson analysis overstates that by orders of magnitude.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

data = sm.datasets.strikes.load_pandas().data
y = data["duration"].to_numpy(float)      # length of the strike, in days
x = data["iprod"].to_numpy(float)        # unanticipated industrial production
X = np.column_stack([np.ones(len(y)), x])
n, p = X.shape

def quasi_irls(X, y, V, steps=60):
    """Solve the quasi-score equations for a log link and variance function V."""
    beta = np.zeros(X.shape[1])
    beta[0] = np.log(y.mean())
    for _ in range(steps):
        eta = X @ beta
        mu = np.exp(eta)
        W = mu ** 2 / V(mu)                # working weight (dmu/deta)^2 / V(mu)
        z = eta + (y - mu) / mu            # working response
        beta = np.linalg.solve((X.T * W) @ X, (X.T * W) @ z)
    return beta
```

```

beta_lin = quasi_irls(X, y, lambda m: m)          #  $V(\mu) = \mu$ 
mu = np.exp(X @ beta_lin)
deviance = 2 * np.sum(y * np.log(y / mu) - (y - mu))    # quasi-deviance,  $V(\mu)$ 
                ) = mu
pearson = np.sum((y - mu) ** 2 / mu)                  #  $X^2$  with  $V(\mu) = \mu$ 
phi_pearson = pearson / (n - p)
beta_null = quasi_irls(X[:, :1], y, lambda m: m)
mu_null = np.exp(X[:, :1] @ beta_null)
deviance_null = 2 * np.sum(y * np.log(y / mu_null) - (y - mu_null))
naive_chisq = deviance_null - deviance                # the Poisson likelihood
                ratio
quasi_f = (deviance_null - deviance) / phi_pearson    # referred to  $F(1, n - p)$ 
print(f"naive chi-squared {naive_chisq:.1f}, p = {stats.chi2.sf(naive_chisq, 1):.2e}")
print(f"quasi F {quasi_f:.2f} on (1, {n - p}) df, p = {stats.f.sf(quasi_f, 1, n - p):.4f}")

```

Idea. The quasi-score does not know about the variance at all ([Theorem 38.2.2\(b\)](#)), so a wrong variance costs efficiency and calibration but not consistency. Whenever a colleague reports that “adding a dispersion parameter did not change the results”, the coefficients were being looked at and the standard errors were not.

38.4.4 Exercises

38.4.4.1 A. Check your understanding

Exercise A1.

Show that for fixed $\phi_0 > 1$ the size [Eq. 38.4.2](#) tends to 1 as $q \rightarrow \infty$. (Use $\chi^2(q)/q \rightarrow 1$ in probability, together with $\chi^2_{1-\alpha}(q)/q \rightarrow 1$, and compare with the event $\chi^2(q)/q > \chi^2_{1-\alpha}(q)/(q\phi_0)$.)

Solution. By the law of large numbers $\chi^2(q)/q \rightarrow 1$ in probability, and the same concentration gives $\chi^2_{1-\alpha}(q)/q = c_q \rightarrow 1$. The event in [Eq. 38.4.2](#) is $\{\chi^2(q)/q > c_q/\phi_0\}$, whose threshold tends to $\phi_0^{-1} < 1$, so its probability tends to 1; at $q = 1$ it is the finite $\Pr\{\chi^2(1) > 3.841/\phi_0\}$. The listing of this section shows the size increasing with q over the range tabulated, but that is a computation, not a proof.

Exercise A2.

A Poisson regression of accident counts on three covariates gives $X^2/(n-p) = 3.2$. Give three distinct explanations, and for each one say what you would compute next.

38.4.4.2 B. Practice

Exercise B1.

In [Proposition 38.4.1\(c\)](#), let S be geometric on $\{1, 2, \dots\}$ with mean $1/\theta$. Compute $\text{Var } Y / \text{E } Y$ and show that it equals $(2 - \theta)/\theta$. For which θ does the compound Poisson

have the variance-to-mean ratio of a negative binomial with $\kappa = \mu$?

Exercise B2.

Grouped binomial data have group sizes m_i spread between 2 and 50. Show that under the constant-dispersion specification the Pearson terms $m_i(y_i - \hat{\mu}_i)^2 / \{\hat{\mu}_i(1 - \hat{\mu}_i)\}$ have expectation ϕ free of m_i , while under [Eq. 38.1.3](#) they have expectation $1 + \rho(m_i - 1)$. Describe the plot this suggests and what each specification predicts for it.

Solution. Under $\text{Var}(Y_i) = \phi\mu_i(1 - \mu_i)/m_i$ the Pearson term at the true mean has expectation ϕ ; under [Eq. 38.1.3](#) the same calculation gives $1 + \rho(m_i - 1)$, linear in m_i with slope ρ . So plot squared Pearson residuals against m_i with a smooth: flat supports a constant dispersion, increasing the exchangeable form.

Exercise B3.

Both the NB1 model and the quasi-Poisson specification have $\text{Var}(Y_i) = \phi\mu_i$. Using [Eq. 37.4.6](#) and [Eq. 38.1.1](#), explain why a single very large count influences the two fits differently, and predict which of the two coefficients in [Example \(Four analyses of the strike data\)](#) would move more if the longest strike were deleted.

Solution. In the quasi-Poisson equation the log link cancels μ_i against $V(\mu_i)$, so observation i enters through the raw residual $y_i - \mu_i$: the longest strike, a count of 216 against a fitted mean of 58.99, contributes 157.0. The NB1 score [Eq. 37.4.6](#) contains y_i only inside $\psi(y_i + \alpha\mu_i)$, which grows like $\log y_i$, so the NB1 fit is far less sensitive to it and the quasi-Poisson coefficient should move more when it is removed.

38.5 Summary and Notes

38.5.1 Summary

Idea.

1. A **variance specification** ([Definition 38.1.1](#)) gives the mean and the variance of each response and nothing else: $EY_i = h(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ and $\text{Var}(Y_i) = \phi V(\mu_i)/w_i$, with ϕ free even for a variance function borrowed from a family that fixed it. No distribution need exist with these moments, and for ungrouped binary data none does with $\phi \neq 1$. Overdispersion of a group proportion has two shapes, a constant multiple of the binomial variance and the factor $1 + \rho(m - 1)$ of exchangeable trials ([Lemma 38.1.1](#)), agreeing at one group size only.
2. A variance function fixes the estimating equations, not the fit: the NB1 model shares the quasi-Poisson variance function and gives a different $\hat{\boldsymbol{\beta}}$ ([Example \(Four analyses of the strike data\)](#)).
3. The **quasi-likelihood** $Q(\mu; y) = w\phi^{-1} \int_y^\mu (y - t)V(t)^{-1} dt$ of [Definition 38.2.1](#) has the score, the two Bartlett identities and the saturated maximum of a log-

- likelihood, and equals the log-likelihood minus its saturated value for an exponential dispersion family ([Proposition 38.2.1](#)); its -2ϕ multiple is the **quasi-deviance**.
4. The **quasi-score** is the score [Eq. 34.3.1](#), so the estimate is the usual iteratively reweighted least squares fit ([Theorem 38.2.2\(a\)](#)), unbiased as soon as the mean model is right whatever the variances; the identity between its variance and its sensitivity needs the variance model too ([Theorem 38.2.2\(b\)–\(e\)](#)).
 5. Among **linear estimating functions** $\mathbf{C}(\boldsymbol{\beta})(\mathbf{y} - \boldsymbol{\mu})$ the quasi-score maximizes the Godambe information, and nothing else does except its nonsingular linear transformations ([Proposition 38.2.3](#)). The proof is Gauss–Markov with an orthogonal projection in place of the completion of the square.
 6. Under (Q1)–(Q5), $\hat{\boldsymbol{\beta}}$ is asymptotically normal with the **sandwich** covariance $\mathbf{A}_n^{-1}\mathbf{B}_n\mathbf{A}_n^{-1}$, whose middle is estimated from the residuals ([Theorem 38.3.1](#)); a correct variance specification makes $\mathbf{B}_n = \mathbf{A}_n$ and collapses it to the model-based $\phi(\mathbf{X}^\top\mathbf{W}\mathbf{X})^{-1}$, then valid and more efficient.
 7. The dispersion is estimated by $X^2/(n-p)$, of expectation exactly ϕ at the true mean, while the deviance version is not in general consistent ([Proposition 38.3.2\(a\),\(b\)](#)). Nested models are compared by the quasi- F statistic [Eq. 38.3.3](#), which needs a correct variance function; the Akaike criterion has no analogue here beyond a convention ([Proposition 38.3.2\(c\),\(d\)](#)).
 8. Overdispersion comes from unobserved heterogeneity, clustering and contagion, each computable exactly ([Proposition 38.4.1\(a\)–\(c\)](#)). Ignoring a dispersion ϕ_0 turns a nominal 5% test of one coefficient into one of size $\Pr\{\chi^2(1) > 3.841/\phi_0\}$, and of six coefficients into something far worse ([Eq. 38.4.2](#)). The repairs assume different things — a mean and a variance shape, a full distribution, a mixing law — and the last changes the estimand.

38.5.2 Notes and sources

Wedderburn’s paper. Quasi-likelihood is due to Wedderburn (1974), written two years after the generalized linear model itself (Nelder and Wedderburn 1972) and in the same spirit: notice which part of the structure the algorithm uses, and keep only that. The definition [Eq. 38.2.1](#), the two Bartlett identities and the table of quasi-likelihoods are all in that paper, as is the name. McCullagh and Nelder (1989, chapter 9) is the standard extended treatment; their chapter 10 develops the joint model for the mean and the dispersion, which this chapter does not cover. Multiplying Poisson or binomial standard errors by $\sqrt{X^2/(n-p)}$ predates the theory — Finney (1947) used it for probit analysis — and Wedderburn said what it estimates.

Estimating functions and optimality. The general theory of unbiased estimating functions is Godambe (1960), who showed the likelihood score optimal among them in the sense used in [Proposition 38.2.3](#); Godambe and Heyde (1987) survey the subject. The projection proof given here makes the analogy exact: “optimal among linear estimating functions” stands to “optimal among all” as “best linear unbiased” stands to “minimum variance unbiased” in [Theorem 7.2.1](#). McCullagh (1983) proved the asymptotics under conditions close to (Q1)–(Q5).

The sandwich. Its history is traced in [Section 21.4](#): Eicker (1963), Huber (1967) and White (1980) in three literatures at once. The generalized-linear-model version, with the working weights in the bread, is in Royall (1986), who argued for it as the default; Liang and Zeger (1986) made it the foundation of generalized estimating equations. Its small-sample bias is analysed by Kauermann and Carroll (2001), and the leverage corrections of [Example \(Coverage](#)

when the variance function is right and when it is wrong) are the HC2 and HC3 of MacKinnon and White (1985).

Binomial overdispersion. The exchangeable-trials calculation Eq. 38.1.3 is the design effect of cluster sampling (Kish 1965), which Chapter 33 met as $1 + (m - 1)\rho$. The beta-binomial distribution is due to Skellam (1948), and Williams (1982) proposed fitting the variance function $\{1 + \rho(m_i - 1)\}\mu(1 - \mu)/m_i$ by alternating a quasi-likelihood step with a moment equation setting X^2 equal to its degrees of freedom.

Which device to use. Ver Hoef and Boveng (2007) is a clear applied statement of the quasi-Poisson against negative binomial question, showing that the choice is between the NB1 and NB2 variance functions and matters most where the fitted means are most spread out — what Example (Four analyses of the strike data) shows in miniature. Cameron and Trivedi (2013) covers the quasi-likelihood, negative binomial and sandwich routes together. The “QAIC” convention of Proposition 38.3.2(d) is from Lebreton, Burnham, Clobert and Anderson (1992), widely used in ecology and resting on no theorem.

The data. The strike durations of Example (Strike durations) are the subset of Kennan’s (1985) contract-strike series distributed with statsmodels, from Bureau of Labor Statistics records. Kennan fitted duration models of a different kind; the Poisson mean model here illustrates the methods of this chapter and is not an account of strike durations.

What comes next. Chapter 39 returns to models with likelihoods, taking up model building, diagnostics and the Bayesian treatment. Chapter 40 extends the estimating-equation idea to correlated responses, where the working variance becomes a working *correlation matrix*. Chapter 41 asks what happens when some responses are not observed at all.

Chapter 39

GLMs in Practice; the Bayesian Thread

Chapters 34 to 38 built the generalized linear model and its inference. This chapter asks two practical questions the theory leaves open. The first is how one arrives at a particular model at all: which family, which link, which scale for the covariates, which interactions, and how candidates are compared. The second is how the model is criticized once fitted, since it has three separable pieces — a mean, a link and a variance function — and a plot that condemns the whole fit is much less useful than one naming the piece at fault.

The rest of the chapter takes up the Bayesian thread, running through the book since [Section 7.6](#). For the normal linear model the posterior was available in closed form and the flat prior reproduced least squares exactly. None of that survives the move to a generalized linear model, for one identifiable reason: the log-likelihood is no longer a quadratic. What replaces it is approximation — the Laplace expansion, which also explains where the BIC comes from — and simulation, in the form of Metropolis–Hastings and Gibbs samplers written out in numpy. The chapter ends where the Bayesian and penalized-likelihood threads meet: a normal prior is ridge regression, a Laplace prior the lasso at its mode, and a merely weakly informative prior is enough to make an estimate exist where maximum likelihood has none.

What you need. [Chapter 34](#) throughout ([Definition 34.2.1](#), [Definition 34.2.2](#), [Definition 34.1.2](#), [Theorem 34.3.1](#), [Theorem 34.4.1](#), [Definition 34.5.1](#), [Theorem 34.5.5](#), [Theorem 34.5.1](#), [Definition 34.5.2](#)); [Chapter 35](#) for separation ([Theorem 35.3.1](#)), Firth’s penalty ([Proposition 35.3.2](#)) and the deviance for binary data ([Proposition 35.4.1](#)); [Chapter 37](#) for offsets ([Proposition 37.2.1](#)); [Chapter 38](#) for dispersion ([Proposition 38.3.2](#)) and overdispersion ([Proposition 38.4.1](#)). From earlier parts: [Chapter 20](#) ([Definition 20.4.1](#), [Theorem 20.3.1](#), [Proposition 20.1.3](#)); [Chapter 22](#) for [Proposition 22.5.1](#) and [Theorem 22.3.2](#); the parametric bootstrap of [Proposition 23.3.3](#); [Chapter 29](#) ([Definition 29.2.2](#), [Proposition 29.2.4](#), [Definition 29.3.1](#), [Proposition 29.5.1](#)); and penalties as priors ([Chapter 27](#), [Chapter 30](#): [Definition 27.2.1](#), [Definition 27.4.1](#), [Proposition 30.1.4](#)). The Bayesian thread so far: [Section 7.6](#) for [Theorem 7.6.2](#) and [Corollary 7.6.4](#), [Section 12.6](#) for [Definition 12.6.1](#), and [Section 32.6](#) for [Proposition 32.6.1](#).

39.1 Building a model

A generalized linear model has three parts that can be chosen separately: a response family, which fixes the variance function $V(\mu)$; a link g ; and a linear predictor $\eta = \mathbf{x}^\top \boldsymbol{\beta}$. [Chapter 34](#) fits whichever combination is handed to it; this section is about how the combination is chosen, and how honest one can be afterwards.

39.1.1 The family follows the variance

Two things are known about a response before any model is fitted: what values it can take, and how its spread changes with its level. The first rules out most families at once — a count is not negative, a proportion is bounded, a duration is positive. The second separates those that remain, because within the exponential dispersion family the variance function determines the family ([Exercise \(B2\)](#)). For the families of [Definition 34.1.2](#) the variance is a power of the mean,

$$\text{Var}(Y_i) = \phi \mu_i^\zeta / w_i, \quad (39.1.1)$$

with $\zeta = 0$ for the normal, 1 for the Poisson, 2 for the gamma and 3 for the inverse Gaussian; in between are the Tweedie families of [Exercise \(C2\)](#). So “which family?” is largely the question “which ζ ?”, and with replicates it can be answered before any model is fitted. A second choice arises at once: the scale on which the systematic part is additive. Transforming the response and transforming the mean are different operations ([Exercise \(B1\)](#)), and models on different response scales are not comparable by their likelihoods unless the change of variable is accounted for. The proposition collects the three facts that make these choices more than a matter of taste.

Proposition 39.1.1 — Three facts about building a generalized linear model

- (Reading the variance function off replicates.)* Suppose the observations fall into $G \geq 2$ groups, group g holding $m_g \geq 2$ independent replicates with mean $\mu_g > 0$, variance $\phi \mu_g^\zeta$ and finite fourth moment. Let $\bar{y}_g$ be the mean of the replicates in group g , let s_g^2 be their variance with divisor $m_g - 1$, and let $\hat{\zeta}$ be the slope of the weighted least squares regression of $\log s_g^2$ on $\log \bar{y}_g$ with any fixed positive weights c_g . If the $\log \mu_g$ are not all equal, then $\hat{\zeta} \rightarrow \zeta$ in probability as $\min_g m_g \rightarrow \infty$ with G , the μ_g and ϕ fixed.
- (Additivity is a property of the link, not of the data.)* Let $g(\mu(x_1, x_2)) = a(x_1) + b(x_2)$ on $I_1 \times I_2$, with a and b continuous and nonconstant, and let J be the interval of values taken by $a + b$. Let $\tilde{g}$ be a second link and $s = \tilde{g} \circ g^{-1}$, twice differentiable on J . Then $\tilde{g}(\mu(x_1, x_2))$ is again a sum of a function of x_1 and a function of x_2 if and only if s is affine on J .
- (Comparing models across response scales.)* Let t be strictly increasing and continuously differentiable with $t' > 0$, and let a model for the transformed responses

$\tilde{y}_i = t(y_i)$ have maximized log-likelihood $\tilde{\ell}$ and d estimated parameters. As a model for $\mathbf{y}$ it has maximized log-likelihood $\tilde{\ell} + \sum_i \log t'(y_i)$, so its AIC on the scale of $\mathbf{y}$ is

$$\text{AIC} = -2\tilde{\ell} + 2d - 2 \sum_{i=1}^n \log t'(y_i). \quad (39.1.2)$$

Proof.

- (a) With m_g replicates of finite fourth moment, $\bar{y}_g \rightarrow \mu_g$ and $s_g^2 \rightarrow \phi \mu_g^\zeta$ in probability as $m_g \rightarrow \infty$, the second because $\text{Var}(s_g^2) \rightarrow 0$ when the fourth moment is finite. Both limits are positive, and log is continuous there, so $L_g = \log \bar{y}_g \rightarrow \log \mu_g$ and $V_g = \log s_g^2 \rightarrow \log \phi + \zeta \log \mu_g$ in probability. The weighted slope

$$\hat{\zeta} = \frac{\sum_g c_g (L_g - \bar{L}_c)(V_g - \bar{V}_c)}{\sum_g c_g (L_g - \bar{L}_c)^2}, \quad \bar{L}_c = \frac{\sum_g c_g L_g}{\sum_g c_g},$$

is a continuous function of $(L_1, V_1, \dots, L_G, V_G)$ wherever the denominator is nonzero. At the limit point the denominator is $\sum_g c_g (\log \mu_g - \overline{\log \mu_c})^2 > 0$, because the $\log \mu_g$ are not all equal, and the numerator is ζ times the same quantity. The continuous mapping theorem gives $\hat{\zeta} \rightarrow \zeta$.

- (b) If $s(u) = \alpha + \beta u$ then $\tilde{g}(\mu) = \alpha + \beta a(x_1) + \beta b(x_2)$, a sum. Conversely suppose $\tilde{g}(\mu(x_1, x_2)) = A(x_1) + B(x_2)$. If $a(x_1) = a(x'_1)$ then $\mu(x_1, x_2) = \mu(x'_1, x_2)$ for every x_2 , so $A(x_1) = A(x'_1)$; hence $A^*(u) = A(x_1)$ is well defined on the range U of a , and likewise B^* on the range V of b . Both are nondegenerate intervals, being continuous images of intervals under nonconstant maps, and

$$s(u + v) = A^*(u) + B^*(v), \quad u \in U, v \in V.$$

Fix u_0, v_0 interior to U, V . For any other such u, v the four terms cancel:

$$s(u + v) - s(u_0 + v) - s(u + v_0) + s(u_0 + v_0) = 0.$$

Differentiating in u and then in v gives $s''(u + v) = 0$. As $u + v$ ranges over an open subinterval of J whose closure is J , and s'' is continuous, $s'' \equiv 0$: s is affine.

- (c) If $\tilde{Y} = t(Y)$ has density $f_{\tilde{Y}}$, then Y has density $f_Y(y) = f_{\tilde{Y}}(t(y)) t'(y)$, because t is a strictly increasing differentiable bijection onto its image. Summing logs over independent observations, $\ell(\cdot; \mathbf{y}) = \tilde{\ell}(\cdot; \tilde{\mathbf{y}}) + \sum_i \log t'(y_i)$ for every parameter value, so the maximizers coincide and the maximized values differ by the stated constant. Substituting into $\text{AIC} = -2\ell + 2d$ gives [Eq. 39.1.2](#). ■

Part (c) is worth stating because the omitted term is enormous. The AIC that software prints for a normal linear model fitted to $\log \mathbf{y}$ compares it with other models *for* $\log \mathbf{y}$; against a gamma model for $\mathbf{y}$ the comparison is meaningless until $2 \sum_i \log y_i$, a sum of order n , is added back.

Warning. The same applies to cross-validation, to the deviance and to any other criterion built on a likelihood. A predictive score is a score *for a particular quantity on a particular scale*; predicting $\log y$ well and predicting y well are different achievements, and the

second is usually what was wanted.

39.1.2 A worked choice

Example. (How long does a strike last)

The durations of 62 contract strikes in United States manufacturing, from one day to 216, are recorded with a measure of unanticipated industrial production at the time. [Example \(Strike durations\)](#) read the same durations as counts and asked only for a variance function; here they are read as what they are, positive and continuous, and the question is which family to use. The response is strongly right-skewed, so a normal linear model is out; which of the positive families fits the mean–variance relationship?

The covariate takes only 9 distinct values, so the data arrive already in replicate groups, of sizes 2 to 18. The weighted regression of [Proposition 39.1.1\(a\)](#) gives $\hat{\zeta} = 1.606$ with a standard error of 0.434, computed from the exact normal-theory variance $\text{Var}(\log s_g^2) = \psi'\{(m_g - 1)/2\}$ — the familiar $2/(m_g - 1)$ is only its large-group limit, and understates it badly for the two groups of size two. Panel (a) of [Figure 39.1.1](#) shows the nine points with the fitted line and the Poisson and gamma references: $\zeta = 2$ is 0.9 standard errors away and $\zeta = 1$ is 1.4, which is weak evidence for the gamma and against anything Poisson-like.

Fit three models with a log link and the same linear predictor, maximizing each over its dispersion parameter as well as over β , and count $d = 3$ for all three. AIC on the scale of the durations is 585.4 for the gamma, 590.9 for the log-normal and 603.3 for the inverse Gaussian. The log-normal figure is the AIC of the least squares fit to $\log \mathbf{y}$, 206.8, plus the Jacobian term $2 \sum_i \log y_i = 384.1$ of [Eq. 39.1.2](#). Without that term the log-normal appears to beat the gamma by 378.7: not a close call, and in the wrong direction, because the uncorrected number answers a different question. Leave-one-out cross-validation with the log score puts the three in the same order, at -4.7192 , -4.7713 and -4.8664 per observation.

The gamma slope is to the last decimal the estimate that [Example \(Strike durations\)](#) obtained from $V(\mu) = \mu^2$ alone: the variance function fixes the estimating equations, and choosing a family on top of it buys a likelihood, not a different fit. The maximum likelihood shape of the gamma fit is $\hat{\nu} = 1.003$, so the durations are close to exponential given the covariate, which is what $\zeta = 2$ with a coefficient of variation near one means. (Software reports instead the moment estimate from the Pearson dispersion $\hat{\phi} = 0.941$, namely 1.063; the two agree here, and for the inverse Gaussian they do not.) The fits also disagree about what they estimate: at the mean covariate value the gamma model puts the *mean* duration at 39.4 days, while the log-normal model puts the *median* at 22.2 and, after the retransformation correction of [Proposition 22.5.1](#), the mean at 46.7.

```
import numpy as np
import statsmodels.api as sm
strikes = sm.datasets.strikes.load_pandas().data      # 62 contract strikes, public
    domain
y = strikes["duration"].to_numpy(float)              # days
x = strikes["iprod"].to_numpy(float)                 # unanticipated industrial
    production
```

Figure 39.1.1: Choosing a family for the strike durations. (a) Log group variance against log group mean, point size proportional to group size; the fitted slope estimates ζ in Eq. 39.1.1, and the reference lines have the Poisson and gamma slopes. (b) The three fitted densities at the mean covariate value, over a histogram of the durations.

```
groups = strikes.groupby("iproduct")["duration"].agg(["count", "mean", "var"])
groups = groups[groups["count"] >= 2]
w = groups["count"].to_numpy() - 1.0
L = np.column_stack([np.ones(len(groups)), np.log(groups["mean"])]])
zeta_fit = np.linalg.solve(L.T @ (w[:, None] * L), L.T @ (w * np.log(groups["var"])))

print(groups.round(2))
print(f"variance-function power zeta = {zeta_fit[1]:.3f}")
```

```
from scipy import optimize, special, stats
X = np.column_stack([np.ones(len(y)), x])
n, p = X.shape
d = p + 1
gam = sm.GLM(y, X, family=sm.families.Gamma(sm.families.links.Log())).fit()
igauss = sm.GLM(y, X, family=sm.families.InverseGaussian(sm.families.links.Log())).fit()
lognorm = sm.OLS(np.log(y), X).fit()

def gamma_loglik(yy, mu, nu):

    ))
sigma_ml = np.sqrt(lognorm.ssr / n) # the maximizing sigma,
    divisor n
ll_ln = np.sum(stats.norm.logpdf(np.log(y), lognorm.fittedvalues, sigma_ml) - np.log
    (y))

for name, ll in [("gamma, log link", ll_gam), ("inverse Gaussian", ll_ig),
    ("log-normal (on the y scale)", ll_ln)]:
    print(f"{name:28s} loglik {ll:9.2f} AIC {-2 * ll + 2 * d:9.2f}")
print(f"gamma: slope {gam.params[1]:8.3f}, maximum likelihood shape {nu_hat:.3f}")

```

39.1.3 Links, scales and interactions

With the family fixed, the link decides what “additive” means. The canonical link ([Definition 34.2.2](#)) keeps the log-likelihood concave ([Theorem 34.3.3](#)) and makes observed and expected information agree ([Theorem 34.3.1\(d\)](#)); neither is a reason to prefer it when its range constrains β . The gamma’s canonical link is the reciprocal, which forces $\mathbf{x}^\top \beta > 0$ and makes every coefficient a statement about $1/\mu$; the log link has no constraint, keeps the concavity ([Exercise \(C1\)](#)), and makes each coefficient a multiplicative effect on the mean. Almost all gamma regressions use the log link, for interpretation rather than fit.

For the covariates, [Theorem 22.3.2](#) transfers verbatim with the linear predictor in place of the mean: to ask whether x_j should enter as x_j^λ , add $x_j \log x_j$ and test its coefficient. Centring matters for a different reason. Under a nonlinear link the intercept is the linear predictor at $\mathbf{x} = \mathbf{0}$, a point no observation resembles when the covariates are uncentred; centring each at a representative value makes $e^{\hat{\beta}_0}$ the fitted mean of a typical case.

Interactions are where the link stops being cosmetic. A two-factor Poisson model with a log link and no interaction says the factors multiply; with an identity link it says they add; by [Proposition 39.1.1\(b\)](#) at most one of these is the additive model of [Definition 16.2.1](#). “No interaction” is therefore never a property of the response alone, and removing an interaction by changing the link is a legitimate simplification, provided the link is reported as part of the finding and was not chosen by looking at the interaction test ([Proposition 29.5.1](#)). On the log scale an interaction coefficient is a ratio of ratios: with binary x_1, x_2 and $\log \mu = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2$, $e^{\beta_{12}}$ is the factor by which the effect of x_1 changes when x_2 switches on; on the logit scale it is a ratio of odds ratios, harder to think about because odds ratios do not collapse over omitted covariates ([Example \(The odds ratio does not collapse\)](#)). Offsets need no new theory ([Proposition 37.2.1](#)): a known exposure enters with coefficient fixed at one, and the model describes a rate.

39.1.4 Comparing and choosing

Because a generalized linear model is fitted by maximum likelihood, everything in [Chapter 29](#) applies: AIC is $-2\ell(\hat{\beta}) + 2d$ with $d = p$ when ϕ is known and $p + 1$ when it is estimated, BIC replaces 2 by $\log n$ ([Definition 29.2.2](#)), and their different targets ([Proposition 29.2.4](#)) are unchanged. Two cautions are specific here. First, by [Proposition 39.1.1\(c\)](#) the likelihoods compared must be for the same random variable, and each must be maximized over the dispersion as well as over β . Second, a quasi-likelihood model has no likelihood, so no AIC; the substitute is the quasi-likelihood information criterion built from the independence-model quasi-likelihood and a sandwich penalty, which [Chapter 40](#) defines. The dispersion estimate is not a likelihood quantity either ([Proposition 38.3.2](#)), which is why an overdispersed fit is compared by quasi- F statistics.

Cross-validation needs a loss, and the natural one is the log score: hold out an observation, fit to the rest, record the predictive log density of what was held out. That is [Definition 29.3.1](#) with the deviance as loss, so [Proposition 29.3.1](#) applies. For a $\phi = 1$ family the log score and the deviance rank models identically; with a dispersion parameter they need not, because the deviance ignores the term in ϕ .

Idea. Three questions, three tools. *Which family?* The support and the mean–variance relationship. *Which link?* What should be additive, checked afterwards ([Section 39.2](#)). *Which terms?* A criterion, plus honesty about what the search cost.

39.1.5 What the search costs

Every warning of [Section 29.5](#) carries over unchanged, because none used normality: after a search the standard errors are too small, the p -values too small and the intervals too short ([Proposition 29.5.1](#)). Two remarks are specific here. A drop in deviance is approximately $\chi^2(q)$ under the smaller model ([Theorem 34.5.5](#)), so a maximum over many candidate terms is not, and the largest always looks significant; and with small n or sparse cells that approximation is itself poor ([Example \(The Hauck–Donner effect\)](#), [Proposition 35.4.1](#)), so the nominal levels being abused were never right to begin with. Sample splitting ([Proposition 29.5.2](#)) and simultaneous inference over the whole search ([Proposition 29.5.3](#)) are the honest ways out.

39.1.6 Exercises

39.1.6.1 A. Check your understanding

Exercise A1.

A colleague fits a normal linear model to $\sqrt{y}$ and a Poisson log-linear model to y , and compares the two AIC values printed by the software. What is the correction term of [Proposition 39.1.1\(c\)](#) here, and in which direction does omitting it push the comparison?

Solution. With $t(y) = \sqrt{y}$, $t'(y) = 1/(2\sqrt{y})$, so the correction term is

$$-2 \sum_i \log t'(y_i) = 2 \sum_i \log(2\sqrt{y_i}) = 2n \log 2 + \sum_i \log y_i,$$

and the AIC of the square-root model on the scale of $\mathbf{y}$ is its printed value plus that amount. It is positive whenever $\prod_i 4y_i > 1$, as for counts of any reasonable size it is, so the printed comparison flatters the square-root model. The Poisson model needs no correction, being already a model for $\mathbf{y}$ — though it is a mass function rather than a density, which makes the comparison dubious anyway.

Exercise A2.

A two-by-two table of counts has fitted means $\mu_{11} = 10$, $\mu_{12} = 20$, $\mu_{21} = 15$ and $\mu_{22} = 30$. Is there an interaction on the log scale? On the identity scale? Reconcile the two answers with [Proposition 39.1.1\(b\)](#).

Solution. On the log scale, $\log \mu_{11} + \log \mu_{22} - \log \mu_{12} - \log \mu_{21} = \log(10 \cdot 30 / (20 \cdot 15)) = \log 1 = 0$: no interaction. On the identity scale, $10 + 30 - 20 - 15 = 5 \neq 0$: there is one. The two links differ by the map $s = \exp$, which is not affine, so [Proposition 39.1.1\(b\)](#) says there is no reason for both to be additive, and here only one is.

39.1.6.2 B. Practice

Exercise B1.

The canonical link of the gamma family is $g(\mu) = -1/\mu$ ([Example \(The gamma and its constant coefficient of variation\)](#)). Show that with this link and a model matrix containing an intercept, the parameter space $\{\boldsymbol{\beta} : \mathbf{x}_{(i)}^\top \boldsymbol{\beta} < 0 \text{ for all } i\}$ is an open convex cone, and that the maximum likelihood estimate may fail to exist by running to its boundary. Contrast with the log link.

Solution. The set is an intersection of n open half-spaces, hence open and convex, and a cone because each constraint is homogeneous. The log-likelihood tends to $-\infty$ as any $\mathbf{x}_{(i)}^\top \boldsymbol{\beta} \rightarrow 0^-$, since $\mu_i \rightarrow \infty$; but the supremum may be approached only as $\|\boldsymbol{\beta}\| \rightarrow \infty$ inside the cone, in which case no maximizer exists, exactly as in [Theorem 35.3.1](#). With the log link the parameter space is all of $\mathbb{R}^p$ and the log-likelihood is concave ([Exercise \(C1\)](#)), so the only obstacle is the analogue of separation.

Exercise B2.

Show that for a family with $\phi = 1$ the leave-one-out log score and the leave-one-out deviance differ by a constant that does not depend on the model, so the two rank models identically. Show that this fails when ϕ is estimated.

39.1.6.3 C. Going deeper

Exercise C1.

Extend [Proposition 39.1.1\(b\)](#) to three covariates: if $g(\mu) = a_1(x_1) + a_2(x_2) + a_3(x_3)$ with all three nonconstant and continuous, and $\tilde{g}(\mu)$ is also a sum of three functions of the separate covariates, must $s = \tilde{g} \circ g^{-1}$ be affine? Does the conclusion change if only two of the three are required to separate?

Exercise C2.

Let the true link belong to the power family $g_\lambda(\mu) = (\mu^\lambda - 1)/\lambda$, which has $g_0 = \log$, and let the model actually fitted use the log link. Following the constructed-variable argument of [Proposition 22.2.4](#), expand g_λ about $\lambda = 0$ to show that a one degree of freedom test of $\lambda = 0$ is obtained by adding a multiple of $\hat{\eta}^2$ to the linear predictor, and identify the constructed variable and the multiple exactly.

39.2 Diagnostics

A fitted generalized linear model can be wrong in three ways: the linear predictor may omit a term or use a covariate on the wrong scale, the link may be wrong, or the variance function may be wrong. A single number — the deviance, say — cannot tell these apart, and for ungrouped binary data it cannot even tell that something is wrong ([Proposition 35.4.1\(b\)](#)). What follows is a set of plots and tests, each aimed at one of the three, and a worked case in which they give different answers.

39.2.1 Residuals in practice

The three residual types of [Definition 34.5.2](#) differ in what they standardize away. Their common first-order behaviour is the generalized linear version of [Eq. 20.1.2](#).

Proposition 39.2.1 — What the standard diagnostics measure

Let a generalized linear model be fitted by maximum likelihood, let $\hat{\mathbf{W}} = \text{diag}\{w_i h'(\hat{\eta}_i)^2 / V(\hat{\mu}_i)\}$ be the working weights, $\mathbf{H} = \hat{\mathbf{W}}^{1/2} \mathbf{X} (\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \mathbf{X}^\top \hat{\mathbf{W}}^{1/2}$ the weighted hat matrix and h_{ii} its diagonal.

- (a) (*Moments of the Pearson residuals.*) To first order in the expansion behind [Theorem 34.5.1](#), $E(r_i^P) \approx 0$ and $\text{Var}(r_i^P) \approx 1 - h_{ii}$, and the standardized residual $r_i^P / \sqrt{1 - h_{ii}}$ has approximate variance one. Moreover $\sum_i h_{ii} = p$, so h_{ii} averages p/n .
- (b) (*Level of a simulated envelope.*) Let $|r|_{(1)} \leq \dots \leq |r|_{(n)}$ be the ordered absolute residuals, and let B independent data sets be generated from the fitted model and refitted, giving vectors of ordered absolute residuals whose k th entries are $R_k^{(1)}, \dots, R_k^{(B)}$. If the model is correct and the fitted parameters are the true ones, and the $B + 1$ values $|r|_{(k)}, R_k^{(1)}, \dots, R_k^{(B)}$ are exchangeable with no ties, then

$$\Pr\{|r|_{(k)} < \min_b R_k^{(b)} \text{ or } |r|_{(k)} > \max_b R_k^{(b)}\} = \frac{2}{B+1} \quad (39.2.1)$$

for each fixed k . The probability that *some* k leaves the band is larger than $2/(B+1)$, and no better than the union bound $\min\{1, 2n/(B+1)\}$ without further argument.

- (c) (*Influence.*) The one-step deletion results of [Theorem 20.3.1](#) hold with $\mathbf{X}$ replaced by $\hat{\mathbf{W}}^{1/2} \mathbf{X}$ and $\mathbf{y}$ by the working response $\mathbf{z}$ of [Eq. 34.4.1](#), giving the Cook-type

measure $C_i = (r_i^P)^2 h_{ii} / \{p(1 - h_{ii})^2\}$ of [Definition 20.4.1](#). The exact deletion identities do not hold, because removing a case changes the weights as well.

- (d) (*Checking the link.*) Let $\hat{\eta}_i$ be the fitted linear predictor and refit the model with $\hat{\eta}_i^2$ added as a covariate. Under the fitted link the extra coefficient is zero, so the deviance drop is asymptotically $\chi^2(1)$; a significant drop says the link is wrong, not which link is right.
- (e) (*Checking a covariate: two plots.*) The partial residual for covariate j on the link scale is $u_{ij} = \hat{\beta}_j x_{ij} + (y_i - \hat{\mu}_i)/h'(\hat{\eta}_i)$. Its weighted least squares regression on $[\mathbf{1}, \mathbf{x}_j]$ with weights $\hat{\mathbf{W}}$ has slope $\hat{\beta}_j$ exactly, so a smooth of u_{ij} against x_{ij} that departs from a straight line indicates a wrong scale for x_j , as in [Proposition 20.1.3](#). The added-variable plot is the other half of the pair: let $\tilde{\mathbf{z}}$ and $\tilde{\mathbf{x}}_j$ be the residuals of the working response $\mathbf{z}$ and of $\mathbf{x}_j$ after $\hat{\mathbf{W}}$ -weighted regression on the remaining columns $\mathbf{X}_{-j}$. Then the $\hat{\mathbf{W}}$ -weighted regression of $\tilde{\mathbf{z}}$ on $\tilde{\mathbf{x}}_j$ has slope exactly $\hat{\beta}_j$, so curvature or a single dominating point in that plot is a statement about $\hat{\beta}_j$ itself.
- (f) (*Checking the variance function.*) Suppose the assumed variance function is correct and each observation carries enough information for r_i^P to be approximately normal: grouped data with large group sizes, or counts with means that are not small. (This fails for ungrouped binary data, where r_i^P takes two values and the constant below is wrong.) Then $E|r_i^P| \approx \sqrt{2/\pi}$ for every i , so a plot of $|r_i^P|$ against $\hat{\eta}_i$ should be level. A systematic trend indicates a variance function of the wrong shape; a level plot at the wrong height indicates a dispersion $\phi \neq 1$.

Proof.

- (a) The expansion used in [Theorem 34.5.1](#) gives, to first order, $\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} \approx (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu})$ and hence $\hat{\boldsymbol{\mu}} - \boldsymbol{\mu} \approx \mathbf{D} \mathbf{X} (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})$, where $\mathbf{D} = \text{diag}(d\mu_i/d\eta_i)$. Put $\mathbf{u} = \mathbf{W}^{1/2} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu})$, whose entries are the Pearson residuals evaluated at the true parameter, with $\text{Cov}(\mathbf{u}) = \mathbf{I}$ by the definition of $\mathbf{W}$. Then

$$\begin{aligned} \mathbf{W}^{1/2} \mathbf{D}^{-1} (\mathbf{y} - \hat{\boldsymbol{\mu}}) &\approx \mathbf{u} - \mathbf{W}^{1/2} \mathbf{X} (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}^{1/2} \mathbf{u} \\ &= (\mathbf{I} - \mathbf{H}) \mathbf{u}, \end{aligned}$$

so $E(r_i^P) \approx 0$ and $\text{Var}(r_i^P) \approx (\mathbf{I} - \mathbf{H})_{ii} = 1 - h_{ii}$. The trace identity is [Proposition 6.3.4](#) applied to $\mathbf{H}$, which is a projection matrix.

- (b) The event that $|r|_{(k)}$ is the strict minimum or the strict maximum of the $B + 1$ exchangeable values has probability $2/(B + 1)$, because each of the $B + 1$ values is equally likely to be the smallest and equally likely to be the largest, and with no ties these two events are disjoint for $B \geq 1$. The final sentence is the usual multiplicity statement: the events for different k are highly dependent, so the probability that some k leaves the band lies between $2/(B + 1)$ and $\min\{1, 2n/(B + 1)\}$ by the union bound, and is not $2/(B + 1)$.
- (c) [Theorem 20.3.1](#) is an algebraic identity about a least squares fit. At convergence the generalized linear fit is a weighted least squares fit of $\mathbf{z}$ on $\mathbf{X}$ with weights $\hat{\mathbf{W}}$ ([Theorem 34.4.1](#)), so the identity applies to that problem, which is what the substitution says. It is only one step of the algorithm, since refitting without case i changes $\hat{\boldsymbol{\mu}}$ and therefore $\hat{\mathbf{W}}$.
- (d) The enlarged model contains the fitted one at coefficient zero and adds one parameter, so [Theorem 34.5.5](#) gives the $\chi^2(1)$ limit under the smaller model. Note that $\hat{\eta}_i$ is itself estimated. Because $\hat{\eta}_i^2$ is a function of the fitted values alone, the

normal-theory analogue is [Theorem 14.7.2](#), which makes the corresponding F test *exact*; here the response is not normal, the limit is the asymptotic one, and the effect of estimating $\hat{\eta}_i$ is of smaller order under the conditions of [Theorem 34.5.1](#).

- (e) The working residual is $(y_i - \hat{\mu}_i)/h'(\hat{\eta}_i) = z_i - \hat{\eta}_i$ by [Eq. 34.4.1](#). The weighted least squares fit of $\mathbf{z}$ on $\mathbf{X}$ has residual vector $\mathbf{z} - \hat{\boldsymbol{\eta}}$ orthogonal to $\mathbf{X}$ in the $\hat{\mathbf{W}}$ inner product, so $\mathbf{u}_j = \hat{\beta}_j \mathbf{x}_j + (\mathbf{z} - \hat{\boldsymbol{\eta}})$ regressed on $[\mathbf{1}, \mathbf{x}_j]$ in that inner product returns $\hat{\beta}_j$ exactly, by [Proposition 20.1.3\(a\)](#) applied in the $\hat{\mathbf{W}}$ metric ([Theorem 6.9.1](#)). For the added-variable statement, at convergence the fit is the weighted least squares regression of $\mathbf{z}$ on $\mathbf{X}$ with weights $\hat{\mathbf{W}}$ ([Theorem 34.4.1](#)), which is an ordinary least squares problem in the $\hat{\mathbf{W}}$ inner product; [Theorem 6.6.2](#) applied in that inner product gives the claim.
- (f) By (a), r_i^P has approximate mean zero and variance $1 - h_{ii} \approx 1$ when the leverages are small. Its approximate normality is the hypothesis of the statement, and it is a statement about the single observation Y_i , not about $\hat{\boldsymbol{\beta}}$: [Theorem 34.5.1](#) concerns the estimate and does not deliver it. For $Z \sim N(0, 1)$, $E|Z| = \sqrt{2/\pi}$. If instead $\text{Var}(Y_i) = \phi V(\mu_i)/w_i$ with $\phi \neq 1$, every r_i^P is inflated by $\sqrt{\phi}$ and the plot is level at $\sqrt{2\phi/\pi}$.

■

Remark (Why absolute residuals). A quantile plot of signed residuals asks two questions at once, and for a discrete response the answer to the first is dominated by the discreteness. Plotting $|r|_{(k)}$ against $\Phi^{-1}\{(k + n - 1/8)/(2n + 1/2)\}$, the expected order statistics of $|Z|$, asks only about magnitude, which is what an outlier or an inflated dispersion changes. The envelope turns the picture into a parametric bootstrap test ([Proposition 23.3.3](#)), of only approximate level because the data sets are generated at $\hat{\boldsymbol{\beta}}$.

39.2.2 A model that fails, and why

Example. (Days of television news)

The 1996 American National Election Studies survey asked its 944 respondents on how many of the past seven days they had watched the television news. Treating the answer as a binomial count out of seven and fitting a logit model in age, education and income gives a deviance of 4447.3 on 940 degrees of freedom and a Pearson statistic of 3598.2, so $\hat{\phi} = 3.828$: the model is not close to fitting.

Panel (a) of [Figure 39.2.1](#) is the half-normal plot with an envelope from $B = 19$ simulated data sets, refitted each time. Every one of the 944 ordered residuals lies above the band — not a little too large in the tail but too large everywhere, the signature of a dispersion problem rather than of outliers.

The targeted checks of [Proposition 39.2.1](#) say where the trouble is not. Adding $\hat{\eta}^2$ drops the deviance by 0.31 on one degree of freedom, $p = 0.580$: the logit link is not the problem. Adding a quadratic in age drops it by 0.03, and panel (a) of [Figure 39.2.2](#) shows the partial residual for age with a smooth that is mildly concave but close to the fitted line, so the scale of age is not the problem either. The leverages are all tiny — the largest 0.0144 against an average of 0.0042 — and the largest Cook-type distance is

Figure 39.2.1: Half-normal plots of the absolute Pearson residuals with an envelope from 19 simulated data sets, refitted each time. (a) The binomial model: every point lies above the envelope. (b) The beta-binomial model: the upper tail is contained, the lower one is not.

0.0970.

What is left is the variance function, and panel (b) makes the case. The local means of $|r^P|$ in ten equal bins of the linear predictor run from 1.25 to 1.91, against a reference height of $\sqrt{2/\pi} \approx 0.80$, and they drift upward: the regression of $\log(r^P)^2$ on the linear predictor has slope 0.381 with $t = 4.21$, so the excess variance is not even constant. The binomial model treats a respondent's seven days as seven independent trials with a common probability, and they are nothing of the kind: 161 respondents watched on none of the seven days and 288 on all seven. Habits are not coin flips.

The repair is a variance function with a second parameter. A beta-binomial model, in which each respondent has a latent probability from a beta distribution with mean π_i and precision s , gives $\hat{s} = 1.072$, a within-respondent correlation of $\rho = 1/(1+s) = 0.483$, and the variance $7\pi_i(1-\pi_i)(7+s)/(1+s)$, about 3.90 times the binomial one, against the $\hat{\phi} = 3.828$ estimated directly. Panel (b) of Figure 39.2.1 repeats the half-normal plot under that model: only 0.2 per cent of the ordered residuals now lie above the envelope, although 22.8 per cent still fall below it, against a pointwise level of 5 per cent on that side — a residual misfit at the bottom of the scale that the beta-binomial does not remove.

The consequences for inference are what Chapter 38 predicts. The age coefficient barely moves, from 0.0424 to 0.0405; its standard error moves from 0.0018 to 0.0033, and the quasi-binomial standard error — the binomial one multiplied by $\sqrt{\hat{\phi}}$ — is 0.0034, which agrees with the beta-binomial one to two figures. The education coefficient is the casualty: 0.0233 with standard error 0.0178 under the binomial, already unconvincing at $t = 1.3$, becomes -0.0013 with standard error 0.0343 — an effect of zero with three times the uncertainty.

39.2.3 Which repair

Example ([Days of television news](#)) had three candidate repairs and took the third; the choice among them is the subject of [Proposition 38.4.1](#). A **quasi-likelihood** fit keeps the mean model and the shape of the variance function and lets ϕ float ([Definition 38.1.1](#)): it changes no coefficient, because the estimating equations are the same, and multiplies every standard error by $\sqrt{\hat{\phi}}$. A **mixture** model, such as the beta-binomial here or the negative binomial of [Definition 37.4.1](#), names a mechanism and is a genuine likelihood, so it has an AIC and a likelihood ratio test, and it generally does move the coefficients. A **random effect** in the linear predictor is the third route, developed in [Chapter 40](#); it changes the meaning of the coefficients as well as their values ([Proposition 40.1.1](#)).

Idea. Read diagnostics for a generalized linear model as three separate questions. Is the mean right? Is the link right? Is the variance function right? A plot that fails is useful only when it belongs to one of the three.

39.2.4 Exercises

39.2.4.1 A. Check your understanding

Exercise A1.

[Proposition 39.2.1](#)(b) gives the pointwise level $2/(B+1)$. What is B for a level of 5 per cent? If instead the envelope is taken to be the second smallest and second largest of B simulated values, what is the pointwise level?

Solution. $2/(B+1) = 0.05$ gives $B = 39$. With the second order statistics as limits the observed value must be among the two smallest or two largest of $B+1$, which has probability $4/(B+1)$, so $B = 79$ is needed: a less jagged envelope at the cost of more simulation.

Exercise A2.

The link test of [Proposition 39.2.1](#)(d) came out non-significant in [Example \(Days of television news\)](#). Is that evidence that the logit link is correct? What would a significant result have shown?

39.2.4.2 B. Practice

Exercise B1.

Show that in a normal linear model with $\phi = \sigma^2$ and the identity link, [Proposition 39.2.1](#)(a) reduces to the exact statement $\text{Cov}(\hat{\epsilon}) = \sigma^2(\mathbf{I} - \mathbf{M})$ of [Eq. 20.1.2](#), and that the standardization by $\sqrt{1 - h_{ii}}$ is then exact rather than approximate.

Solution. With the identity link and constant variance $h'(\eta) = 1$, $V(\mu) = 1$, $w_i = 1$, so $\mathbf{W} = \mathbf{D} = \mathbf{I}$ and $\mathbf{H} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top = \mathbf{M}$. The expansion in the proof becomes an identity, $\hat{\boldsymbol{\mu}} - \boldsymbol{\mu} = \mathbf{M}(\mathbf{y} - \boldsymbol{\mu})$, whence $\text{Cov}(\mathbf{y} - \hat{\boldsymbol{\mu}}) = \sigma^2(\mathbf{I} - \mathbf{M})$ and $r_i^P = (y_i - \hat{\mu}_i)/\sigma$ has

variance exactly $1 - h_{ii}$.

Exercise B2.

Let $Y | \Pi \sim \text{Binomial}(m, \Pi)$ with $\Pi \sim \text{Beta}(s\pi, s(1 - \pi))$. Show that $E(Y) = m\pi$ and $\text{Var}(Y) = m\pi(1 - \pi)(m + s)/(1 + s)$, and that the ratio to the binomial variance is $1 + (m - 1)\rho$ with $\rho = 1/(1 + s)$. Evaluate at $m = 7$ and the fitted $\hat{s} = 1.072$.

Solution. $E\Pi = \pi$ and $\text{Var}\Pi = \pi(1 - \pi)/(1 + s)$ for that beta distribution. By the tower property $EY = mE\Pi = m\pi$, and

$$\text{Var}Y = E\{m\Pi(1 - \Pi)\} + \text{Var}(m\Pi) = m\{\pi - E\Pi^2\} + m^2 \text{Var}\Pi.$$

With $E\Pi^2 = \text{Var}\Pi + \pi^2$ this is $m\pi(1 - \pi) - m \text{Var}\Pi + m^2 \text{Var}\Pi = m\pi(1 - \pi)\{1 + (m - 1)/(1 + s)\}$, which is the stated formula since $1 + (m - 1)/(1 + s) = (m + s)/(1 + s)$. The ratio to $m\pi(1 - \pi)$ is $1 + (m - 1)\rho$. At $m = 7$ and $s = 1.072$, $\rho = 0.483$ and the ratio is $1 + 6 \times 0.483 = 3.90$, close to the $\hat{\phi} = 3.828$ that [Example \(Days of television news\)](#) estimates directly.

39.2.4.3 C. Going deeper

Exercise C1.

[Proposition 39.2.1\(b\)](#) says the simultaneous level of an envelope exceeds the pointwise one. Construct a simultaneous band from the same B simulations, by computing for each simulated data set the maximum over k of the standardized deviation $\{R_k^{(b)} - \bar{R}_k\}/\text{sd}_k$ and using its $(1 - \alpha)$ quantile. Show that the resulting band has simultaneous level at most α under the same exchangeability assumption, and say what it costs.

39.3 Bayesian thread IV: what carries over

The Bayesian thread has three instalments behind it. [Section 7.6](#) put a normal-inverse-gamma prior on $(\boldsymbol{\beta}, \sigma^2)$ in the normal linear model and found the posterior in closed form ([Theorem 7.6.2](#)): precisions add, the posterior mean is a precision-weighted average of the prior mean and the least squares estimate ([Proposition 7.6.3](#)), and the improper prior $\pi(\boldsymbol{\beta}, \sigma^2) \propto 1/\sigma^2$ reproduces least squares and its t intervals exactly ([Corollary 7.6.4](#)). [Section 12.6](#) summarized that posterior by credible sets ([Definition 12.6.1](#)), and [Section 32.6](#) read a random effect as a prior, showed that the BLUP is a posterior mean and REML a marginal posterior mode ([Proposition 32.6.1](#)), and ran a Gibbs sampler to do what the closed form could not. This short section says which of those survive the move to a generalized linear model, and why the others do not.

39.3.1 What survives

Three things carry over unchanged, being definitions rather than computations. **The posterior is still prior times likelihood:** Bayes' theorem does not know what family $\mathbf{y}$ came from. **Credible sets still mean what they meant:** [Definition 12.6.1](#) is a statement about a posterior

distribution, not about a normal one. **A random effect is still a prior:** the generalized linear mixed models of Chapter 40 are Eq. 32.6.1 with a non-normal first level, and the empirical Bayes reading (Proposition 27.5.4) survives with them.

39.3.2 What does not, and why

Everything that made Section 7.6 *closed form* rests on one fact: the normal log-likelihood is a quadratic in $\boldsymbol{\beta}$, so prior times likelihood is again the exponential of a quadratic and completing the square finishes the job. Nothing weaker will do.

Proposition 39.3.1 — Why the conjugate machinery stops at the normal family

Let $\mathbf{y}$ follow the exponential dispersion family of Definition 34.2.1 with the canonical link, so that $\theta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$ and $\ell(\boldsymbol{\beta}) = \phi^{-1} \sum_i w_i \{y_i \theta_i - b(\theta_i)\} + c$. Suppose b is twice continuously differentiable on an open interval Θ . Then the following are equivalent.

- (a) For every n , every $\mathbf{X}$ with $\text{rank}(\mathbf{X}) = p$ and every $\mathbf{y}$, the function $\boldsymbol{\beta} \mapsto \ell(\boldsymbol{\beta})$ is a quadratic polynomial on $\{\boldsymbol{\beta} : \mathbf{x}_{(i)}^\top \boldsymbol{\beta} \in \Theta\}$.
- (b) b'' is constant on Θ .
- (c) The variance function is constant: $V(\mu) = b''(\theta)$ does not depend on μ , so the family is normal (Exercise (B2)).

Consequently, for every family except the normal, a normal prior on $\boldsymbol{\beta}$ gives a posterior that is not normal and has no closed-form normalizing constant.

Proof. The Hessian of ℓ is $-\phi^{-1} \mathbf{X}^\top \text{diag}\{w_i b''(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\} \mathbf{X}$ by Theorem 34.3.1(d). If (b) holds this is constant in $\boldsymbol{\beta}$, and a function with a constant Hessian is a quadratic polynomial, giving (a). Conversely, if (a) holds, take $p = 1$, $n = 1$, $w_1 = 1$, $x_{11} = 1$: the Hessian is the scalar $-b''(\beta)/\phi$, which must then be constant over Θ , which is (b). The equivalence of (b) and (c) is the definition $V(\mu) = b''(\theta)$ of Definition 34.1.2 with $\mu = b'(\theta)$, which makes $\theta \mapsto \mu$ a bijection: $b'' \equiv \sigma^2$ gives $b(\theta) = \sigma^2 \theta^2/2$ up to an affine term, the normal cumulant function.

For the last sentence, with π the $N_p(\mathbf{m}, \boldsymbol{\Sigma})$ density the log posterior is $\ell(\boldsymbol{\beta}) - \frac{1}{2}(\boldsymbol{\beta} - \mathbf{m})^\top \boldsymbol{\Sigma}^{-1}(\boldsymbol{\beta} - \mathbf{m})$ up to a constant; were it the log of a normal density it would be a quadratic in $\boldsymbol{\beta}$, hence so would ℓ , which forces the normal family. ■

So the failure is not a want of cleverness. It is the same failure that made the likelihood equations of Theorem 34.3.1 nonlinear and forced iteratively reweighted least squares on the frequentist side: the score is not linear in $\boldsymbol{\beta}$, so the posterior is not normal, and the integrals defining the posterior mean, the posterior variance and the marginal likelihood

$$m(\mathbf{y}) = \int L(\boldsymbol{\beta}; \mathbf{y}) \pi(\boldsymbol{\beta}) d\boldsymbol{\beta} \quad (39.3.1)$$

have no closed form.

39.3.3 Conjugate priors do exist

It is worth being precise, because “generalized linear models have no conjugate priors” is false as stated. Diaconis and Ylvisaker (1979) characterized the conjugate priors of an exponential family; the canonical-link likelihood is an exponential family in $\boldsymbol{\beta}$, and their construction gives the density

$$\pi(\boldsymbol{\beta} \mid \mathbf{m}_0, \kappa_0) \propto \exp\left[\kappa_0^{-1}\{\mathbf{m}_0^\top \mathbf{X}\boldsymbol{\beta} - \sum_i v_i b(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}\right] \quad (39.3.2)$$

in the form developed for generalized linear models by Bedrick, Christensen and Johnson (1996) and Chen and Ibrahim (2003), with a pseudo-response vector $\mathbf{m}_0$ and a prior weight v_i on each observation. It has the shape of the likelihood, so the posterior belongs to the same family with $\mathbf{m}_0$ and the v_i updated by addition — the “precisions add” structure of Eq. 7.6.2, the prior read as $\sum_i v_i$ observations at $\mathbf{m}_0$. What is missing is everything one wants afterwards: outside the normal family, and outside degenerate designs such as the intercept-only Poisson model of Exercise (B1), Eq. 39.3.2 has no closed-form normalizing constant, so neither have the posterior mean, the variance, the marginal likelihood or a credible interval. In practice the normal prior of the next section — not conjugate, but interpretable — is what is used.

Idea. Everything in the Bayesian thread that was a *definition* survives; everything that was a *closed form* does not. The next two sections replace the closed form by an approximation accurate when n is large and a simulation accurate when it is run long enough.

39.3.4 Exercises

39.3.4.1 A. Check your understanding

Exercise A1.

Verify directly, from the form of the Poisson log-likelihood with a log link, that it is not a quadratic in $\boldsymbol{\beta}$ for $p = 1$, and identify the term that spoils it.

Solution. With $\mu_i = e^{x_i\beta}$ the log-likelihood is $\sum_i \{y_i x_i \beta - e^{x_i \beta}\}$ up to a constant. The first term is linear; the second has second derivative $-\sum_i x_i^2 e^{x_i \beta}$, which depends on β . That is the cumulant term $b(\theta) = e^\theta$, whose b'' is not constant, as Proposition 39.3.1(b) requires.

Exercise A2.

An equal-tailed credible interval for β_j transforms to an equal-tailed credible interval for e^{β_j} by exponentiating its endpoints. Is the same true of a highest-posterior-density interval? Explain.

39.3.4.2 B. Practice

Exercise B1.

Take the Poisson family with a log link, $p = 1$ and $x_{i1} = 1$ for all i , so the model has a single parameter β and $\mu = e^\beta$. Write out Eq. 39.3.2 explicitly, show that it is the density of $\beta = \log \mu$ when μ has a gamma distribution, and identify the shape and rate in terms of $\mathbf{m}_0$ and the v_i . Why does the closed form appear here and not in general?

Solution. With $b(\theta) = e^\theta$, $\theta = \beta$ and $\kappa_0 = 1$, Eq. 39.3.2 is $\pi(\beta) \propto \exp\{a\beta - ve^\beta\}$ with $a = \mathbf{1}^\top \mathbf{m}_0$ and $v = \sum_i v_i$. Substituting $\mu = e^\beta$, so $d\beta = d\mu/\mu$, the density of μ is proportional to $\mu^{a-1}e^{-v\mu}$: a gamma with shape a and rate v , normalizing constant $v^a/\Gamma(a)$. That constant is available because the single linear predictor lets the integral factor into one dimension. With $p > 1$ the exponent $\mathbf{m}_0^\top \mathbf{X}\boldsymbol{\beta} - \sum_i v_i e^{\mathbf{x}_{(i)}^\top \boldsymbol{\beta}}$ is a sum of exponentials of different linear forms, and no change of variable makes it a product of gamma integrals.

39.3.4.3 C. Going deeper**Exercise C1.**

Proposition 39.3.1 assumed the canonical link. Show that with a non-canonical link the conclusion still holds in the following sense: if the log-likelihood is a quadratic in $\boldsymbol{\beta}$ for every design and every response, then the working weights of Theorem 34.4.1 do not depend on $\boldsymbol{\beta}$ and the mean is affine in $\boldsymbol{\beta}$. Deduce that the model is the normal linear model up to a reparameterization.

39.4 Bayesian generalized linear models and MCMC

Proposition 39.3.1 closed off the closed form. What is left is a posterior known only up to a constant, and two ways to work with it: approximate it by a normal density at its mode, accurate to order n^{-1} and the origin of the BIC; or sample from it, accurate to whatever the Monte Carlo error allows. This section does both, with the samplers written out rather than delegated.

39.4.1 The posterior

Definition 39.4.1 — The Bayesian generalized linear model

Let $\mathbf{y}$ follow the generalized linear model of Definition 34.2.1 with link g , dispersion ϕ and log-likelihood $\ell(\boldsymbol{\beta})$, and let π be a prior density on $\mathbb{R}^p$. The **posterior density** of $\boldsymbol{\beta}$ is

$$\pi(\boldsymbol{\beta} \mid \mathbf{y}) = \frac{\exp\{\ell(\boldsymbol{\beta})\} \pi(\boldsymbol{\beta})}{m(\mathbf{y})}, \quad m(\mathbf{y}) = \int_{\mathbb{R}^p} \exp\{\ell(\mathbf{b})\} \pi(\mathbf{b}) d\mathbf{b}, \quad (39.4.1)$$

whenever $0 < m(\mathbf{y}) < \infty$; the posterior is then **proper**. The **maximum a posteriori** estimate $\hat{\boldsymbol{\beta}}_{\text{MAP}}$ maximizes Eq. 39.4.1, equivalently maximizes the penalized log-likelihood $\ell(\boldsymbol{\beta}) + \log \pi(\boldsymbol{\beta})$. The default choice throughout this chapter is the independent normal prior $\boldsymbol{\beta} \sim N_p(\mathbf{m}, \boldsymbol{\Sigma})$, for which

$$\log \pi(\boldsymbol{\beta} \mid \mathbf{y}) = \ell(\boldsymbol{\beta}) - \frac{1}{2}(\boldsymbol{\beta} - \mathbf{m})^\top \boldsymbol{\Sigma}^{-1}(\boldsymbol{\beta} - \mathbf{m}) + \text{const.} \quad (39.4.2)$$

Because Eq. 39.4.2 is concave whenever ℓ is (Theorem 34.3.3), $\hat{\boldsymbol{\beta}}_{\text{MAP}}$ is found by the Fisher scoring of Theorem 34.4.1 with the score replaced by $\mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu})/\phi - \boldsymbol{\Sigma}^{-1}(\boldsymbol{\beta} - \mathbf{m})$ and the information by $\mathbf{X}^\top \mathbf{W} \mathbf{X}/\phi + \boldsymbol{\Sigma}^{-1}$: one extra term in each. What the prior buys is not only shrinkage but existence.

Proposition 39.4.1 — When a flat prior gives a posterior

Let π be a prior on $\mathbb{R}^p$.

- (a) If π is proper and the likelihood is bounded, the posterior is proper. Both the logistic and the Poisson likelihoods are bounded.
- (b) Take the improper prior $\pi \propto 1$ and the ungrouped logistic model with $\text{rank}(\mathbf{X}) = p$. Then the posterior is proper if and only if the data are in overlap in the sense of Definition 35.3.1, that is if and only if the maximum likelihood estimate exists (Theorem 35.3.1).

Proof.

- (a) If $L \leq L_{\max} < \infty$ then $m(\mathbf{y}) \leq L_{\max} \int \pi = L_{\max} < \infty$, and $m(\mathbf{y}) > 0$ because the integrand is positive on a set of positive measure. The logistic likelihood is a product of probabilities, so $L \leq 1$; the Poisson likelihood $\prod_i \mu_i^{y_i} e^{-\mu_i} / y_i!$, maximized freely over $\boldsymbol{\mu} \in (0, \infty)^n$ at $\mu_i = y_i$, is bounded by $\prod_i y_i^{y_i} e^{-y_i} / y_i!$ (with $0^0 = 1$).
- (b) Write $s_i = 2y_i - 1$ and use Eq. 35.3.1: $-\ell(\boldsymbol{\beta}) = \sum_i \log\{1 + \exp(-s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta})\}$.

Overlap implies propriety. Since $\log(1 + e^{-t}) \geq \max(0, -t) = t_-$,

$$-\ell(\boldsymbol{\beta}) \geq \sum_{i=1}^n (s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta})_- =: c(\boldsymbol{\beta}),$$

with c continuous and homogeneous of degree one. Under overlap $c(\mathbf{b}) > 0$ for every $\mathbf{b} \neq \mathbf{0}$, since $c(\mathbf{b}) = 0$ forces $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ for all i , which overlap permits only at the origin. The unit sphere is compact, so $\delta = \min_{\|\mathbf{b}\|=1} c(\mathbf{b}) > 0$ and, by homogeneity, $c(\boldsymbol{\beta}) \geq \delta \|\boldsymbol{\beta}\|$. Hence $\exp\{\ell(\boldsymbol{\beta})\} \leq e^{-\delta \|\boldsymbol{\beta}\|}$, integrable over $\mathbb{R}^p$.

Separation implies impropriety. Let $\mathbf{b} \neq \mathbf{0}$ satisfy $s_i \mathbf{x}_{(i)}^\top \mathbf{b} \geq 0$ for all i , put $S = \{i : \mathbf{x}_{(i)}^\top \mathbf{b} = 0\}$, $\varrho = \min_{i \notin S} s_i \mathbf{x}_{(i)}^\top \mathbf{b} > 0$, $\omega = \max_i \|\mathbf{x}_{(i)}\|$, and fix $\rho > 0$. For $\boldsymbol{\beta} = t\mathbf{b} + \mathbf{u}$ with $t \geq t_0 := 2\omega\rho/\varrho$ and $\|\mathbf{u}\| \leq \rho$, every $i \notin S$ has $s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta} \geq t\varrho - \omega\rho \geq 0$ and every $i \in S$ has $s_i \mathbf{x}_{(i)}^\top \boldsymbol{\beta} = s_i \mathbf{x}_{(i)}^\top \mathbf{u} \geq -\omega\rho$. So $-\ell(\boldsymbol{\beta}) \leq n \log\{1 + e^{\omega\rho}\}$ on that whole tube, giving $\exp\{\ell(\boldsymbol{\beta})\} \geq \{1 + e^{\omega\rho}\}^{-n}$ there; and the tube has infinite Lebesgue measure, containing a half-infinite cylinder about the ray. Hence $m(\mathbf{y}) = \infty$.

Warning. The second part is not a curiosity. Separation is common in small samples and with rare outcomes, and a “noninformative” Bayesian analysis of separated binary data summarizes a measure of infinite mass: whatever the sampler prints is an artefact of where it wandered. [Example \(The separated subgroup, three priors\)](#) makes the divergence visible.

39.4.2 The Laplace approximation

For large n the integral in [Eq. 39.4.1](#) is dominated by a shrinking neighbourhood of the mode, where the integrand looks normal. Write $q_n(\boldsymbol{\beta}) = \ell(\boldsymbol{\beta}) + \log \pi(\boldsymbol{\beta})$ for the unnormalized log posterior, $\hat{\boldsymbol{\beta}}_n$ for its maximizer and $\mathbf{H}_n = -\nabla^2 q_n(\hat{\boldsymbol{\beta}}_n)$.

Theorem 39.4.2 — Laplace approximation

Let $\rho_n = n^{-3/8}$ and $B_n = \{\boldsymbol{\beta} : \|\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}_n\| \leq \rho_n\}$, and suppose there are constants $0 < c \leq C < \infty$ and $a, K > 0$, free of n , with:

- (L1) q_n is four times continuously differentiable on B_n , with $\nabla q_n(\hat{\boldsymbol{\beta}}_n) = \mathbf{0}$ and $\mathbf{H}_n$ positive definite;
- (L2) $cn \leq \lambda_{\min}(\mathbf{H}_n) \leq \lambda_{\max}(\mathbf{H}_n) \leq Cn$, and every third and fourth partial derivative of q_n is bounded in absolute value by Cn on B_n ;
- (L3) $\int_{\mathbb{R}^p \setminus B_n} \exp\{q_n(\boldsymbol{\beta}) - q_n(\hat{\boldsymbol{\beta}}_n)\} d\boldsymbol{\beta} \leq K \exp(-an^{1/4})$.

Then

$$\int_{\mathbb{R}^p} e^{q_n(\boldsymbol{\beta})} d\boldsymbol{\beta} = (2\pi)^{p/2} \det(\mathbf{H}_n)^{-1/2} e^{q_n(\hat{\boldsymbol{\beta}}_n)} \{1 + O(n^{-1})\}. \quad (39.4.3)$$

Proof. Write I_n for the integral and $J_n = I_n \det(\mathbf{H}_n)^{1/2} e^{-q_n(\hat{\boldsymbol{\beta}}_n)}$, so the claim is $J_n = (2\pi)^{p/2} \{1 + O(n^{-1})\}$. Substitute $\boldsymbol{\beta} = \hat{\boldsymbol{\beta}}_n + \mathbf{H}_n^{-1/2} \mathbf{u}$, Jacobian $\det(\mathbf{H}_n)^{-1/2}$:

$$J_n = \int_{\mathbb{R}^p} \exp\{q_n(\hat{\boldsymbol{\beta}}_n + \mathbf{H}_n^{-1/2} \mathbf{u}) - q_n(\hat{\boldsymbol{\beta}}_n)\} d\mathbf{u}.$$

Because $\nabla q_n(\hat{\boldsymbol{\beta}}_n) = \mathbf{0}$, Taylor’s theorem on B_n gives

$$q_n(\hat{\boldsymbol{\beta}}_n + \mathbf{H}_n^{-1/2} \mathbf{u}) - q_n(\hat{\boldsymbol{\beta}}_n) = -\frac{1}{2} \|\mathbf{u}\|^2 + A_n(\mathbf{u}) + r_n(\mathbf{u}),$$

where A_n is the cubic form built from the third derivatives at $\hat{\boldsymbol{\beta}}_n$ and r_n is the fourth-order remainder. By (L2) the derivatives are bounded by Cn and $\|\mathbf{H}_n^{-1/2} \mathbf{u}\| \leq (cn)^{-1/2} \|\mathbf{u}\|$, so

$$|A_n(\mathbf{u})| \leq c_3 n^{-1/2} \|\mathbf{u}\|^3, \quad |r_n(\mathbf{u})| \leq c_4 n^{-1} \|\mathbf{u}\|^4, \quad (39.4.4)$$

with $c_3 = p^3 C / (6c^{3/2})$ and $c_4 = p^4 C / (24c^2)$, valid whenever $\hat{\boldsymbol{\beta}}_n + \mathbf{H}_n^{-1/2} \mathbf{u} \in B_n$.

Let $S_n = \{\mathbf{u} : \|\mathbf{u}\| \leq \sqrt{c}n^{1/8}\}$ and U_n the image of B_n . Every $\mathbf{u} \in S_n$ has $\|\mathbf{H}_n^{-1/2}\mathbf{u}\| \leq (cn)^{-1/2}\|\mathbf{u}\| \leq n^{-3/8} = \rho_n$, so $S_n \subseteq U_n$; and every $\mathbf{u} \in U_n$ has $\|\mathbf{u}\| \leq \lambda_{\max}(\mathbf{H}_n)^{1/2}\rho_n \leq \sqrt{C}n^{1/8}$. Split J_n over S_n , over $U_n \setminus S_n$ and outside U_n .

Outside U_n . Changing back to $\boldsymbol{\beta}$ and using (L3) with $\det(\mathbf{H}_n)^{1/2} \leq (Cn)^{p/2}$ bounds that piece by $(Cn)^{p/2}Ke^{-an^{1/4}}$, which is $o(n^{-1})$.

Between S_n and U_n . There $\|\mathbf{u}\| \leq \sqrt{C}n^{1/8}$, so Eq. 39.4.4 gives $|A_n| + |r_n| \leq c_3C^{3/2}n^{-1/8} + c_4C^2n^{-1/2} \leq 1$ for large n ; the integrand is then at most $e^{1-\|\mathbf{u}\|^2/2}$, whose integral over $\|\mathbf{u}\| > \sqrt{c}n^{1/8}$ is $O(e^{-cn^{1/4}/4}) = o(n^{-1})$.

Inside S_n . Put $R_n = A_n + r_n$, so $|R_n| \leq 1$ there for large n . From $|e^x - 1 - x - \frac{1}{2}x^2| \leq \frac{1}{6}|x|^3e^{|x|}$ for $|x| \leq 1$,

$$\begin{aligned} \int_{S_n} e^{-\|\mathbf{u}\|^2/2} e^{R_n} d\mathbf{u} &= \int_{S_n} e^{-\|\mathbf{u}\|^2/2} \left\{ 1 + R_n + \frac{1}{2}R_n^2 \right\} d\mathbf{u} + \mathcal{E}_n, \\ |\mathcal{E}_n| &\leq \frac{\epsilon}{6} \int_{S_n} e^{-\|\mathbf{u}\|^2/2} |R_n|^3 d\mathbf{u}. \end{aligned}$$

Four pieces. First, $\int_{S_n} e^{-\|\mathbf{u}\|^2/2} d\mathbf{u} = (2\pi)^{p/2} + O(e^{-cn^{1/4}/2})$. Second, A_n is homogeneous of degree three, hence odd, and S_n is a ball about the origin, so $\int_{S_n} e^{-\|\mathbf{u}\|^2/2} A_n(\mathbf{u}) d\mathbf{u} = 0$ exactly. Third, $\int_{S_n} e^{-\|\mathbf{u}\|^2/2} |r_n| d\mathbf{u} \leq c_4n^{-1} \int e^{-\|\mathbf{u}\|^2/2} \|\mathbf{u}\|^4 d\mathbf{u} = O(n^{-1})$. Fourth, by Eq. 39.4.4 $R_n^2 \leq 2c_3^2n^{-1}\|\mathbf{u}\|^6 + 2c_4^2n^{-2}\|\mathbf{u}\|^8$, of Gaussian integral $O(n^{-1})$, and $|R_n|^3 = O(n^{-3/2}\|\mathbf{u}\|^9) + O(n^{-3}\|\mathbf{u}\|^{12})$, of Gaussian integral $O(n^{-3/2})$. Adding the three regions gives $J_n = (2\pi)^{p/2} + O(n^{-1})$, which is Eq. 39.4.3. ■

Remark (When the conditions hold). For a generalized linear model with a proper, positive, twice continuously differentiable prior and the conditions (G1)–(G4) of Theorem 34.5.1, (L1) and (L2) hold with probability tending to one, because $\mathbf{H}_n = \mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X} / \phi + O(1)$ and (G4) makes its smallest eigenvalue grow linearly. Condition (L3) says the posterior concentrates; verifying it in general is a separate argument this book does not give. Kass and Raftery (1995, section 4) discuss the regularity conditions and the accuracy of the approximation.

Corollary 39.4.3 — Where the BIC comes from

Under the conditions of Theorem 39.4.2, suppose in addition that $\mathbf{H}_n/n \rightarrow \bar{\mathbf{H}}$ positive definite, that the prior is continuous and positive at the limit of $\hat{\boldsymbol{\beta}}_n$, and that $\hat{\boldsymbol{\beta}}$ maximizes ℓ with $\ell(\hat{\boldsymbol{\beta}}) - \ell(\hat{\boldsymbol{\beta}}_n) = O(n^{-1})$. Then

$$-2 \log m(\mathbf{y}) = -2\ell(\hat{\boldsymbol{\beta}}) + p \log n + O(1), \quad (39.4.5)$$

where the $O(1)$ term is $\log \det(\mathbf{H}_n/n) - p \log(2\pi) - 2 \log \pi(\hat{\boldsymbol{\beta}}_n) + o(1)$. The leading two terms are the BIC of Definition 29.2.2.

Proof. Take logarithms in Eq. 39.4.3:

$$2 \log m(\mathbf{y}) = 2\ell(\hat{\boldsymbol{\beta}}_n) + 2 \log \pi(\hat{\boldsymbol{\beta}}_n) + p \log(2\pi) - \log \det \mathbf{H}_n + O(n^{-1}).$$

Write $\log \det \mathbf{H}_n = p \log n + \log \det(\mathbf{H}_n/n)$ and replace $\ell(\hat{\boldsymbol{\beta}}_n)$ by $\ell(\hat{\boldsymbol{\beta}})$ at a cost of $O(n^{-1})$; rearranging gives Eq. 39.4.5 with the stated remainder, which converges because $\mathbf{H}_n/n \rightarrow \bar{\mathbf{H}}$.

■

The remainder in Eq. 39.4.5 is $O(1)$, not $o(1)$: the BIC stays a bounded distance from $-2 \log m(\mathbf{y})$, and that distance carries the whole influence of the prior, so a BIC difference is only a crude approximation to a log Bayes factor (Proposition 29.2.4). What makes it useful is that a difference in dimension contributes $\log n$, which grows, while the neglected term does not. A third criterion belongs to the same family: the deviance information criterion of Spiegelhalter, Best, Carlin and van der Linde (2002) replaces p by an effective number of parameters estimated from posterior draws, which suits a model whose parameters are themselves shrunk by a prior.

Example. (How good is the approximation)

Take a logistic regression with an intercept and one covariate, a $N(0, 5^2)$ prior on each coefficient, and data simulated at $\boldsymbol{\beta} = (-0.4, 1.2)^\top$. Adaptive Gauss–Hermite quadrature on a tensor grid centred at the mode computes Eq. 39.4.1 to machine accuracy, so the Laplace error can be measured exactly.

At $n = 25$ the Laplace marginal likelihood is too small by 0.10700, or eleven per cent; the relative error falls to 0.001114 at $n = 1600$. Regressing the log error on $\log n$ over seven sample sizes gives a slope of -1.06 , and over those seven sizes the product $n \times \text{error}$ stays between 1.530 and 2.675: the $O(n^{-1})$ of Eq. 39.4.3, over a decade and a half of sample sizes (Figure 39.4.1, panel (b)).

Panel (a) shows what that error looks like at $n = 25$: the marginal posterior of the slope is visibly right-skewed, mean 2.3291 against mode 1.9271, with total variation distance 0.1827 to the normal approximation. Reporting the mode with the curvature as a standard error would put the estimate in the wrong place and the interval on the wrong side. The corollary is visible too: over the same seven sizes the gap between the BIC and $-2 \log m(\mathbf{y})$ stays between -3.41 and -1.61 , an $O(1)$ that does not grow.

```
import numpy as np
from scipy import special, stats

    print(f" {n:5d} {e:.3e}  n * error = {n * e:.3f}")
print(f"log-log slope {slope:.3f}")

```

Two refinements are quoted without proof. For a positive smooth f , applying [Theorem 39.4.2](#) to $\exp\{q_n + \log f\}$ in the numerator of $E\{f(\boldsymbol{\beta}) \mid \mathbf{y}\} = \int f e^{q_n} / \int e^{q_n}$ raises the accuracy of the ratio to $O(n^{-2})$, the leading errors cancelling (Tierney and Kadane, 1986); and the Bernstein–von Mises theorem says the posterior of $\mathbf{H}_n^{1/2}(\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}_n)$ converges in total variation to $N_p(\mathbf{0}, \mathbf{I})$, so a credible set is asymptotically a confidence set (van der Vaart, 1998, chapter 10).

39.4.3 Sampling the posterior

When n is small, or the posterior skewed as in [Example \(How good is the approximation\)](#), an approximation at the mode is not enough. The alternative is a Markov chain whose stationary distribution is the posterior.

Definition 39.4.2 — Metropolis–Hastings, Gibbs, and the two diagnostics

Let $\pi(\cdot \mid \mathbf{y})$ be a density known up to a constant.

- (a) The **Metropolis–Hastings** chain with proposal density $q(\cdot \mid \cdot)$ moves from $\boldsymbol{\beta}^{(t)}$ by drawing $\boldsymbol{\beta}^* \sim q(\cdot \mid \boldsymbol{\beta}^{(t)})$ and setting $\boldsymbol{\beta}^{(t+1)} = \boldsymbol{\beta}^*$ with probability

$$\alpha(\boldsymbol{\beta}^* \mid \boldsymbol{\beta}^{(t)}) = \min\left\{1, \frac{\pi(\boldsymbol{\beta}^* \mid \mathbf{y}) q(\boldsymbol{\beta}^{(t)} \mid \boldsymbol{\beta}^*)}{\pi(\boldsymbol{\beta}^{(t)} \mid \mathbf{y}) q(\boldsymbol{\beta}^* \mid \boldsymbol{\beta}^{(t)})}\right\}, \quad (39.4.6)$$

and $\boldsymbol{\beta}^{(t+1)} = \boldsymbol{\beta}^{(t)}$ otherwise. The normalizing constant cancels. A symmetric proposal, $q(\mathbf{b} \mid \mathbf{b}') = q(\mathbf{b}' \mid \mathbf{b})$, gives the **random-walk Metropolis** algorithm, in which α is the ratio of posterior densities capped at one.

- (b) The **Gibbs sampler** partitions $\boldsymbol{\psi} = (\boldsymbol{\psi}_1, \dots, \boldsymbol{\psi}_K)$ and replaces each block in turn by a draw from its **full conditional** $\pi(\boldsymbol{\psi}_k \mid \boldsymbol{\psi}_{-k}, \mathbf{y})$. It is the special case of (a) in which every proposal is accepted.
- (c) For c chains of length N , split each in half and let W be the mean of the $2c$ within-sequence variances and B the variance of the $2c$ sequence means. The **potential scale reduction** is

$$\hat{R} = \left\{ \frac{(N/2 - 1)W/(N/2) + B}{W} \right\}^{1/2}. \quad (39.4.7)$$

- (d) With ρ_t the lag- t autocorrelation of the stationary chain, the **effective sample size** of cN draws is $\text{ESS} = cN/(1 + 2 \sum_{t \geq 1} \rho_t)$, the sum truncated by Geyer's rule in the form used here: add the autocorrelations in consecutive pairs $\rho_{2k-1} + \rho_{2k}$,

$k = 1, 2, \dots$, and stop at the first pair that is negative.

Proposition 39.4.4 — The chain has the right stationary distribution

Let π be a density on $\mathbb{R}^p$ and $q(\cdot | \cdot)$ a transition density with $q(\mathbf{b}' | \mathbf{b}) > 0$ whenever $q(\mathbf{b} | \mathbf{b}') > 0$. The Metropolis–Hastings kernel of Eq. 39.4.6 satisfies detailed balance with respect to π :

$$\pi(\mathbf{b}) q(\mathbf{b}' | \mathbf{b}) \alpha(\mathbf{b}' | \mathbf{b}) = \pi(\mathbf{b}') q(\mathbf{b} | \mathbf{b}') \alpha(\mathbf{b} | \mathbf{b}') \quad \text{for all } \mathbf{b} \neq \mathbf{b}',$$

and consequently π is a stationary distribution of the chain.

Proof. Fix $\mathbf{b} \neq \mathbf{b}'$ and write $u = \pi(\mathbf{b})q(\mathbf{b}' | \mathbf{b})$, $v = \pi(\mathbf{b}')q(\mathbf{b} | \mathbf{b}')$. By Eq. 39.4.6, $\alpha(\mathbf{b}' | \mathbf{b}) = \min(1, v/u)$ and $\alpha(\mathbf{b} | \mathbf{b}') = \min(1, u/v)$, so both sides of the identity equal $\min(u, v)$. For stationarity let $P(\mathbf{b}, \cdot)$ be the kernel; for any measurable A ,

$$\int P(\mathbf{b}, A) \pi(\mathbf{b}) d\mathbf{b} = \int_A \int \pi(\mathbf{b}) q(\mathbf{b}' | \mathbf{b}) \alpha(\mathbf{b}' | \mathbf{b}) d\mathbf{b} d\mathbf{b}' + \int_A \pi(\mathbf{b}') \varrho(\mathbf{b}') d\mathbf{b}',$$

where $\varrho(\mathbf{b}') = 1 - \int q(\mathbf{b}'' | \mathbf{b}') \alpha(\mathbf{b}'' | \mathbf{b}') d\mathbf{b}''$ is the probability of staying put. By detailed balance the inner integral of the first term is $\pi(\mathbf{b}') \int q(\mathbf{b} | \mathbf{b}') \alpha(\mathbf{b} | \mathbf{b}') d\mathbf{b} = \pi(\mathbf{b}') \{1 - \varrho(\mathbf{b}')\}$, so the two terms add to $\int_A \pi(\mathbf{b}') d\mathbf{b}'$. ■

Detailed balance is all that is checked here; convergence to π from an arbitrary start needs irreducibility and aperiodicity, and a central limit theorem for the ergodic averages more still (Tierney, 1994). The one design decision is the proposal. A covariance $\varsigma^2 \mathbf{\Sigma}_{\text{prop}}$ mixes well only when $\mathbf{\Sigma}_{\text{prop}}$ resembles the posterior covariance, and the Laplace matrix $\mathbf{H}_n^{-1}$ of Theorem 39.4.2 is the obvious candidate, at the cost of one Newton solve. Roberts, Gelman and Gilks (1997) showed that in a high-dimensional limit the optimal scale is $\varsigma = 2.38/\sqrt{p}$, with acceptance rate near 0.234 — derived for a product target, used everywhere as a rule of thumb.

39.4.4 Data augmentation for the probit model

A Gibbs sampler needs full conditionals that can be drawn from, and Proposition 39.3.1 says the conditional of $\boldsymbol{\beta}$ is not normal. Albert and Chib (1993) observed that enlarging the parameter space restores normality, through the latent variable representation of the probit model (Definition 35.2.1).

Proposition 39.4.5 — The Albert–Chib sampler

Consider the ungrouped probit model $\Pr(Y_i = 1) = \Phi(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ with prior $\boldsymbol{\beta} \sim N_p(\mathbf{m}, \mathbf{\Sigma})$. Introduce latent variables $Z_i | \boldsymbol{\beta} \sim N(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}, 1)$, independent, and set $Y_i = \mathbf{1}\{Z_i > 0\}$. Then:

- (a) the marginal distribution of $\mathbf{Y}$ given $\boldsymbol{\beta}$ is the probit model, so the posterior of $\boldsymbol{\beta}$

is unchanged;

- (b) given $\mathbf{z}$ and $\mathbf{y}$, $\boldsymbol{\beta} \sim N_p(\mathbf{V}(\mathbf{X}^\top \mathbf{z} + \boldsymbol{\Sigma}^{-1} \mathbf{m}), \mathbf{V})$ with $\mathbf{V} = (\mathbf{X}^\top \mathbf{X} + \boldsymbol{\Sigma}^{-1})^{-1}$;
- (c) given $\boldsymbol{\beta}$ and $\mathbf{y}$, the Z_i are independent, Z_i being $N(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}, 1)$ truncated to $(0, \infty)$ if $y_i = 1$ and to $(-\infty, 0)$ if $y_i = 0$.

Proof.

- (a) $\Pr(Y_i = 1 \mid \boldsymbol{\beta}) = \Pr(Z_i > 0 \mid \boldsymbol{\beta}) = \Phi(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$, and the Z_i are independent given $\boldsymbol{\beta}$, hence so are the Y_i .
- (b) The joint density of $(\boldsymbol{\beta}, \mathbf{z}, \mathbf{y})$ is proportional to

$$\exp\left\{-\frac{1}{2}(\boldsymbol{\beta} - \mathbf{m})^\top \boldsymbol{\Sigma}^{-1}(\boldsymbol{\beta} - \mathbf{m}) - \frac{1}{2}\|\mathbf{z} - \mathbf{X}\boldsymbol{\beta}\|^2\right\} \prod_i \mathbf{1}\{\text{sign}(z_i) \text{ matches } y_i\}.$$

With $\mathbf{z}$ fixed the indicator is constant in $\boldsymbol{\beta}$, and the exponent is that of the conjugate normal update of [Exercise \(A2\)](#) with $\sigma^2 = 1$, response $\mathbf{z}$ and prior precision $\boldsymbol{\Sigma}^{-1}$; completing the square as in the proof of [Theorem 7.6.2](#) gives the stated normal law.

- (c) With $\boldsymbol{\beta}$ fixed, the joint density factors over i into $\phi(z_i - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ times the indicator, which is the stated truncated normal density up to its normalizing constant.

■

The price is n extra draws per sweep; the gain is that every step is accepted and nothing needs tuning. The same device works for the logit link by a different route — the logistic distribution is a scale mixture of normals (Holmes and Held, 2006), the binomial likelihood a mixture over Pólya–gamma variables (Polson, Scott and Windle, 2013) — and, more intricately, for multinomial and ordinal models.

Example. (The 1996 survey, sampled)

Return to the logistic regression of [Example \(Voting intention in the 1996 American election\)](#): the intended vote of 944 respondents on party identification, age in decades, education and income. Put an independent $N(0, 10^2)$ prior on each of the 5 coefficients — nearly flat on this scale — and run four random-walk Metropolis chains of 8000 draws from starts 8 posterior standard deviations away in every coordinate, with the Laplace covariance as the proposal shape and scale $2.38/\sqrt{5}$. The acceptance rate is 0.298, and discarding the first half of each chain leaves 16000 draws.

Panel (a) of [Figure 39.4.2](#) shows the four chains for the party coefficient: two of them climb far above the mode before turning back, and all four are indistinguishable once the first few hundred iterations are past. Panel (b) applies the whole recipe — discard the first half, then split what is left — at each run length, and plots $\hat{R} - 1$ on a log scale. It starts at 5.63 with 200 draws per chain, is below 1.05 by 1000 and below 1.02 by 1400, and its own Monte Carlo variability keeps it brushing the 1.01 line until about 6000; at the full eight thousand the largest value over the five coefficients is 1.0066. Effective sample size is the binding constraint: 1079, or 0.067 effective draws per iteration.

The posterior mean of that coefficient is 1.2300 with posterior standard deviation 0.0705, against the maximum likelihood 1.2188 and standard error 0.0709: with $n = 944$ and a prior this weak the two analyses agree to the second decimal, as [Theorem 39.4.2](#) and the

Figure 39.4.2: Diagnostics for the samplers of [Example \(The 1996 survey, sampled\)](#). (a) The first 1200 draws of four Metropolis chains for the party-identification coefficient, from starts eight posterior standard deviations away in every coordinate. (b) $\hat{R} - 1$, on a log scale, against draws generated per chain, recomputed from scratch at each length after discarding the first half; the reference line is $\hat{R} = 1.01$. (c) Autocorrelation functions of the Metropolis and Albert–Chib chains.

Bernstein–von Mises theorem say they must. What the simulation buys is the ability to ask for any posterior summary at all.

The probit version, sampled by [Proposition 39.4.5](#) with 4000 draws per chain, gives posterior mean 0.6780 against the maximum likelihood 0.6733; the ratio of the logistic coefficient to it is 1.814, against the $\pi/\sqrt{3} = 1.8138$ of [Proposition 35.2.2](#). Its effective sample size per iteration is 0.092, half again as good and with no tuning, though each iteration costs n truncated normal draws. Panel (c) compares the two autocorrelation functions.

39.4.5 Checking the fit from the posterior

Definition 39.4.3 — Posterior predictive distribution and check

The **posterior predictive** distribution of a replicate data set $\mathbf{Y}^{\text{rep}}$ is

$$p(\mathbf{y}^{\text{rep}} | \mathbf{y}) = \int f(\mathbf{y}^{\text{rep}} | \boldsymbol{\beta}) \pi(\boldsymbol{\beta} | \mathbf{y}) d\boldsymbol{\beta}, \quad (39.4.8)$$

which is sampled by drawing $\boldsymbol{\beta}$ from the posterior and then $\mathbf{y}^{\text{rep}}$ from the model. For a statistic T the **posterior predictive p -value** is $\Pr\{T(\mathbf{Y}^{\text{rep}}) \geq T(\mathbf{y}) | \mathbf{y}\}$, or the lower-tail version $\Pr\{T(\mathbf{Y}^{\text{rep}}) \leq T(\mathbf{y}) | \mathbf{y}\}$ when small values of T are the departure of interest, estimated by the proportion of replicates on the relevant side of the observed value.

The check is only as good as the statistic. One the model was fitted to match — the total number of successes in a model with an intercept — has a p -value near 1/2 by construction; a useful statistic is one the model does *not* control, such as a subgroup total, a count of zeros or a maximum.

Warning. The data are used twice: once to form the posterior and again to compute $T(\mathbf{y})$. The resulting p -value is conservative — its distribution under the model is concentrated towards 1/2 rather than uniform — so a middling value is weak evidence of nothing while an extreme one is strong. Bayarri and Berger (2000) quantify the conservatism; Meng (1994) and Gelman, Meng and Stern (1996) give the general framework, including discrepancies $T(\mathbf{y}, \boldsymbol{\beta})$ that depend on the parameter too.

Example. (Where the survey model fails)

The model of [Example \(The 1996 survey, sampled\)](#) treats party identification as a single linear term. Take T to be the number of Dole votes among the 108 respondents who called themselves independent Democrats — a subgroup the model has no parameter for. Observed: 7; across four thousand posterior predictive replicates the mean is 14.4, and only 0.034 of them are as low as seven ([Figure 39.4.3](#), panel (a)). Given the conservatism just described, that is a real signal.

It is not one a quadratic term would catch: adding PID^2 drops the deviance by 0.019, while treating party identification as a seven-level factor drops it by 12.68 on five degrees of freedom, $p = 0.027$ — the same finding from the likelihood side. Panel (b) shows why: at average covariates the fitted curve passes well above the observed proportion at

Figure 39.4.3: (a) Posterior predictive distribution of the number of Dole votes among the 108 independent Democrats, with the observed value marked. (b) Fitted probability of a Dole vote against party identification at the average of the other covariates, with a 95 per cent pointwise credible band and the raw category proportions (unadjusted).

party identification two and below it at four. The monotone logistic curve is not flexible enough near the middle of this scale.

```
group = anes["PID"].to_numpy() == 2                                # the independent
    Democrats
observed = y[group].sum()
short4 = np.array([metropolis(2000, 3980 + c, mle.params)[0] for c in range(4)][:,
    1000:, :])

    }")
```

39.4.6 Exercises

39.4.6.1 A. Check your understanding

Exercise A1.

Show that for a symmetric proposal the acceptance probability [Eq. 39.4.6](#) reduces to $\min\{1, \exp(q_n(\boldsymbol{\beta}^*) - q_n(\boldsymbol{\beta}^{(t)}))\}$, and that an uphill move is always accepted.

Solution. Symmetry gives $q(\boldsymbol{\beta}^{(t)} \mid \boldsymbol{\beta}^*) = q(\boldsymbol{\beta}^* \mid \boldsymbol{\beta}^{(t)})$, so those factors cancel and $\alpha = \min\{1, \pi(\boldsymbol{\beta}^* \mid \mathbf{y})/\pi(\boldsymbol{\beta}^{(t)} \mid \mathbf{y})\}$. The normalizing constant cancels too, leaving the

ratio of the unnormalized densities, which is $\exp\{q_n(\boldsymbol{\beta}^*) - q_n(\boldsymbol{\beta}^{(t)})\}$. If $q_n(\boldsymbol{\beta}^*) \geq q_n(\boldsymbol{\beta}^{(t)})$ the ratio is at least one and $\alpha = 1$.

Exercise A2.

A chain is run once, from a start far from the posterior mode, and $\hat{R}$ computed from its two halves is 1.00. Is that evidence of convergence? What does the definition in Eq. 39.4.7 require?

Solution. No. $\hat{R}$ near one says only that the pieces compared agree; a single chain stuck in one region has two halves that agree perfectly. The definition compares $2c$ sequences, and the value of the diagnostic comes from starting the c chains *over-dispersed relative to the posterior*, so that disagreement is detectable. A single chain also cannot reveal a second mode it never visited.

39.4.6.2 B. Practice

Exercise B1.

Take $q_n(\beta) = n g(\beta)$ for a fixed smooth g with a unique interior maximum at β^* and $g''(\beta^*) < 0$, and suppose g is bounded away from its maximum outside any neighbourhood of β^* . Verify (L1)–(L3) of Theorem 39.4.2 and write out the approximation explicitly.

Exercise B2.

Corollary 39.4.3 says the prior enters only the $O(1)$ remainder. Show that if the prior is itself allowed to depend on n — say $\boldsymbol{\beta} \sim N_p(\mathbf{0}, n\boldsymbol{\Sigma}_0)$ with $\boldsymbol{\Sigma}_0$ fixed, so that the prior is made vaguer as data accumulate — then the remainder grows like $p \log n$, and say what that does to the BIC.

Solution. With π the $N_p(\mathbf{0}, n\boldsymbol{\Sigma}_0)$ density, $-2 \log \pi(\hat{\boldsymbol{\beta}}_n) = p \log(2\pi) + p \log n + \log \det \boldsymbol{\Sigma}_0 + \hat{\boldsymbol{\beta}}_n^\top \boldsymbol{\Sigma}_0^{-1} \hat{\boldsymbol{\beta}}_n / n$, so the term $-2 \log \pi(\hat{\boldsymbol{\beta}}_n)$ in the remainder grows like $p \log n$ instead of staying bounded. The expansion then reads $-2 \log m(\mathbf{y}) = -2\ell(\hat{\boldsymbol{\beta}}) + 2p \log n + O(1)$: a prior whose spread grows with n doubles the dimension penalty. This is Lindley's paradox in miniature — a prior that is made vaguer as data accumulate penalizes extra parameters more and more heavily — and it is why the BIC's derivation assumes a fixed prior.

Exercise B3.

A chain of 16 000 draws has effective sample size 1000. A colleague thins it by keeping every sixteenth draw, obtaining 1000 nearly independent draws, and says nothing has been lost. Is that right? What is thinning good for?

39.4.6.3 C. Going deeper

Exercise C1.

Show that the Gibbs update of a block $\boldsymbol{\psi}_k$ is a Metropolis–Hastings step with proposal $q(\boldsymbol{\psi}^* \mid \boldsymbol{\psi}) = \pi(\boldsymbol{\psi}_k^* \mid \boldsymbol{\psi}_{-k}, \mathbf{y})$ and that its acceptance probability is one. Deduce that [Proposition 39.4.4](#) covers the Gibbs sampler, and explain why a Gibbs sampler can nevertheless fail to be irreducible.

39.5 Priors as regularizers

[Proposition 30.1.4](#) already said that every penalty is a prior and every prior a penalty: the maximizer of a penalized log-likelihood is the mode of a posterior whose log prior is minus the penalty. This section takes that identity in the other direction and asks what a prior *does* in a generalized linear model. The answer is more than shrinkage: a prior carrying almost no information can still be the difference between an estimate and no estimate at all.

39.5.1 Two correspondences and a warning about scale

Proposition 39.5.1 — What a prior does

Let ℓ be the log-likelihood of a generalized linear model with $\text{rank}(\mathbf{X}) = p$ and a concave log-likelihood ([Theorem 34.3.3](#)), and write $\boldsymbol{\beta} = (\beta_0, \boldsymbol{\gamma}^\top)^\top$ with β_0 an intercept.

- (a) (*Normal prior, ridge penalty.*) Under $\gamma_j \sim N(0, \tau^2)$ independently and a flat prior on β_0 , the posterior mode maximizes $\ell(\boldsymbol{\beta}) - \frac{1}{2}\lambda\|\boldsymbol{\gamma}\|^2$ with $\lambda = 1/\tau^2$. If ℓ is bounded above, as it is for the binomial and the Poisson, and the response is not constant — for the binomial, both outcomes occur — the mode exists and is unique whether or not the data are separated. The hypothesis on the response cannot be dropped: with a flat prior on β_0 the objective is not coercive in β_0 when every y_i is 1. Penalizing the intercept as well makes existence unconditional.
- (b) (*Laplace prior, lasso penalty.*) Under γ_j independent with density $(2b)^{-1}e^{-|\gamma_j|/b}$ and a flat prior on β_0 , the posterior mode maximizes $\ell(\boldsymbol{\beta}) - \lambda \sum_j |\gamma_j|$ with $\lambda = 1/b$, and is therefore the lasso-penalized estimate of [Definition 27.4.1](#), with exact zeros. The *posterior*, by contrast, is never sparse: whenever it is proper, $\Pr(\gamma_j = 0 \mid \mathbf{y}) = 0$ for every j .
- (c) (*What a normal prior says about a probability.*) In a binary model with logit link, suppose the linear predictor at some covariate value has the prior $\eta \sim N(0, \sigma^2)$. The induced prior density of $\pi = e^\eta/(1 + e^\eta)$ on $(0, 1)$ is unimodal with mode $1/2$ if $\sigma^2 \leq 2$, and has exactly two modes, symmetric about $1/2$, with a local minimum at $1/2$, if $\sigma^2 > 2$.
- (d) (*Existence.*) Under the prior of (a), or under independent Cauchy priors on the γ_j with a flat prior on β_0 , the logistic posterior mode exists for every data set in which both outcomes occur, separated or not; under (a) it is also unique. Under any proper prior the posterior itself is proper ([Proposition 39.4.1\(a\)](#)), so posterior means and credible intervals exist whether or not the maximum likelihood estimate

does.

Proof.

- (a) The log posterior is $\ell(\boldsymbol{\beta}) - \|\boldsymbol{\gamma}\|^2/(2\tau^2)$ up to a constant, which is the stated penalized log-likelihood with $\lambda = 1/\tau^2$; this is [Proposition 30.1.4](#) for the normal prior. Existence and uniqueness for the logistic model with the intercept left out of the penalty are [Exercise \(B1\)](#), under exactly the stated hypothesis; the same argument — a concave ℓ bounded above, coercive in β_0 at fixed $\boldsymbol{\gamma}$, plus a strictly concave coercive quadratic — applies to any family whose log-likelihood is concave and bounded above. When $\boldsymbol{\gamma}$ is penalized and β_0 is not, and every y_i equals 1, the supremum 0 is approached only along $\boldsymbol{\gamma} = \mathbf{0}$, $\beta_0 \rightarrow +\infty$ and is not attained.
- (b) The log prior is $-\sum_j |\gamma_j|/b$ up to a constant, giving the penalty with $\lambda = 1/b$; this is [Proposition 30.1.4](#) for the Laplace prior. For the second claim, the unnormalized posterior density is positive and continuous on $\mathbb{R}^p$, so when it integrates the marginal posterior of each γ_j is absolutely continuous and $\Pr(\gamma_j = 0 \mid \mathbf{y}) = 0$. The sparsity of the lasso is a property of the *mode* of a density with a kink, not of the distribution; [Example \(Posterior mode and posterior mean under a Laplace prior\)](#) makes the same point in the orthonormal linear model. Note what is *not* claimed: the posterior mean can be exactly zero, as it is whenever the posterior happens to be symmetric in γ_j about the origin.
- (c) Write $t = \log\{\pi/(1-\pi)\}$, so $dt/d\pi = 1/\{\pi(1-\pi)\} > 0$. The induced density satisfies

$$f(\pi) \propto \exp\left(-\frac{t^2}{2\sigma^2}\right) \frac{1}{\pi(1-\pi)},$$

with a constant of proportionality free of π . Since $t \mapsto \pi$ is strictly increasing, the stationary points of f in π are the stationary points of $\psi(t) = \log f(\pi(t))$ in t . Using $\pi(1-\pi) = e^t/(1+e^t)^2$,

$$\begin{aligned}\psi(t) &= -\frac{t^2}{2\sigma^2} + 2\log(1+e^t) - t + \text{const}, \\ \psi'(t) &= -\frac{t}{\sigma^2} + \frac{2e^t}{1+e^t} - 1 = \tanh(t/2) - \frac{t}{\sigma^2}.\end{aligned}$$

Call the last expression $G(t)$; it is odd and $G(0) = 0$. Now $G'(t) = \frac{1}{2} \text{sech}^2(t/2) - 1/\sigma^2$, which is even, strictly decreasing in $|t|$, and has maximum $\frac{1}{2} - 1/\sigma^2$ at $t = 0$. If $\sigma^2 \leq 2$ then $G' \leq 0$ everywhere, with equality only at $t = 0$ in the boundary case, so G is strictly decreasing and $t = 0$ is its only root: f has one stationary point. It is a maximum because $f(\pi) \rightarrow 0$ as $\pi \rightarrow 0$ or $\pi \rightarrow 1$, which follows from $\exp\{-t^2/(2\sigma^2) + |t|\} \rightarrow 0$.

If $\sigma^2 > 2$ then $G'(0) > 0$ and G' has exactly two zeros, so G has at most three roots; it has at least three, because $G(0) = 0$, $G > 0$ just to the right of zero while $G(t) \rightarrow -\infty$ as $t \rightarrow \infty$, and by oddness on the left. So there are roots $t_- < 0 = t_0 < t_+$ with $t_- = -t_+$. Since $f \rightarrow 0$ at both ends and f is continuous and positive, the outer two are maxima and the middle one, at $\pi = 1/2$, is a minimum.

- (d) With the normal prior the objective is coercive and strictly concave, as in (a). With independent Cauchy priors of scales s_j , the log posterior is $\ell(\boldsymbol{\beta}) - \sum_j \log\{1 + (\gamma_j/s_j)^2\}$ up to a constant. For the logistic model $\ell \leq 0$, and the penalty tends to $-\infty$ as $\|\boldsymbol{\gamma}\| \rightarrow \infty$; if $\boldsymbol{\gamma}$ stays bounded while $|\beta_0| \rightarrow \infty$ then $\ell \rightarrow -\infty$, provided both outcomes occur, by the argument of [Exercise \(B1\)](#). So the objective is

coercive and continuous and attains its maximum on a compact sublevel set. It need not be unique: the Cauchy log density is not concave. The last sentence is [Proposition 39.4.1\(a\)](#).

■

Part (c) is the warning. A prior that is “noninformative” about a coefficient is a strong statement about a probability: a $N(0, 10^2)$ prior on the linear predictor puts half of its mass on probabilities below 0.0012 or above $1 - 0.0012$, saying before any data that the event is nearly certain or nearly impossible and that the analyst does not know which. Panel (a) of [Figure 39.5.1](#) shows the three shapes: a gentle hump at $\sigma = 1$, flat at the boundary $\sigma = \sqrt{2}$, a deep U at $\sigma = 4$.

This is why the default priors recommended for logistic regression are much tighter than “vague”. Gelman, Jakulin, Pittau and Su (2008) rescale every covariate to mean zero and standard deviation 1/2, then put an independent Cauchy prior of scale 2.5 on each coefficient and 10 on the intercept. On that scale a coefficient of 5 multiplies the odds by $e^{2.5} \approx 12$ for a one standard deviation change, beyond anything social or biomedical data produce; the Cauchy’s heavy tail nonetheless leaves a genuinely large coefficient nearly alone, which a normal prior of the same scale would not.

39.5.2 Priors as penalties, checked

Remark (Scaling is not optional). Both correspondences put the same λ on every coefficient, which is a statement about the units of the covariates: multiplying x_j by ten divides γ_j by ten and changes its penalty by a factor of a hundred. Every penalized or weakly-informative fit therefore standardizes first ([Proposition 27.2.1](#), [Proposition 30.2.3](#)). A prior of fixed scale is meaningful only once the covariates have one.

On the 944 respondents of [Example \(Voting intention in the 1996 American election\)](#), with the four covariates standardized, maximizing $\ell(\boldsymbol{\beta}) - \frac{1}{2}\lambda\|\boldsymbol{\gamma}\|^2$ by Newton’s method and maximizing $\ell(\boldsymbol{\beta}) - \lambda\sum_j |\gamma_j|$ by coordinate descent gives the two paths. At $\lambda = 64$, which is a normal prior with $\tau = 1/8$, the ridge estimates of the four slopes are 1.465, 0.105, 0.032 and 0.153; the lasso estimates are 1.773 and three exact zeros. Both have shrunk the party-identification coefficient from its unpenalized value of 2.769 on this standardized scale, the ridge further than the lasso, because the lasso has removed the competitors and the party term absorbs what they explained.

```

The Bayesian reading does not stop at the mode. Park and Casella (2008) noted that the Laplace prior is a scale mixture of normals — $\gamma_j \mid \tau_j^2 \sim N(0, \tau_j^2)$ with τ_j^2 exponential — which turns the lasso into a hierarchical model with normal full conditionals, and so into a Gibbs sampler whose output is the whole posterior rather than a sparse point. Priors designed to be *more* selective make the mixing distribution heavy-tailed at both ends: a spike-and-slab prior mixes a point mass at zero with a diffuse component, and the horseshoe of Carvalho, Polson and Scott (2010) takes τ_j half-Cauchy, so small coefficients are shrunk almost to zero and large ones almost not at all. The other penalties of [Chapter 30](#) carry over by the same substitution, penalized least squares becoming penalized log-likelihood: the elastic net of [Definition 30.2.1](#), the group lasso of [Definition 30.3.1](#) for a factor's dummy variables, and the componentwise boosting of [Definition 30.4.1](#) with the negative log-likelihood as loss and one Newton step per round.

39.5.3 A prior that rescues an estimate

Example. (The separated subgroup, three priors)

[Example \(A separated subgroup\)](#) fitted the intended vote on party identification among the 13 respondents whose schooling stopped at or before the eighth grade, and found

complete separation: no maximum likelihood estimate exists, and software reports whatever coefficient its iteration limit produced. With only two parameters the posterior can be computed by quadrature, under any prior at all — over the whole plane, by the substitution $\beta = s \tan u$, since under separation a Cauchy posterior has a polynomial tail and any fixed box would discard a large part of it.

Under the flat prior the posterior is not a distribution at all, and the arithmetic shows it: integrating the likelihood over a square box centred at the origin gives 8.7 for half-width ten and 778.6 for half-width eighty, each doubling multiplying the mass by at least 4.13. That is the area of the separating cone growing, as in the proof of [Proposition 39.4.1\(b\)](#), and no amount of sampling will reveal it — a chain started near the data's own scale looks well behaved while wandering up a ridge of infinite mass.

An independent $N(0, 2.5^2)$ prior on the slope and $N(0, 10^2)$ on the intercept gives a proper posterior with mean 3.077, median 2.931 and a central 95 per cent credible interval of (1.046, 5.922). Independent Cauchy priors of the same scales give mean 6.091, median 4.001 and interval (1.127, 22.995). Both exclude zero decisively. Both lower endpoints agree to within a tenth, and the upper endpoints differ by a factor of 3.9: the data bound the effect from below, and everything above that is prior. Panel (b) of [Figure 39.5.1](#) shows the two posteriors.

Set these beside the frequentist answers of [Section 35.3](#). The ordinary likelihood ratio gives the one-sided interval $(0.902, \infty)$: the most honest statement available without a prior, and the least useful. Firth's penalty, the mode under the Jeffreys prior ([Proposition 35.3.2](#)), gives 1.362 with the penalized likelihood ratio interval (0.364, 4.045) — smaller than either posterior median, and a mode rather than a mean. The Jeffreys penalty falls off exponentially along the separating ray ([Proposition 35.3.2](#)) while a Cauchy of scale 2.5 falls off only polynomially, so it bites hardest on exactly the direction the data do not constrain. There is no way to choose among these numbers from the data. Thirteen observations that separate perfectly contain a bound and nothing more, and every method reports that bound plus whatever it assumed. The discipline is to say which assumption produced which number, and to notice that the flat prior is not the assumption-free option but the one whose assumption is inconsistent.

Idea. A penalty is a prior and a prior a penalty, but the two readings answer different questions. The penalty reading asks what estimate to report and tunes λ by cross-validation; the prior reading asks what is believed before the data, and its scale must be defensible on the scale of the parameter — for a binary response, as a statement about probabilities.

39.5.4 Exercises

39.5.4.1 A. Check your understanding

Exercise A1.

A colleague reports a ridge-penalized logistic fit with $\lambda = 100$ on standardized covariates. What normal prior does that correspond to, and what odds ratio for a one standard deviation change does the prior regard as, say, two standard deviations from zero?

Solution. $\lambda = 1/\tau^2$ gives $\tau = 0.1$. Two prior standard deviations is $\gamma_j = 0.2$, an odds ratio of $e^{0.2} = 1.22$. The prior therefore says that a one standard deviation change in any covariate almost certainly multiplies the odds by less than about 1.22: a strong belief, not a weak one, which may be appropriate in a high-dimensional screening problem and absurd in a four-covariate model.

Exercise A2.

Explain in words why the induced prior of [Proposition 39.5.1\(c\)](#) becomes U-shaped for large σ , without using the calculus of the proof.

39.5.4.2 B. Practice

Exercise B1.

Show that a Cauchy prior with scale s is a scale mixture of normals: $\gamma \mid \lambda \sim N(0, \lambda)$ with λ having an inverse gamma distribution with shape $1/2$ and rate $s^2/2$. Explain how this turns a Cauchy prior into a Gibbs sampler with normal full conditionals in the probit model.

Solution. If $\lambda \sim \text{IG}(1/2, s^2/2)$ then the marginal density of γ is

$$\begin{aligned} & \int_0^\infty \frac{1}{\sqrt{2\pi\lambda}} e^{-\gamma^2/(2\lambda)} \frac{(s^2/2)^{1/2}}{\Gamma(1/2)} \lambda^{-3/2} e^{-s^2/(2\lambda)} d\lambda \\ & \propto \int_0^\infty \lambda^{-2} e^{-(\gamma^2+s^2)/(2\lambda)} d\lambda \propto \frac{1}{\gamma^2 + s^2}, \end{aligned}$$

the Cauchy density of scale s , the last step by the substitution $v = 1/\lambda$. In the Albert–Chib scheme of [Proposition 39.4.5](#), conditioning on the λ_j as well as on $\mathbf{z}$ makes the prior on $\boldsymbol{\gamma}$ normal with covariance $\text{diag}(\lambda_j)$, so the full conditional of $\boldsymbol{\beta}$ is normal, and that of each λ_j is inverse gamma with shape 1 and rate $(\gamma_j^2 + s^2)/2$: every step is a standard draw.

Exercise B2.

For $\sigma = 10$, compute the prior probability that $\pi = e^\eta/(1+e^\eta) < 0.01$ when $\eta \sim N(0, \sigma^2)$, and compare with $\sigma = 1$. Relate the answers to [Proposition 39.5.1\(c\)](#).

Exercise B3.

Proposition 35.3.2 adds $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{W} \mathbf{X})$ to the log-likelihood. Show that this is the log of the Jeffreys prior density for the logistic model, so Firth's estimate is a posterior mode. Why does that mode exist even under separation, when the maximum likelihood estimate does not?

Solution. The Jeffreys prior is $\propto \det\{\mathcal{I}(\boldsymbol{\beta})\}^{1/2}$ for the expected information $\mathcal{I}$, which for the logistic model is $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ with $\mathbf{W} = \text{diag}\{\pi_i(1 - \pi_i)\}$ at $\boldsymbol{\beta}$ (**Proposition 35.1.3**); its logarithm is $\frac{1}{2} \log \det(\mathbf{X}^\top \mathbf{W} \mathbf{X})$ up to a constant, so adding it to ℓ gives Firth's penalized log-likelihood and its maximizer is the posterior mode under that prior. It exists under separation for the reason **Proposition 35.3.2** proves: along a separating ray $t\mathbf{b}$ the weights decay like $e^{-t\delta}$, so the log prior falls linearly in t while the log-likelihood, already at most zero, has nothing left to gain. The likelihood alone is flat along that ray; the prior supplies the curvature.

39.5.4.3 C. Going deeper**Exercise C1.**

Redo **Proposition 39.5.1(c)** for the probit link: with $\eta \sim N(0, \sigma^2)$ and $\pi = \Phi(\eta)$, show that the induced density of π is unimodal when $\sigma^2 \leq 1$ and bimodal when $\sigma^2 > 1$, and say why the threshold differs from the logit's.

39.6 Summary and Notes

39.6.1 Summary

Idea.

1. A response family is chosen from the support and from the mean–variance relationship; with replicates, the variance-function power is estimated by regressing log group variance on log group mean (**Proposition 39.1.1(a)**).
2. Additivity belongs to the link, not to the data: a mean additive on one link scale is additive on another only when the two differ by an affine map (**Proposition 39.1.1(b)**).
3. Likelihood criteria compare models for the same random variable. A model fitted to $t(\mathbf{y})$ needs the correction $-2 \sum_i \log t'(y_i)$, itself of order n , before its AIC can stand beside one for $\mathbf{y}$ (**Proposition 39.1.1(c)**, **Example (How long does a strike last)**).
4. Diagnostics should be aimed. Pearson residuals have approximate variance $1 - h_{ii}$; a simulated envelope has pointwise level $2/(B + 1)$; the link is tested by adding $\hat{\eta}^2$; a covariate's scale by partial-residual and added-variable plots; the variance function by the height and trend of $|r^P|$ (**Proposition 39.2.1**). In **Example (Days of television news)** only the last is wrong.
5. The log-likelihood is quadratic in $\boldsymbol{\beta}$ for every design exactly when the family is

normal ([Proposition 39.3.1](#)): in the Bayesian thread every definition survives, every closed form does not.

6. The Bayesian generalized linear model is [Definition 39.4.1](#). A proper prior with a bounded likelihood gives a proper posterior; a flat prior on a logistic model gives one exactly when the data are in overlap, that is exactly when the maximum likelihood estimate exists ([Proposition 39.4.1](#)).
7. Under local smoothness, a growing Hessian and a concentration condition, the Laplace approximation to the marginal likelihood has relative error $O(n^{-1})$ ([Theorem 39.4.2](#)); its logarithm is the BIC with an $O(1)$ remainder carrying the whole influence of the prior ([Corollary 39.4.3](#)).
8. Metropolis–Hastings and Gibbs leave the posterior invariant by detailed balance ([Proposition 39.4.4](#), [Definition 39.4.2](#)); Albert–Chib augmentation makes every probit full conditional normal or truncated normal ([Proposition 39.4.5](#)). Convergence is judged by $\hat{R}$, mixing by effective sample size ([Example \(The 1996 survey, sampled\)](#)).
9. Posterior predictive checks compare the data with replicates from [Eq. 39.4.8](#); using the data twice makes them conservative, so an extreme p -value is evidence and a middling one is not ([Definition 39.4.3](#), [Example \(Where the survey model fails\)](#)).
10. A normal prior is ridge, a Laplace prior the lasso at its mode, and a normal prior on a logit is bimodal on the probability scale exactly when $\sigma^2 > 2$ ([Proposition 39.5.1](#)). A proper prior makes the mode exist under separation, where maximum likelihood has none ([Example \(The separated subgroup, three priors\)](#)).

39.6.2 Notes and sources

Model building. The three-part structure — random component, systematic component, link — is Nelder and Wedderburn’s (1972); McCullagh and Nelder (1989) remains the standard account of how the pieces are chosen, their chapter 8 for the log link being preferred to the canonical reciprocal in gamma models and their chapter 11 for mean–variance diagnostics. Fahrmeir, Kneib, Lang and Marx (2021, §5.3) develop the log-normal and gamma alternatives for nonnegative responses. The Jacobian correction of [Proposition 39.1.1\(c\)](#) is elementary, widely known, and as widely omitted from software output.

Diagnostics. Pregibon (1981) transferred the linear-model diagnostics of [Chapter 20](#) to generalized linear models by the substitution $\mathbf{X} \mapsto \hat{\mathbf{W}}^{1/2}\mathbf{X}$, and Pregibon (1980) introduced the goodness-of-link test of [Proposition 39.2.1\(d\)](#). The half-normal plot with a simulated envelope is Atkinson’s (1981, 1985), and the exchangeability argument behind [Eq. 39.2.1](#) is the one that justifies Monte Carlo tests generally. Cook and Weisberg (1983) read a trend in absolute residuals as evidence about the variance function.

The Bayesian thread. Lindley and Smith (1972) is the origin of the hierarchical linear model. Diaconis and Ylvisaker (1979) characterized the conjugate priors of an exponential family; the generalized linear form [Eq. 39.3.2](#), with a pseudo-response and per-observation weights, is Bedrick, Christensen and Johnson (1996) and Chen and Ibrahim (2003). Rencher and Schaalje (2008, chapter 11) and Agresti (2015, chapter 10) are the source treatments closest to this chapter, and Gelman, Carlin, Stern, Dunson, Vehtari and Rubin (2013) the standard modern reference for its last two sections.

Laplace and the BIC. Laplace’s method is two centuries old; its use for posterior moments

and marginal likelihoods is Tierney and Kadane's (1986). Schwarz (1978) derived the BIC, and Kass and Raftery (1995) made the link between Bayes factors, the Laplace approximation and the BIC standard; their section 4 discusses the regularity conditions that [Theorem 39.4.2](#) assumes, and the set used here — a shrinking ball, bounded scaled derivatives, a concentration bound — is convenient rather than weakest. The deviance information criterion is Spiegelhalter, Best, Carlin and van der Linde (2002); the Bernstein–von Mises theorem in the form quoted is van der Vaart (1998, chapter 10).

MCMC. The algorithm of [Eq. 39.4.6](#) is Metropolis, Rosenbluth, Rosenbluth, Teller and Teller (1953) as generalized by Hastings (1970); Tierney (1994) gave the rigorous account for continuous state spaces and Robert and Casella (2004) the textbook treatment. The Gibbs sampler is Geman and Geman (1984), brought into mainstream statistics by Gelfand and Smith (1990). Optimal scaling is Roberts, Gelman and Gilks (1997), and the iteratively reweighted proposal follows Gamerman (1997). Data augmentation for the probit model is Albert and Chib (1993); for the logit, Holmes and Held (2006) use a scale mixture and Polson, Scott and Windle (2013) the Pólya–gamma identity now in general use. [Eq. 39.4.7](#) is Gelman and Rubin (1992) and the truncation rule for the effective sample size is Geyer's (1992). Posterior predictive checking is Rubin (1984), Meng (1994) and Gelman, Meng and Stern (1996), its p -values analysed by Bayarri and Berger (2000). Hamiltonian Monte Carlo, which is what modern software actually runs, is omitted because its justification needs machinery this book does not develop.

Priors as penalties. The ridge–normal correspondence is as old as ridge regression ([Theorem 27.2.2](#)); the lasso–Laplace one was noted by Tibshirani (1996) and turned into a sampler by Park and Casella (2008). Gelman, Jakulin, Pittau and Su (2008) proposed the Cauchy default prior for logistic regression with the rescaling to standard deviation 1/2, and gave the separation argument that [Proposition 39.5.1\(d\)](#) formalizes. That Firth's (1993) penalty is the Jeffreys (1946) prior was observed by Firth himself; Heinze and Schemper (2002) made it the standard remedy. The horseshoe is Carvalho, Polson and Scott (2010). The propriety argument of [Proposition 39.4.1\(b\)](#) is the Bayesian face of [Theorem 35.3.1](#).

Chapter 40

GLMMs and Generalized Estimating Equations

Part VII replaced independent errors by a covariance matrix with structure; Part VIII has so far replaced the normal response by an exponential dispersion family. This chapter does both at once, and the combination is not the sum of its parts. In a linear model the mean is unaffected by what happens to the covariance, so a random effect changes the standard errors and leaves the coefficients alone. Once the link is nonlinear that is false: averaging a curve over a random intercept does not give the same curve back, so the model has *two* sets of coefficients — one for a single cluster, one for the population — and they are not equal.

Two families of methods follow from that fork. If the interest is in what happens within a cluster, and a full probability model is acceptable, the answer is the generalized linear mixed model: random effects inside the linear predictor and a likelihood obtained by integrating them out, numerically, with different approximations giving visibly different answers. If the interest is in the population average, and no model for the dependence is wanted, the answer is generalized estimating equations: solve a quasi-score built from a *working* correlation that is allowed to be wrong, and price the estimate with a sandwich. The second route buys robustness by giving up the likelihood, and with it the deviance, the random-effect predictions, and any tolerance for data that go missing for the wrong reasons.

What you need. Chapter 34 throughout (the generalized linear model [Definition 34.2.1](#) and [Definition 34.2.2](#), the likelihood equations [Theorem 34.3.1](#), iteratively reweighted least squares [Theorem 34.4.1](#), the asymptotics [Theorem 34.5.1](#)), Chapter 35 (the logistic model [Definition 35.1.1](#), non-collapsibility [Example \(The odds ratio does not collapse\)](#) and case-control sampling [Theorem 35.5.1](#)), Chapter 36 and Chapter 37 (Poisson regression [Definition 37.1.1](#) and the negative binomial [Definition 37.4.1](#)). From Part VII: the linear mixed model [Definition 32.2.1](#), best linear unbiased prediction [Theorem 32.3.1](#) and its shrinkage reading, REML [Definition 32.4.1](#), the boundary problem [Theorem 32.5.2](#), the covariance models [Definition 33.4.1](#) and the working-covariance result [Proposition 33.4.1](#). From Part V: the sandwich covariance [Theorem 21.4.2](#). Chapter 29 (AIC and BIC, [Definition 29.2.2](#)) and Chapter 25 (what a coefficient means) are used in places. Chapter 38 supplies the quasi-likelihood machinery this chapter generalizes, and Chapter 41 the missingness conditions that [Section 40.4](#) needs.

40.0.1 Roadmap

- [Summary and notes](#)

40.1 Marginal versus conditional models

A clinician asks what a treatment would do to *this* patient's odds of recovery; a health minister asks what it would do to the recovery rate of the *whole population*. In a linear model the two questions have the same answer, because averaging a straight line over patients returns the same straight line. As soon as the link is nonlinear they do not, and no amount of data removes the difference: it is a property of the model, not of the sample. This section sets up the two targets and proves that the population-averaged coefficient of a logistic model is strictly smaller in magnitude than the individual one.

40.1.1 Two coefficients, one model

Throughout this chapter the data are **clustered**: units $i = 1, \dots, m$ each carry n_i observations $Y_{i1}, \dots, Y_{in_i}$, with $n = \sum_i n_i$ — a patient observed repeatedly, a school with its pupils, a firm across years. The simplest model that makes observations within a cluster dependent gives each cluster its own level U_i , with the link g of [Chapter 34](#):

$$g\{E(Y_{ij} | U_i)\} = \alpha + \beta x_{ij} + U_i, \quad U_i \sim N(0, \tau^2), \quad (40.1.1)$$

with $Y_{i1}, \dots, Y_{in_i}$ conditionally independent given U_i . Here β is a **conditional**, or *subject-specific*, coefficient: it compares two covariate values *within one cluster*, with that cluster's level held wherever it happens to be. Write it β^C when the distinction matters.

The other target concerns the response averaged over clusters. Write $h = g^{-1}$ and

$$m(x) = E\{h(\alpha + \beta x + U)\}, \quad U \sim N(0, \tau^2), \quad (40.1.2)$$

for the **marginal mean function**: the mean response at x in a cluster drawn at random. The **marginal**, or *population-averaged*, coefficients are the ones a model with the same link would report if fitted to the population: the solution (α^M, β^M) of

$$E \left[\begin{pmatrix} 1 \\ X \end{pmatrix} \{m(X) - h(\alpha^M + \beta^M X)\} \right] = \mathbf{0}, \quad (40.1.3)$$

the expectation being over the covariate distribution, and assumed to have a unique solution — which it does whenever $E\{(1, X)^\top(1, X)\}$ is nonsingular and the marginal mean function stays away from the ends of the range of h . This is the population version of the likelihood

equations [Eq. 34.3.1](#) with the dispersion and the prior weights dropped; for a canonical link the remaining factor $h'(\eta)/V(\mu)$ is identically one, so for the logit, log and identity links of this section (α^M, β^M) is exactly what an ordinary generalized linear model fitted to the clustered data estimates consistently — a point [Section 40.4](#) returns to. For a binary covariate [Eq. 40.1.3](#) is solved by matching the two means exactly, $h(\alpha^M) = m(0)$ and $h(\alpha^M + \beta^M) = m(1)$, so that β^M is the log odds ratio between the two marginal probabilities.

Warning. Neither coefficient is “the” right one and neither is an approximation to the other. They are answers to different questions, and a paper that reports one while discussing the other has made a substantive error, not a numerical one.

40.1.2 The attenuation inequality

Proposition 40.1.1 — Marginal and conditional coefficients

Let U have mean zero and let h be the inverse link of the model [Eq. 40.1.1](#).

- (a) **Identity link.** If $h(\eta) = \eta$ then $m(x) = \alpha + \beta x$, so $\alpha^M = \alpha$ and $\beta^M = \beta$ for every distribution of U with mean zero. The two targets coincide.
- (b) **Log link.** If $h(\eta) = e^\eta$ and $E e^U < \infty$, then $m(x) = E(e^U) e^{\alpha + \beta x}$, so $\beta^M = \beta$ and $\alpha^M = \alpha + \log E e^U$. For $U \sim N(0, \tau^2)$ the shift is $\tau^2/2$. Only the intercept moves.
- (c) **Probit link.** If $h = \Phi$ and $U \sim N(0, \tau^2)$ then

$$m(x) = \Phi\left(\frac{\alpha + \beta x}{\sqrt{1 + \tau^2}}\right), \quad (40.1.4)$$

so the marginal mean function is again a probit, with $\alpha^M = \alpha/\sqrt{1 + \tau^2}$ and $\beta^M = \beta/\sqrt{1 + \tau^2}$.

- (d) **Logit link.** Let $h(\eta) = e^\eta/(1 + e^\eta)$, let U be any random variable with $0 < \text{Var}\{h(\theta + U)\} < \infty$ for every θ , and put $P_\theta = h(\theta + U)$ and $F(\theta) = g\{E P_\theta\}$, the marginal linear predictor. Then

$$F'(\theta) = 1 - \frac{\text{Var}(P_\theta)}{E(P_\theta) E(1 - P_\theta)} \in (0, 1). \quad (40.1.5)$$

Consequently, if $\beta \neq 0$, then for any $x_1 < x_2$ the marginal log odds ratio is strictly attenuated:

$$0 < \text{sign}(\beta) \{g m(x_2) - g m(x_1)\} < |\beta| (x_2 - x_1).$$

In particular a binary covariate has $0 < |\beta^M| < |\beta^C|$.

Proof.

- (a) $E(\alpha + \beta x + U) = \alpha + \beta x$, and this is exactly [Eq. 40.1.3](#) with h the identity.
- (b) $E e^{\alpha + \beta x + U} = e^{\alpha + \beta x} E e^U$. For a normal U , [Theorem 3.2.1](#) gives $E e^U = e^{\tau^2/2}$. The right-hand side is again of the form $\exp(\alpha^M + \beta^M x)$, so it solves [Eq. 40.1.3](#) exactly.
- (c) Let $Z \sim N(0, 1)$ be independent of U and write $\eta = \alpha + \beta x$. Then

$$E \Phi(\eta + U) = E \Pr(Z \leq \eta + U \mid U) = \Pr(Z - U \leq \eta),$$

and $Z - U \sim N(0, 1 + \tau^2)$, which is [Eq. 40.1.4](#). Again the result is of the assumed

form, so it solves Eq. 40.1.3.

- (d) Write $P_\theta = h(\theta + U)$ and $\bar{p}(\theta) = E P_\theta$. The logistic inverse link satisfies $h' = h(1-h)$, so differentiating under the expectation (legitimate because $0 \leq h' \leq 1/4$, so the difference quotients are dominated) gives $\bar{p}'(\theta) = E\{P_\theta(1 - P_\theta)\}$. Since $F(\theta) = \log \bar{p}(\theta) - \log\{1 - \bar{p}(\theta)\}$,

$$F'(\theta) = \frac{\bar{p}'(\theta)}{\bar{p}(\theta)\{1 - \bar{p}(\theta)\}} = \frac{E(P_\theta) - E(P_\theta^2)}{E(P_\theta) E(1 - P_\theta)}.$$

The denominator is $E(P_\theta) - \{E(P_\theta)\}^2$, so numerator minus denominator equals $\{E(P_\theta)\}^2 - E(P_\theta^2) = -\text{Var}(P_\theta)$, which gives Eq. 40.1.5. The ratio is positive because $P_\theta \in (0, 1)$ makes $E\{P_\theta(1 - P_\theta)\} > 0$, and it is strictly less than one because $\text{Var}(P_\theta) > 0$. Integrating F' from $\alpha + \beta x_1$ to $\alpha + \beta x_2$, an interval of positive length because $\beta \neq 0$, gives the stated inequality; for a binary covariate the left-hand side is β^M by the remark after Eq. 40.1.3. ■

Part (d) needs no normality of U , no particular covariate and no asymptotics; it is an identity about the logistic function. Its factor $F'(\theta)$ is one minus the ratio of the variance of the individual probabilities to the variance a single Bernoulli variable with the average probability would have, so the more the clusters differ, the flatter the population curve.

Idea. A nonlinear link and a random effect do not commute. Averaging $h(\eta + U)$ over U gives a *different function* of η , and for the logit and probit it is a flatter one. The linear and log links are the exceptions, because for them averaging changes at most an additive or multiplicative constant.

40.1.3 How large is the difference?

The probit factor in Eq. 40.1.4 is exact; the logit has no closed form, but the two links are so nearly proportional that a good approximation comes from pretending it does. Matching a standard logistic distribution to a normal one scaled by $c = 16\sqrt{3}/(15\pi) = 0.5881$ and applying Eq. 40.1.4 gives the classical factor

$$\beta^M \approx \frac{\beta^C}{\sqrt{1 + c^2 \tau^2}}, \quad c = \frac{16\sqrt{3}}{15\pi}, \quad (40.1.6)$$

due to Zeger, Liang and Albert (1988). It is an approximation, not a theorem.

Example. (Attenuation in a logistic random-intercept model)

Take $\alpha = 0$, $\beta^C = 1$ and a covariate $X \sim N(0, 1)$, and solve Eq. 40.1.3 numerically. With $\tau = 0.5$ the marginal slope is 0.9502; with $\tau = 1$ it is 0.8379; with $\tau = 2$ it is 0.6142. The approximation Eq. 40.1.6 gives 0.8620 and 0.6477 in the last two cases, too large by about three and five per cent. The probit factor at $\tau = 1$ is 0.7071, far smaller — but that is a different model, with a different meaning for β^C . The covariate distribution matters little: at $\tau = 1$ a binary covariate gives a marginal log odds ratio of 0.8318. Figure 40.1.1(a) shows why the approximation works at all — the average of

Figure 40.1.1: Attenuation in a random-intercept binary model. (a) With $\tau = 1.5$: five conditional logistic curves (grey), their average, and the logistic curve solving Eq. 40.1.3. (b) The ratio β^M / β^C against τ for the logit (exact and approximate) and for the probit.

the conditional curves is almost exactly a flatter logistic curve — and panel (b) tracks β^M / β^C as the clusters become more heterogeneous.

40.1.4 Attenuation is not bias

Attenuation is not bias: both coefficients are correct answers to different questions. The phenomenon is the **non-collapsibility** of the odds ratio, met in [Section 35.5](#) as [Example \(The odds ratio does not collapse\)](#) — averaging 2×2 tables that all share one odds ratio produces a table whose odds ratio is closer to one, with no confounding whatever. Risk differences and risk ratios do not behave this way, which is parts (a) and (b).

It follows that the conditional coefficient depends on what else is in the model: adding a covariate that explains part of the cluster heterogeneity lowers τ^2 and, by [Eq. 40.1.5](#), moves the conditional and marginal coefficients of the *other* covariates closer together. That is not evidence of confounding. Nor is either coefficient a causal quantity by itself: randomization ([Theorem 25.2.3](#)) licenses a causal reading of the marginal contrast between treated and untreated, but does not turn the marginal log odds ratio into the conditional one, and does not license a conditional reading of β^C unless the random effect really is a property of the cluster that the intervention leaves alone.

Which target, then? The conditional coefficient answers questions about a change *within a unit* — a dose for a patient, a policy for a school — and is comparable across studies with different amounts of unmeasured heterogeneity, provided the random-effect distribution is right. The marginal coefficient answers questions about a population total or rate, and is safer when the cluster structure is a nuisance, because it assumes nothing about the cluster effects. For the identity link the distinction disappears, which is why [Chapter 32](#) never raised it: in [Definition 32.2.1](#) the marginal model [Eq. 32.2.2](#) has the same $\mathbf{X}\boldsymbol{\beta}$ as the conditional one.

40.1.5 Exercises

40.1.5.1 A. Check your understanding

Exercise A1.

A random-intercept logistic model for whether a pupil passes an examination has $\hat{\beta}^C = 0.60$ for one extra hour of study per week and $\hat{\tau} = 1.2$. Use [Eq. 40.1.6](#) to say roughly what a population-averaged logistic model would report, and state in one sentence each what the two numbers mean.

Solution. The factor is $(1 + 0.5881^2 \times 1.2^2)^{-1/2}$. Now $0.5881^2 = 0.3459$ and $1.2^2 = 1.44$, so the factor is $(1 + 0.4981)^{-1/2} = 1.4981^{-1/2} \approx 0.817$, giving $\hat{\beta}^M \approx 0.49$. The first says: for a given pupil, an extra hour of study multiplies the odds of passing by $e^{0.60} \approx 1.82$. The second says: comparing two randomly chosen pupils from the population who differ

by an hour of study, the odds ratio is about $e^{0.49} \approx 1.63$.

Exercise A2.

A Poisson random-intercept model with a log link is fitted and reports $\hat{\alpha} = -1.2$, $\hat{\beta} = 0.35$, $\hat{\tau}^2 = 0.8$. What does a population-averaged log-linear model estimate? Which of the three numbers changes?

40.1.5.2 B. Practice

Exercise B1.

Use [Eq. 40.1.5](#) to show that in a logistic random-intercept model with $\Pr(Y = 1 | U) = h(U)$ and U symmetric about 0, the attenuation factor at $\theta = 0$ equals $1 - 4 \text{Var}\{h(U)\}$. Evaluate it for $U \sim N(0, 1)$, for which $\text{Var}\{h(U)\} = 0.0434$, and compare with the ratio 0.8379 of [Example \(Attenuation in a logistic random-intercept model\)](#).

Solution. By symmetry $Eh(U) = 1/2$, so the denominator of [Eq. 40.1.5](#) is $1/4$ and $F'(0) = 1 - 4 \text{Var}\{h(U)\}$. With $\text{Var}\{h(U)\} = 0.0434$ this is $1 - 4 \times 0.0434 = 0.8264$. This is the *local* attenuation at $\theta = 0$, and it is the strongest: as $|\theta|$ grows, P_θ concentrates near 0 or 1, its variance vanishes faster than $E P_\theta E(1 - P_\theta)$ and $F' \rightarrow 1$. The global ratio $\beta^M/\beta^C = 0.8379$ of [Example \(Attenuation in a logistic random-intercept model\)](#) is accordingly a little larger, because [Eq. 40.1.3](#) averages F' over the whole range of X .

Exercise B2.

Extend [Proposition 40.1.1\(c\)](#) to a probit model with a random *slope*: $\Pr(Y = 1 | U_0, U_1) = \Phi(\alpha + \beta x + U_0 + U_1 x)$ with $(U_0, U_1) \sim N_2(\mathbf{0}, \mathbf{G})$. Show that the marginal curve is $\Phi\{(\alpha + \beta x)/s(x)\}$ with $s(x)^2 = 1 + (1, x)\mathbf{G}(1, x)^\top$, and explain why the marginal model is now not a probit model in x at all.

Solution. Exactly as in the proof of (c), with $Z = U_0 + U_1 x$ normal with mean zero and variance $1 + g_{00} + 2g_{01}x + g_{11}x^2 = s(x)^2$. The marginal linear predictor $(\alpha + \beta x)/s(x)$ is a ratio of a linear function to the square root of a quadratic, which is linear in x only if $g_{11} = g_{01} = 0$. With a random slope the attenuation is different at different x , so no single marginal coefficient describes it.

40.2 Generalized linear mixed models

Replace the scalar U_i of [Section 40.1](#) by a vector of random effects with a covariance matrix, and the single covariate by a model matrix, and the result is the generalized linear mixed model: the linear mixed model of [Chapter 32](#) with a link function and an exponential dispersion family in place of the normal error.

That one change costs more than it looks. In [Definition 32.2.1](#) the marginal distribution was still normal, with covariance $\mathbf{V} = \mathbf{ZGZ}^\top + \mathbf{R}$, so everything Part VII knew about generalized

least squares applied unchanged. Here it is an integral with no closed form, and the marginal moments have to be computed one family at a time.

40.2.1 The model

Definition 40.2.1 — Generalized linear mixed model

Let $\mathbf{u} \sim N_q\{\mathbf{0}, \mathbf{G}(\boldsymbol{\theta})\}$ be a vector of **random effects** with covariance depending on unknown variance components $\boldsymbol{\theta}$. Given $\mathbf{u}$, let the responses $Y_1, \dots, Y_n$ be independent, each from the exponential dispersion family [Definition 34.1.1](#) with prior weight w_i , dispersion ϕ and variance function V , and with conditional mean

$$\mu_i(\mathbf{u}) = E(Y_i | \mathbf{u}) = h(\eta_i), \quad \eta_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \mathbf{z}_{(i)}^\top \mathbf{u}, \quad (40.2.1)$$

so that $\text{Var}(Y_i | \mathbf{u}) = \phi V\{\mu_i(\mathbf{u})\}/w_i$. In matrix form $\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$ with $\mathbf{X}$ of size $n \times p$ and $\mathbf{Z}$ of size $n \times q$, both known. The parameters are the **fixed effects** $\boldsymbol{\beta}$, the variance components $\boldsymbol{\theta}$ and, if it is not fixed by the family, the dispersion ϕ .

Setting $\mathbf{Z} = \mathbf{0}$ recovers the generalized linear model [Definition 34.2.1](#) exactly; taking the family normal and h the identity, with $\mathbf{R} = \phi\mathbf{I}$, recovers [Definition 32.2.1](#). Two structures cover most applications.

Clustered data. Units $i = 1, \dots, m$ with n_i observations each, one random effect vector $\mathbf{u}_i \sim N_{q_0}(\mathbf{0}, \mathbf{G}_0)$ per unit, independent across units. Then $\mathbf{Z}$ is block diagonal, $q = mq_0$, and both the likelihood and the marginal covariance break into m independent pieces. The **random-intercept** model takes $q_0 = 1$ and $\mathbf{z}_{(ij)} = 1$:

$$g(\mu_{ij}) = \mathbf{x}_{(ij)}^\top \boldsymbol{\beta} + u_i, \quad u_i \stackrel{\text{iid}}{\sim} N(0, \tau^2). \quad (40.2.2)$$

Crossed or nested effects. Pupils in classes in schools; raters and items. Here $\mathbf{G}$ is block diagonal in the *effects* rather than the units and the likelihood does not factorize. [Chapter 32](#) described the linear versions ([Example \(Nested and crossed random factors\)](#)); the difficulty a link function adds is computational, and severe, because the integral in [Section 40.3](#) is then genuinely high-dimensional.

Remark (Two extensions, and why they are rarer). A cluster-level random effect can be put into the linear predictor of a baseline-category model [Definition 36.1.1](#) or of a cumulative-logit model [Definition 36.2.1](#), giving mixed models for nominal and ordinal responses; in the ordinal case the effect shifts every cutpoint together, leaving the proportional-odds structure intact. Conditional independence given $\mathbf{u}_i$ can also be relaxed, by letting the random effects themselves follow an AR(1) process within the cluster — the mixed-model counterpart of the non-diagonal working correlation of [Section 40.5](#). That is rare, because it raises each cluster's integral from dimension q_0 to n_i .

Example. (A random-intercept logistic model)

m physicians each treat n_i patients; $Y_{ij} = 1$ if patient j of physician i recovers. With the

logistic link of [Definition 35.1.1](#), logit $\Pr(Y_{ij} = 1 \mid u_i) = \mathbf{x}_{(ij)}^\top \boldsymbol{\beta} + u_i$ and $u_i \sim N(0, \tau^2)$, the coefficient of a patient-level covariate compares two patients *of the same physician*, and τ measures how much physicians differ. A useful summary is the **median odds ratio** $\exp(\sqrt{2}\tau z_{0.75})$, the median odds ratio between two randomly chosen physicians treating identical patients ([Exercise \(B1\)](#)). Replacing u_i by $u_{0i} + u_{1i}x_{ij}$ gives a random-slope model, at the price of three parameters in $\mathbf{G}_0$ and, by [Exercise \(B2\)](#), no single marginal coefficient at all.

Example. (The Poisson–lognormal model)

With $Y_i \mid u_i$ Poisson ([Definition 37.1.1](#)) of mean $\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta} + u_i)$ and $u_i \sim N(0, \tau^2)$, the conditional mean is multiplied by the lognormal variable e^{u_i} . Unlike the binary case this model is identified with a *single* observation per unit, because the Poisson variance is determined by its mean and any excess must come from u_i : it is an overdispersion model in the sense of [Chapter 38](#) ([Proposition 38.4.1](#)), and a direct competitor to the negative binomial of [Definition 37.4.1](#), which arises the same way with a gamma mixing variable ([Lemma 37.4.1](#)).

40.2.2 The moments a random effect induces

Proposition 40.2.1 — Marginal moments of a GLMM

In [Definition 40.2.1](#) write $\mu_i(\mathbf{u}) = h(\eta_i)$ and $\mu_i^M = E\{\mu_i(\mathbf{u})\}$.

$$(a) \quad E(Y_i) = \mu_i^M,$$

$$\text{Var}(Y_i) = \frac{\phi}{w_i} E[V\{\mu_i(\mathbf{u})\}] + \text{Var}\{\mu_i(\mathbf{u})\}, \quad (40.2.3)$$

and $\text{Cov}(Y_i, Y_k) = \text{Cov}\{\mu_i(\mathbf{u}), \mu_k(\mathbf{u})\}$ for $i \neq k$. The marginal variance always exceeds the average conditional variance.

(b) **Binomial.** If $Y_i \mid \mathbf{u} \sim \text{Bin}\{N_i, \pi_i(\mathbf{u})\}$ and $\bar{\pi}_i = E\pi_i(\mathbf{u})$, then $E(Y_i) = N_i\bar{\pi}_i$ and

$$\text{Var}(Y_i) = N_i\bar{\pi}_i(1 - \bar{\pi}_i) \left\{ 1 + (N_i - 1) \frac{\text{Var}\{\pi_i(\mathbf{u})\}}{\bar{\pi}_i(1 - \bar{\pi}_i)} \right\}. \quad (40.2.4)$$

The overdispersion factor is the beta-binomial one, and it equals 1 when $N_i = 1$: a *single* Bernoulli response carries no trace of the random effect.

(c) **Poisson with a log link**, $\phi = 1$, and a random intercept $u_i \sim N(0, \tau^2)$ shared by the observations of a cluster. Then $\mu_{ij}^M = \exp(\mathbf{x}_{(ij)}^\top \boldsymbol{\beta} + \tau^2/2)$,

$$\begin{aligned} \text{Var}(Y_{ij}) &= \mu_{ij}^M + (\mu_{ij}^M)^2 (e^{\tau^2} - 1), \\ \text{Cov}(Y_{ij}, Y_{ik}) &= \mu_{ij}^M \mu_{ik}^M (e^{\tau^2} - 1). \end{aligned} \quad (40.2.5)$$

The marginal variance function is *exactly* the NB2 function $V(\mu) = \mu + \mu^2/\kappa$ of [Definition 37.4.1](#), with $\kappa = 1/(e^{\tau^2} - 1)$ — although the marginal distribution is not negative binomial and has no closed form.

Proof.

- (a) Condition on $\mathbf{u}$ and use the variance decomposition $\text{Var}(Y) = \text{E}\{\text{Var}(Y | \mathbf{u})\} + \text{Var}\{\text{E}(Y | \mathbf{u})\}$ and, for $i \neq k$, $\text{Cov}(Y_i, Y_k) = \text{E}\{\text{Cov}(Y_i, Y_k | \mathbf{u})\} + \text{Cov}\{\text{E}(Y_i | \mathbf{u}), \text{E}(Y_k | \mathbf{u})\}$, whose first term vanishes by conditional independence. The final claim is $\text{Var}\{\mu_i(\mathbf{u})\} \geq 0$.
- (b) With $\pi = \pi_i(\mathbf{u})$, Eq. 40.2.3 gives $\text{Var}(Y_i) = N_i \text{E}\{\pi(1 - \pi)\} + N_i^2 \text{Var}(\pi)$. Now $\text{E}\{\pi(1 - \pi)\} = \bar{\pi}_i - \text{E}(\pi^2) = \bar{\pi}_i(1 - \bar{\pi}_i) - \text{Var}(\pi)$, so $\text{Var}(Y_i) = N_i \bar{\pi}_i(1 - \bar{\pi}_i) + N_i(N_i - 1) \text{Var}(\pi)$, which is Eq. 40.2.4.
- (c) For a lognormal factor, $\text{E} e^{su} = e^{s^2 \tau^2 / 2}$. Hence $\mu_{ij}^M = e^{\eta_{ij}^0} \text{E} e^{u_i} = e^{\eta_{ij}^0 + \tau^2 / 2}$, writing $\eta_{ij}^0 = \mathbf{x}_{(ij)}^\top \boldsymbol{\beta}$. By Eq. 40.2.3 with $V(\mu) = \mu$ and $\phi = w_{ij} = 1$,

$$\text{Var}(Y_{ij}) = \mu_{ij}^M + e^{2\eta_{ij}^0} (\text{E} e^{2u_i} - (\text{E} e^{u_i})^2) = \mu_{ij}^M + e^{2\eta_{ij}^0} (e^{2\tau^2} - e^{\tau^2}),$$

and $e^{2\eta^0} (e^{2\tau^2} - e^{\tau^2}) = (e^{\eta^0 + \tau^2 / 2})^2 (e^{\tau^2} - 1)$. The covariance is the same computation with $\eta_{ij}^0 + \eta_{ik}^0$ in the exponent. Matching $\mu + \mu^2(e^{\tau^2} - 1)$ with $\mu + \mu^2/\kappa$ gives κ .

■

Part (b) explains why a random-intercept model for *ungrouped* binary data needs repeated observations: with $N_i = 1$ the marginal distribution is Bernoulli whatever τ is, and τ is identified only through the within-cluster *correlation*. Part (c) explains why the Poisson–lognormal and the negative binomial are so hard to tell apart: they agree in their first two moments exactly and differ only in shape, so a likelihood ratio between them compares tails, not overdispersion. The listing checks Eq. 40.2.5 by simulation at $\tau = 0.6$, where the matching NB2 shape is $\kappa = 1/(e^{0.36} - 1) = 2.3077$.

```

40.2.3 What a random intercept cannot do

Lemma 40.2.2 — A shared random intercept induces nonnegative correlation

Let U be a random variable and $f, g : \mathbb{R} \rightarrow \mathbb{R}$ both nondecreasing, with $\text{E} f(U)^2$ and $\text{E} g(U)^2$ finite. Then $\text{Cov}\{f(U), g(U)\} \geq 0$. Consequently, in a random-intercept

GLMM Eq. 40.2.2 with any inverse link h that is nondecreasing,

$$\text{Cov}(Y_{ij}, Y_{ik}) = \text{Cov}\{h(\eta_{ij}^0 + u_i), h(\eta_{ik}^0 + u_i)\} \geq 0 \quad (j \neq k).$$

Proof. Let U' be an independent copy of U . Because both functions are nondecreasing, $\{f(U) - f(U')\}\{g(U) - g(U')\} \geq 0$ pointwise. Taking expectations and expanding,

$$0 \leq \mathbb{E}[\{f(U) - f(U')\}\{g(U) - g(U')\}] = 2[\mathbb{E}\{f(U)g(U)\} - \mathbb{E}f(U)\mathbb{E}g(U)] = 2\text{Cov}\{f(U), g(U)\}.$$

The second claim is Proposition 40.2.1(a) with $f(u) = h(\eta_{ij}^0 + u)$ and $g(u) = h(\eta_{ik}^0 + u)$, both nondecreasing. ■

Every link in this book has a nondecreasing inverse, so the consequence is a real restriction: **a model whose only random effect is a cluster-level intercept cannot describe negatively correlated responses.** Such data exist. If exactly one of a traveller's four options is chosen, or exactly one of a litter survives a fixed food supply, the responses compete and their correlation is negative by construction. Section 40.4 analyses a data set of that kind, and the estimating-equation approach has no difficulty with it precisely because it never commits to a mechanism for the dependence.

40.2.4 Estimation, inference and prediction

Fitting is the subject of Section 40.3. The random effects cannot be estimated by maximizing a joint likelihood, because their number grows with the sample size — the incidental-parameter trap of Example (Many means, one variance). They are integrated out, giving the **integrated likelihood**

$$L(\boldsymbol{\beta}, \boldsymbol{\theta}, \phi) = \int_{\mathbb{R}^q} \prod_{i=1}^n f(y_i | \mathbf{u}; \boldsymbol{\beta}, \phi) p(\mathbf{u}; \boldsymbol{\theta}) d\mathbf{u}, \quad (40.2.6)$$

which is maximized numerically. Inference for $\boldsymbol{\beta}$ is then the usual likelihood inference — Wald intervals from the inverse observed information, likelihood ratio tests between nested mean models — as $m \rightarrow \infty$ with cluster sizes bounded. That claim is imported, not proved here: Theorem 34.5.1 covers a generalized linear model, not a GLMM, and the conditions under which the integrated likelihood behaves like an ordinary one are set out by McCulloch, Searle and Neuhaus (2008, chapter 14). Two warnings carry over from Part VII unchanged. First, a test of $\tau^2 = 0$, or of any variance component on the boundary of its range, is *not* a $\chi^2(1)$ test: the limiting null distribution is the mixture $\frac{1}{2}\chi^2(0) + \frac{1}{2}\chi^2(1)$ under the conditions of Theorem 32.5.2, so the naive p -value is twice what it should be. Second, REML has no clean analogue, because Definition 32.4.1 was built on the distribution of $\mathbf{K}^\top \mathbf{Y}$ for $\mathcal{C}(\mathbf{K}) = \mathcal{C}(\mathbf{X})^\perp$, a construction that needs the normal linear model; the approximate versions in use inherit the bias of the working linear model they are built on.

In the linear mixed model Theorem 32.3.1 produced a linear predictor of the random effects, and Eq. 32.3.3 showed it shrinks the cluster's own estimate towards zero. Neither linearity nor an explicit formula survives the link function, but the shrinkage does.

Proposition 40.2.3 — Empirical Bayes prediction and shrinkage

Consider Eq. 40.2.2 with β , τ^2 and ϕ known, write $\ell_i(u) = \sum_j \log f(y_{ij} | u)$ for cluster i 's conditional log-likelihood, and assume ℓ_i is concave in u — as it is for a canonical link by Theorem 34.3.3, and for the gamma with a log link by direct differentiation.

- (a) The posterior density of u_i given $\mathbf{y}_i$, proportional to $\exp\{\ell_i(u) - u^2/(2\tau^2)\}$, is log-concave and its mode $\hat{u}_i$ is unique.
- (b) If ℓ_i attains its maximum at a finite $\hat{a}_i \neq 0$, then $\hat{u}_i$ lies strictly between 0 and $\hat{a}_i$: the prediction has the same sign as the cluster's own estimate and is strictly smaller in magnitude. If ℓ_i has no finite maximizer — as when every response in a binary cluster is 0 — then $\hat{u}_i$ is finite all the same.
- (c) Replacing ℓ_i by its quadratic expansion at $\hat{a}_i$ gives $\hat{u}_i \approx \{\tau^2/(\tau^2 + I_i^{-1})\} \hat{a}_i$ with $I_i = -\ell_i''(\hat{a}_i)$. In the two cases used in this chapter $I_i^{-1} = \phi/n_i$ exactly, which is Eq. 32.3.3: clusters with few observations are shrunk harder, and all clusters are shrunk harder when τ^2 is small relative to the noise.

Proof.

- (a) Adding the strictly concave $-u^2/(2\tau^2)$ to the concave ℓ_i keeps it concave and makes it strictly so, and the sum tends to $-\infty$ in both directions, so a unique maximizer exists.
- (b) Write $\psi(u) = \ell_i(u) - u^2/(2\tau^2)$ and suppose $\hat{a}_i > 0$. Then $\ell_i'(\hat{a}_i) = 0$ gives $\psi'(\hat{a}_i) = -\hat{a}_i/\tau^2 < 0$, while $\psi'(0) = \ell_i'(0) > 0$ because ℓ_i is concave with maximum to the right of 0. A continuous derivative positive at 0 and negative at $\hat{a}_i$ vanishes strictly between them, and by strict concavity that zero is the unique maximizer; the case $\hat{a}_i < 0$ is symmetric. If ℓ_i increases everywhere, ψ' is still eventually negative because of the penalty, so $\hat{u}_i$ is finite.
- (c) With $\ell_i(u) \approx \ell_i(\hat{a}_i) - \frac{1}{2}I_i(u - \hat{a}_i)^2$, the penalized maximizer is $\hat{u}_i = I_i\hat{a}_i/(I_i + \tau^{-2}) = \{\tau^2/(\tau^2 + I_i^{-1})\}\hat{a}_i$. For a canonical link $I_i = \sum_j w_{ij}V(\hat{\mu}_{ij})/\phi$, so $I_i^{-1} = \phi/(n_i\bar{V}_i)$ with $\bar{V}_i$ the average of the $w_{ij}V(\hat{\mu}_{ij})$; in the normal case $V \equiv 1$, $w \equiv 1$ and $\bar{V}_i = 1$. For the gamma with a log link $\ell_i''(u) = -\nu \sum_j y_{ij}e^{-\eta_{ij}}$ with $\nu = 1/\phi$, and $\ell_i'(\hat{a}_i) = 0$ forces $\sum_j y_{ij}e^{-\eta_{ij}} = n_i$ there, so again $I_i = n_i/\phi$ exactly.

■

Remark (The predictions are not estimates). $\hat{u}_i$ predicts a random variable, so its error is a prediction error variance and the interval covering u_i is a *prediction* interval (Theorem 12.3.1), exactly as in Theorem 32.3.1(b). The usual intervals ignore the estimation of β and θ and are therefore too short when m is small.

40.2.5 An investment panel with a multiplicative mean

Example. (Grunfeld's firms, again)

Chapter 32 fitted a linear mixed model to Grunfeld's panel of 11 US firms observed in

each of 20 years ([Example \(Grunfeld's panel with a random firm effect\)](#)). Investment there ranges over three orders of magnitude and is far more variable for large firms than for small ones, which a constant-variance model cannot represent; a gamma response with a log link can, because the mean is multiplicative and the conditional coefficient of variation is constant. With Y_{ij} the gross investment of firm i in year j ,

$Y_{ij} \mid u_i \sim \text{Gamma}$ with $\log E(Y_{ij} \mid u_i) = \beta_0 + \beta_1 \log(\text{value}_{ij}) + \beta_2 \log(\text{capital}_{ij}) + u_i$, $u_i \sim N(0, \tau^2)$, and $\text{Var}(Y_{ij} \mid u_i) = \phi E(Y_{ij} \mid u_i)^2$. Fitting by adaptive Gauss–Hermite quadrature ([Section 40.3](#)) gives

	β_1 (value)	β_2 (capital)	ϕ	τ
marginal	0.8421	0.3386	0.2644	—
gamma GLM				
gamma GLMM	0.6825	0.2315	0.0930	0.5188

The firm-to-firm standard deviation $\hat{\tau} = 0.5188$ is large: firms a standard deviation apart on the log scale differ by a factor of $e^{0.5188} \approx 1.68$ in investment at the same value and capital stock. The conditional coefficient of variation is $\sqrt{\hat{\phi}} = 0.3049$. For a gamma with shape $1/\hat{\phi}$ the conditional variance of $\log Y$ is the trigamma function of the shape, 0.0974, so the fraction of the variance of $\log Y$ attributable to the firm is $\hat{\tau}^2/(\hat{\tau}^2 + 0.0974) = 0.734$.

The fitted conditional intercept is -1.3032 ; by [Proposition 40.1.1\(b\)](#) the log link causes no attenuation of the slopes, and the marginal intercept is $-1.3032 + \hat{\tau}^2/2 = -1.1686$. The difference between the two rows is therefore *not* the marginal–conditional distinction. It is the older within-versus-between problem of [Section 6.6](#): the independence fit lets differences between firms contribute to the slopes, while the mixed model assigns most of them to u_i and estimates the slopes mainly from movement within a firm. A gap of this size accuses the mean model, and [Section 40.5](#) returns to it with a diagnostic and two candidate explanations, [Exercise \(C1\)](#) with a remedy.

With 20 years per firm and $\hat{\phi} = 0.0930$ small there is almost nothing to shrink: the empirical slope of $\hat{u}_i$ on $\hat{a}_i$ is 0.9830, and [Proposition 40.2.3\(c\)](#) predicts 0.9830. Using only each firm's first three years, the same parameters give 0.8951. Shrinkage measures how much a cluster's own data are worth, and is not a fixed property of the model.

40.2.6 Exercises

40.2.6.1 A. Check your understanding

Exercise A1.

For each of the following, say whether the random-intercept variance τ^2 is identified, and why: (a) one Bernoulli response per cluster; (b) one binomial response with $N_i = 40$ trials per cluster; (c) one Poisson count per cluster; (d) five Bernoulli responses per cluster.

Figure 40.2.1: Shrinkage of the firm effects in the gamma GLMM of [Example \(Grunfeld's firms, again\)](#). (a) $\hat{u}_i$ against the firm's own estimate $\hat{a}_i$, for 20 years (circles) and for the first 3 only (triangles); the diagonal is no shrinkage. (b) The factor $\tau^2/(\tau^2 + \phi/n_i)$ of [Proposition 40.2.3\(c\)](#) at $\hat{\phi}$.

Exercise A2.

A Poisson–lognormal model is fitted and gives $\hat{\tau}^2 = 0.5$. What NB2 shape parameter κ would produce the same marginal variance function? Would you expect the two models to give noticeably different fitted means?

40.2.6.2 B. Practice

Exercise B1.

In [Example \(A random-intercept logistic model\)](#), let two physicians be drawn at random and let OR be the odds ratio between them for identical patients, taken in the direction that makes it at least one. Show that the median of OR is $\exp(\sqrt{2}\tau z_{0.75})$, where $z_{0.75} = 0.6745$ is the upper quartile of the standard normal. Evaluate it for $\tau = 1$.

Solution. The log odds ratio between physicians i and k is $u_i - u_k$, which is $N(0, 2\tau^2)$. Taking it in the positive direction gives $|u_i - u_k|$, whose median is the upper quartile of $N(0, 2\tau^2)$, namely $\sqrt{2}\tau z_{0.75}$. Exponentiating gives the claim. For $\tau = 1$, $\sqrt{2} \times 0.6745 = 0.9539$ and $e^{0.9539} \approx 2.6$: a typical pair of physicians differs by a factor of about 2.6 in the odds of recovery, for identical patients.

Exercise B2.

Give a two-level model with a *vector* random effect whose induced within-cluster correlation is negative, and explain why [Lemma 40.2.2](#) does not apply. (Hint: let $\mathbf{z}_{(ij)}$ differ in sign across j .)

Solution. Take $n_i = 2$, $q_0 = 1$, $z_{i1} = +1$ and $z_{i2} = -1$, so $\eta_{i1} = \eta_{i1}^0 + u_i$ and $\eta_{i2} = \eta_{i2}^0 - u_i$. Then $f(u) = h(\eta_{i1}^0 + u)$ is nondecreasing and $g(u) = h(\eta_{i2}^0 - u)$ is nonincreasing, so the

association inequality applies with $-g$ and gives $\text{Cov}\{f(U), g(U)\} \leq 0$. The lemma assumed both functions nondecreasing, which is automatic only when every $z_{(ij)}$ has the same sign — as for an intercept.

40.2.6.3 C. Going deeper

Exercise C1.

In [Example \(Grunfeld's firms, again\)](#) the mixed-model slopes differ markedly from the independence ones. Add the firm means $\overline{\log \text{value}}_i$ and $\overline{\log \text{capital}}_i$ to the model as extra fixed effects, so that the original covariates carry only within-firm variation. Explain why this makes the random effect orthogonal to the covariates in the population, refit, and compare. What test does the difference between the two specifications suggest?

40.3 Integrated likelihood approximations

Everything the last section promised rests on the integral [Eq. 40.2.6](#), which has no closed form except in the normal linear case. Fitting a GLMM is therefore a numerical problem before it is a statistical one, and the choice of method is not innocent: three methods in common use can differ in the second significant figure of $\hat{\beta}$ and in the first of $\hat{\tau}$.

40.3.1 Why it is hard, and what makes it easier

For the normal linear mixed model $\mathbf{Y} \mid \mathbf{u}$ and $\mathbf{u}$ are both normal, so [Eq. 40.2.6](#) is a Gaussian integral and gives [Eq. 32.2.2](#) in closed form. Nothing of the sort happens otherwise: a Poisson likelihood in e^u against a normal density in u is not a recognizable integral in any dimension. What *does* help is independence. If the random effects are attached to clusters that are independent of each other, the q -dimensional integral splits into m integrals of dimension q_0 each, and with a random intercept $q_0 = 1$. A one-dimensional integral repeated m times is tractable; a q -dimensional one with q in the hundreds is not.

Theorem 40.3.1 — The integrated likelihood and its approximations

In [Definition 40.2.1](#) write $\psi_i(\mathbf{u}_i) = \log f(\mathbf{y}_i \mid \mathbf{u}_i; \boldsymbol{\beta}, \phi) + \log p(\mathbf{u}_i; \boldsymbol{\theta})$.

- (a) **Factorization.** If the random effects split into independent blocks $\mathbf{u}_1, \dots, \mathbf{u}_m$ with $\mathbf{u}_i$ entering only the observations of cluster i , then

$$L(\boldsymbol{\beta}, \boldsymbol{\theta}, \phi) = \prod_{i=1}^m \int_{\mathbb{R}^{q_0}} \exp\{\psi_i(\mathbf{u}_i)\} d\mathbf{u}_i, \quad (40.3.1)$$

a product of m integrals of dimension q_0 .

- (b) **Laplace approximation.** Fix i and take $q_0 = 1$. Let ψ_i be four times continuously differentiable with a unique interior maximizer $\hat{u}_i$, and $c_i = -\psi_i''(\hat{u}_i) > 0$. Then, formally,

$$\int e^{\psi_i(u)} du = \sqrt{\frac{2\pi}{c_i}} e^{\psi_i(\hat{u}_i)} \{1 + \delta_i + \dots\}, \quad (40.3.2)$$

$$\delta_i = \frac{\psi_i^{(4)}(\hat{u}_i)}{8c_i^2} + \frac{5\{\psi_i'''(\hat{u}_i)\}^2}{24c_i^3}.$$

Suppose $\psi_i = n_i k_i + s_i$, where k_i does not depend on n_i and has a nondegenerate maximum and s_i has derivatives bounded uniformly in n_i . (In a GLMM $n_i k_i$ is the conditional log-likelihood and s_i the log prior density of $\mathbf{u}_i$, which does not grow with n_i .) Then both terms of δ_i are $O(n_i^{-1})$: the Laplace approximation has *relative error* $O(n_i^{-1})$ and the error in the log-likelihood is $O(\sum_i n_i^{-1})$.

- (c) **Adaptive Gauss–Hermite quadrature.** Let $(z_k, w_k)_{k=1}^K$ be the nodes and weights of K -point Gauss–Hermite quadrature, so that $\int e^{-z^2} P(z) dz = \sum_k w_k P(z_k)$ for every polynomial P of degree at most $2K-1$. With $\hat{\sigma}_i = c_i^{-1/2}$, the substitution $u = \hat{u}_i + \sqrt{2} \hat{\sigma}_i z$ gives the approximation

$$\int e^{\psi_i(u)} du \approx \sqrt{2} \hat{\sigma}_i \sum_{k=1}^K w_k e^{z_k^2} e^{\psi_i(\hat{u}_i + \sqrt{2} \hat{\sigma}_i z_k)}. \quad (40.3.3)$$

It is exact whenever $e^{\psi_i(\hat{u}_i + \sqrt{2} \hat{\sigma}_i z) + z^2}$ is a polynomial of degree at most $2K-1$ in z , and $K=1$ reproduces Eq. 40.3.2 without its correction terms.

- (d) **Penalized quasi-likelihood** avoids the integral altogether, by a penalized maximization that is cheaper than either of the above and carries a bias that does not vanish. It is stated and proved separately as Proposition 40.3.2.

Proof.

- (a) Under the stated independence the integrand factorizes and Fubini's theorem applies, every factor being nonnegative.
- (b) Substitute $u = \hat{u}_i + s/\sqrt{c_i}$ and expand ψ_i about $\hat{u}_i$, using $\psi_i'(\hat{u}_i) = 0$:

$$\psi_i(u) = \psi_i(\hat{u}_i) - \frac{1}{2}s^2 + a_3 s^3 + a_4 s^4 + \dots,$$

$$a_3 = \frac{\psi_i'''(\hat{u}_i)}{6c_i^{3/2}}, \quad a_4 = \frac{\psi_i^{(4)}(\hat{u}_i)}{24c_i^2}.$$

Hence $\int e^{\psi_i} du = c_i^{-1/2} e^{\psi_i(\hat{u}_i)} \int e^{-s^2/2} e^{a_3 s^3 + a_4 s^4 + \dots} ds$. Expanding the second exponential as $1 + (a_3 s^3 + a_4 s^4) + \frac{1}{2} a_3^2 s^6 + \dots$ and using the standard normal moments $ES^3 = 0$, $ES^4 = 3$, $ES^6 = 15$ gives the factor $\sqrt{2\pi} \{1 + 3a_4 + \frac{15}{2} a_3^2 + \dots\}$, which is Eq. 40.3.2. If $\psi_i = n_i k_i + s_i$ then $c_i = n_i |k_i''| + O(1)$, $\psi_i''' = n_i k_i''' + O(1)$ and $\psi_i^{(4)} = n_i k_i^{(4)} + O(1)$, so $a_4 = O(n_i^{-1})$ and $a_3^2 = O(n_i^{-1})$.

- (c) The substitution is a change of variable, and $e^{\psi_i(u)} = e^{-z^2} \{e^{z^2} e^{\psi_i(\hat{u}_i + \sqrt{2} \hat{\sigma}_i z)}\}$, so the quadrature rule applies to the term in braces. For $K=1$ the node is $z_1 = 0$ and the weight is $w_1 = \sqrt{\pi}$, giving $\sqrt{2} \hat{\sigma}_i \sqrt{\pi} e^{\psi_i(\hat{u}_i)} = \sqrt{2\pi/c_i} e^{\psi_i(\hat{u}_i)}$. ■

Remark (What “formally” means in (b)). The expansion in the proof interchanges an infinite series with an integral over the whole line, which the argument does not justify, and the remainder can also be affected by the behaviour of ψ_i far from its mode. The

rigorous statement — that the expansion is asymptotic in n_i , with an explicit remainder, under conditions on the derivatives of k_i and on the tails — is classical, and is given in the form used here by Tierney and Kadane (1986) and Barndorff-Nielsen and Cox (1989, chapter 3). [Chapter 39](#) proves the companion statement for the posterior and the marginal likelihood ([Theorem 39.4.2](#)). We take the error order as given; [Example \(Three methods on clustered binary data\)](#) checks it numerically.

Two readings of (b). First, the accuracy of the Laplace approximation is governed by the observations *per cluster*, not by the sample size: a study with 10 000 patients seen twice each is the hard case, and no number of extra patients repairs it. Second, the relevant n_i is an *effective* one — a cluster of twenty Bernoulli responses says much less about its own u_i than a cluster of twenty gamma responses — which is why the same approximation behaves so differently in [Example \(Three methods on clustered binary data\)](#) and [Example \(Grunfeld's firms, again\)](#).

Part (c) matters because plain Gauss–Hermite quadrature places its nodes where the *prior* is large. When the data are informative the posterior of u_i sits elsewhere and is much narrower, so most nodes fall where the integrand is negligible. The adaptive version puts them at each cluster's own mode and curvature — the same $\hat{u}_i$ and $\hat{\sigma}_i$ that [Proposition 40.2.3](#) predicts the random effect with — at the cost of one Newton iteration per cluster per likelihood evaluation.

40.3.2 Penalized quasi-likelihood

The oldest practical method avoids the integral by treating the random effects as parameters with a penalty.

Proposition 40.3.2 — Penalized quasi-likelihood

In [Definition 40.2.1](#) let $\ell(\boldsymbol{\beta}, \mathbf{u})$ be the conditional log-likelihood of the data given $\mathbf{u}$, and consider the **penalized quasi-likelihood**

$$\ell^{\text{pen}}(\boldsymbol{\beta}, \mathbf{u}) = \ell(\boldsymbol{\beta}, \mathbf{u}) - \frac{1}{2} \mathbf{u}^\top \mathbf{G}^{-1} \mathbf{u}. \quad (40.3.4)$$

- (a) For fixed $\boldsymbol{\theta}$, the stationary equations of [Eq. 40.3.4](#) are

$$\mathbf{X}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}, \quad \mathbf{Z}^\top \mathbf{W} \mathbf{D}^{-1} (\mathbf{y} - \boldsymbol{\mu}) = \phi \mathbf{G}^{-1} \mathbf{u},$$

with $\mathbf{W}$ and $\mathbf{D}$ the working weights and derivatives of [Theorem 34.3.1](#) evaluated at $\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$. Equivalently, with the working response $\mathbf{z} = \boldsymbol{\eta} + \mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu})$ of [Eq. 34.4.1](#), they are Henderson's mixed-model equations ([Theorem 32.3.2](#)) for the linear mixed model $\mathbf{z} \mid \mathbf{u} \sim N_n(\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}, \phi \mathbf{W}^{-1})$, $\mathbf{u} \sim N_q(\mathbf{0}, \mathbf{G})$.

- (b) Iterating — update $(\boldsymbol{\beta}, \mathbf{u})$ by those equations, then update $\boldsymbol{\theta}$ by maximum likelihood or REML in the working linear mixed model, and repeat — is the Breslow–Clayton PQL algorithm. It is therefore the Laplace approximation [Eq. 40.3.2](#) with

the further simplification that $\mathbf{W}$ is treated as fixed when $\boldsymbol{\theta}$ is updated, so that c_i contributes no derivative terms.

- (c) The resulting $\hat{\boldsymbol{\beta}}$ and $\hat{\boldsymbol{\theta}}$ are biased towards zero, and the bias does **not** vanish as $m \rightarrow \infty$ with cluster sizes fixed: PQL is inconsistent. It is worst for binary responses with small n_i and large τ , and negligible for responses that carry much information per observation.

Proof.

- (a) Differentiating ℓ with respect to $\boldsymbol{\beta}$ and $\mathbf{u}$ reproduces Eq. 34.3.1 with model matrix $[\mathbf{X}, \mathbf{Z}]$, because $\mathbf{u}$ enters the linear predictor exactly as $\boldsymbol{\beta}$ does; the penalty contributes $-\mathbf{G}^{-1}\mathbf{u}$ to the second block and nothing to the first. Multiplying by ϕ gives the displayed pair. For the second form, $\mathbf{W}\mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{W}(\mathbf{z} - \boldsymbol{\eta})$ by the definition of $\mathbf{z}$, so the equations read $\mathbf{X}^\top \mathbf{W}(\mathbf{z} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) = \mathbf{0}$ and $\mathbf{Z}^\top \mathbf{W}(\mathbf{z} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}) = \phi \mathbf{G}^{-1}\mathbf{u}$, which are Eq. 32.3.5 with $\mathbf{R} = \phi \mathbf{W}^{-1}$.
- (b) is the observation that maximizing Eq. 40.3.4 over $\mathbf{u}$ locates $\hat{\mathbf{u}}$ at the mode of the integrand of Eq. 40.2.6, which is the first ingredient of Eq. 40.3.2; the remaining ingredient, $\log|c_i|$, is what the $\boldsymbol{\theta}$ update drops.
- (c) We do not prove this. The asymptotic bias expansions, and corrections built from them, are given by Breslow and Lin (1995) and Lin and Breslow (1996); Example (Three methods on clustered binary data) measures the bias by simulation.

■

Remark (PQL is empirical Bayes). Since $\exp\{\ell^{\text{pen}}\}$ is proportional to the joint density of $\mathbf{y}$ and $\mathbf{u}$, the PQL estimate of $\mathbf{u}$ is the posterior mode of Proposition 40.2.3 with $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$ replaced by estimates: an empirical Bayes predictor, and nothing about it is wrong. What is wrong is using the same objective to estimate $\boldsymbol{\theta}$, because it has been maximized over $\mathbf{u}$ rather than integrated over it, and the two differ by exactly the $\log c_i$ term that carries the information about τ .

40.3.3 Monte Carlo alternatives

When q_0 exceeds two or three, a product grid needs K^{q_0} nodes and stops being practical. **Monte Carlo EM** treats $\mathbf{u}$ as missing data: the E step's expectation over the posterior of $\mathbf{u}$ is replaced by an average over Markov chain Monte Carlo draws, and the M step is an ordinary weighted GLM fit. EM's monotonicity survives only up to Monte Carlo error, so the number of draws must grow with the iterations; Chapter 41 develops the algorithm and proves that the exact version never decreases the likelihood. **Simulated maximum likelihood** estimates each factor of Eq. 40.3.1 by importance sampling with the Laplace approximation as proposal — Eq. 40.3.3 with random nodes. **Fully Bayesian inference** samples $\boldsymbol{\beta}$, $\mathbf{u}$ and $\boldsymbol{\theta}$ together, as Section 32.6 did for the linear mixed model (Proposition 32.6.1); without conjugacy the full conditionals need Metropolis–Hastings steps or data augmentation, which Chapter 39 builds (Definition 39.4.2).

40.3.4 How different are the answers?

Figure 40.3.1: Approximations to the integrated likelihood, on clustered binary data with $m = 150$, $n_i = 5$ and $\tau = 1$. (a), (b) Sampling distributions of $\hat{\beta}_1$ and $\hat{\tau}$ over 200 replications under three methods; the horizontal line is the truth. (c) Error in the integrated log-likelihood against the number of quadrature nodes, adaptive and plain.

Example. (Three methods on clustered binary data)

Simulate 150 clusters of 5 binary observations from a random-intercept logistic model with $\boldsymbol{\beta} = (-0.5, 1.0)^\top$, a covariate varying within the cluster, and $\tau = 1$. Over 200 replications the average estimates are

	$\hat{\beta}_1$ (truth 1.0)	$\hat{\tau}$ (truth 1.0)
PQL	0.8970	0.8168
Laplace	1.0022	0.9353
adaptive Gauss–Hermite, $K = 9$	1.0087	0.9909

PQL attenuates the slope by 10.3 per cent and the standard deviation by 18.3 per cent. The Laplace approximation is nearly unbiased for the slope but still shrinks $\hat{\tau}$ by about six per cent, which is consistent with the $O(n_i^{-1})$ error of [Theorem 40.3.1\(b\)](#) at $n_i = 5$; the direction and size of the induced bias are measured here, not derived, since part (b) bounds the error in the likelihood and says nothing about where its maximizer moves. Nine adaptive nodes leave a bias of about one per cent, which is the ordinary finite-sample bias of maximum likelihood rather than a numerical error.

Panel (c) of [Figure 40.3.1](#) separates the numerical question from the statistical one. At a fixed parameter value, the error in the integrated log-likelihood with $K = 5$ is 3.65136×10^{-3} for the adaptive rule and 1.01404×10^{-1} for the plain one — a factor of about 28 — and the adaptive rule is down to 3.759×10^{-10} by $K = 13$, while the plain one is still above 10^{-6} , at 2.460×10^{-6} , when $K = 19$.

```

The contrast with [Example \(Grunfeld’s firms, again\)](#) is instructive. That fit has $n_i = 20$ continuous responses per firm, and refitting it with one adaptive node instead of nine changes no parameter by more than 5×10^{-4} and the maximized log-likelihood, which is -937.100 , by less than 0.01. What separates the two is not the software but the information each cluster carries about its own random effect, exactly as [Theorem 40.3.1\(b\)](#) says.

Idea. Report which approximation was used. “A random-intercept logistic model was fitted” is not a complete description when PQL and adaptive quadrature can differ by a tenth of the coefficient. With binary responses in small clusters, use quadrature with enough nodes that the answer stops moving, and say how many.

40.3.5 Exercises

40.3.5.1 A. Check your understanding

Exercise A1.

A GLMM with two correlated random effects per cluster is fitted by non-adaptive Gauss–Hermite quadrature on a product grid. How many likelihood evaluations per cluster does $K = 20$ cost? What if there are four random effects per cluster? What does this say about crossed random effects, where q_0 is effectively the whole vector?

Exercise A2.

For each of the following, say whether PQL is likely to be adequate and why: (a) counts with means in the hundreds, ten per cluster; (b) binary responses, three per cluster, with a large estimated τ ; (c) grouped binomial responses with $N_i = 200$ trials, one per cluster.

40.3.5.2 B. Practice

Exercise B1.

Verify [Theorem 40.3.1\(c\)](#) for $K = 1$ directly: show that the one-point Gauss–Hermite rule has node $z_1 = 0$ and weight $w_1 = \sqrt{\pi}$, and that [Eq. 40.3.3](#) then reduces to [Eq. 40.3.2](#) without its correction terms. Then explain why the *non*-adaptive rule with $K = 1$ gives something quite different, and say what.

Solution. The one-point rule must integrate $e^{-z^2}P(z)$ exactly for P of degree ≤ 1 . Taking $P = 1$ gives $w_1 = \int e^{-z^2} dz = \sqrt{\pi}$; taking $P = z$ gives $w_1 z_1 = \int z e^{-z^2} dz = 0$, so $z_1 = 0$. Substituting in [Eq. 40.3.3](#) gives $\sqrt{2}\hat{\sigma}_i\sqrt{\pi}e^{\psi_i(\hat{u}_i)}$, which is $\sqrt{2\pi/c_i}e^{\psi_i(\hat{u}_i)}$. The non-adaptive rule puts its single node at $u = 0$ with scale τ , giving $\sqrt{2\pi}\tau e^{\psi_i(0)}$: the integrand evaluated at the *prior* mode with the prior's width, which is the right answer only when the data say nothing.

Exercise B2.

For a cluster of n Bernoulli responses with common success probability π and a random intercept, show that $c_i = n\pi(1 - \pi) + \tau^{-2}$. Compare with the gamma case of [Example \(Grunfeld's firms, again\)](#), where $c_i = n/\phi + \tau^{-2}$, and use [Theorem 40.3.1\(b\)](#) to explain the difference between the two fits in terms of an effective cluster size.

Solution. For the logit, $\psi_i''(u) = -\sum_j \mu_{ij}(1 - \mu_{ij}) - \tau^{-2}$, which at a common π is $-n\pi(1 - \pi) - \tau^{-2}$. For the gamma with a log link, $\psi_i''(u) = -\nu \sum_j y_{ij}e^{-\eta_{ij}} - \tau^{-2}$, which at the mode is about $-n/\phi - \tau^{-2}$ since $\nu = 1/\phi$ and $y_{ij}e^{-\eta_{ij}} \approx 1$. The Laplace error is governed by $c_i\tau^2$, so the effective cluster size is $n\pi(1 - \pi)\tau^2$ against $n\tau^2/\phi$. With $n = 5$, $\pi = 1/2$, $\tau = 1$ the first is 1.25; with $n = 20$, $\phi = 0.0930$, $\tau = 0.52$ the second is about 58. The two fits are in completely different regimes.

40.4 Generalized estimating equations

Suppose the question is the marginal one and the cluster structure a nuisance. Then a generalized linear mixed model asks for more than is needed: a distribution for the random effects, a conditional distribution for the responses, and an intractable integral. Everything the question needs is in the *mean*, and [Chapter 38](#) showed that a mean and a variance function suffice to build a usable estimating equation without a likelihood.

Carrying that across to clustered data gives the method of Liang and Zeger (1986), the most widely used in this chapter and the most widely misunderstood. It estimates a marginal coefficient consistently even when the correlation structure it assumes is wrong. It does not estimate a conditional coefficient at all; it produces no likelihood, so most of the model-comparison machinery of the book does not apply; and its robustness to a wrong correlation does not extend to data that go missing for the wrong reasons.

40.4.1 The estimating equation

Clusters $i = 1, \dots, m$ are independent, with response vectors $\mathbf{Y}_i$ of length n_i and model matrices $\mathbf{X}_i$ of size $n_i \times p$. The model constrains the marginal mean only:

$$E(\mathbf{Y}_i) = \boldsymbol{\mu}_i(\boldsymbol{\beta}), \quad \mu_{ij}(\boldsymbol{\beta}) = h(\mathbf{x}_{(ij)}^\top \boldsymbol{\beta}), \quad (40.4.1)$$

with h the inverse of a link as in [Definition 34.2.2](#). Nothing is assumed about the joint distribution of $\mathbf{Y}_i$, and in particular nothing about its covariance — although a guess at that covariance is used, deliberately.

Definition 40.4.1 — Generalized estimating equations

Let V be a variance function and ϕ a dispersion, and write

$$\begin{aligned} \mathbf{A}_i^V(\boldsymbol{\beta}) &= \text{diag}\{V(\mu_{i1}), \dots, V(\mu_{in_i})\}, \\ \mathbf{D}_i(\boldsymbol{\beta}) &= \frac{\partial \boldsymbol{\mu}_i}{\partial \boldsymbol{\beta}^\top} = \text{diag}\{h'(\eta_{ij})\} \mathbf{X}_i. \end{aligned}$$

Let $\mathbf{R}_i(\boldsymbol{\alpha})$ be a **working correlation matrix**: a correlation matrix for the n_i observations of cluster i , depending on a finite parameter $\boldsymbol{\alpha}$, chosen by the analyst and *not* assumed correct. The **working covariance** is

$$\mathbf{V}_i(\boldsymbol{\beta}, \boldsymbol{\alpha}, \phi) = \phi (\mathbf{A}_i^V)^{1/2} \mathbf{R}_i(\boldsymbol{\alpha}) (\mathbf{A}_i^V)^{1/2}, \quad (40.4.2)$$

and the **generalized estimating equation** is

$$\mathbf{U}_m(\boldsymbol{\beta}; \boldsymbol{\alpha}, \phi) = \sum_{i=1}^m \mathbf{D}_i(\boldsymbol{\beta})^\top \mathbf{V}_i^{-1} \{\mathbf{Y}_i - \boldsymbol{\mu}_i(\boldsymbol{\beta})\} = \mathbf{0}. \quad (40.4.3)$$

In practice $\boldsymbol{\alpha}$ and ϕ are replaced by moment estimates computed from the Pearson

residuals $r_{ij} = (y_{ij} - \hat{\mu}_{ij})/\sqrt{V(\hat{\mu}_{ij})}$ at the current $\hat{\beta}$, and Eq. 40.4.3 is re-solved, until nothing changes.

Within this chapter $\mathbf{R}_i$ denotes the working correlation matrix, not the error covariance $\mathbf{R}$ of Part VII.

Remark (Three familiar special cases). With $\mathbf{R}_i = \mathbf{I}$ and one observation per cluster, Eq. 40.4.3 is exactly the likelihood equation Eq. 34.3.1, with $\mathbf{W}\mathbf{D}^{-1}$ written out. With $\mathbf{R}_i = \mathbf{I}$ and several observations per cluster it is still that equation, applied as if the observations were independent: the same $\hat{\beta}$, different standard errors. And with a general $\mathbf{R}_i$ but one cluster, it is the quasi-score of Chapter 38 (Theorem 38.2.2) with a full covariance matrix — which for the identity link and $V \equiv 1$ is the generalized least squares of Proposition 33.4.1.

Solving Eq. 40.4.3 is Fisher scoring. Write $\mathbf{S}_i = \text{diag}\{h'(\eta_{ij})/\sqrt{V(\mu_{ij})}\}$; then $\mathbf{D}_i^\top \mathbf{V}_i^{-1} = \phi^{-1} \mathbf{X}_i^\top \mathbf{S}_i \mathbf{R}_i^{-1} (\mathbf{A}_i^V)^{-1/2}$, so the update is

$$\hat{\beta} \leftarrow \hat{\beta} + \left(\sum_i \mathbf{X}_i^\top \mathbf{S}_i \mathbf{R}_i^{-1} \mathbf{S}_i \mathbf{X}_i \right)^{-1} \sum_i \mathbf{X}_i^\top \mathbf{S}_i \mathbf{R}_i^{-1} \mathbf{r}_i, \quad (40.4.4)$$

in which ϕ cancels. It is the iteratively reweighted least squares of Theorem 34.4.1 with $\mathbf{R}_i^{-1}$ inserted between the weights, and it converges just as quickly.

40.4.2 What the estimate does and does not have

Theorem 40.4.1 — Consistency, asymptotic normality and the sandwich

Let the clusters be independent, let β^0 be the true value in Eq. 40.4.1, and let $\Sigma_i^0 = \text{Cov}(\mathbf{Y}_i)$ be arbitrary and unknown. Assume

- (E1) $n_i \leq n_{\max}$ and $\|\mathbf{x}_{(ij)}\| \leq C$ for all i, j ;
- (E2) h is twice continuously differentiable with h' bounded, V is continuous and bounded away from 0 on the relevant range, and β^0 is interior to a compact parameter set;
- (E3) the eigenvalues of $\mathbf{R}_i(\alpha)$ are bounded above and away from zero, uniformly in i and in α near its limit;
- (E4) $E\|\mathbf{Y}_i\|^4 \leq K$ for all i ;
- (E5) $\hat{\alpha}$ and $\hat{\phi}$ are $\sqrt{m}$ -consistent for some limits α^*, ϕ^* , which need not make $\mathbf{V}_i$ equal to Σ_i^0 ;
- (E6) with $\mathbf{V}_i$ evaluated at $(\beta^0, \alpha^*, \phi^*)$,

$$\mathbf{A}_m = \frac{1}{m} \sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i \rightarrow \mathbf{A},$$

$$\mathbf{B}_m = \frac{1}{m} \sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \Sigma_i^0 \mathbf{V}_i^{-1} \mathbf{D}_i \rightarrow \mathbf{B},$$

both positive definite.

Then:

- (a) **Unbiasedness.** For every fixed α and ϕ , $E\{\mathbf{U}_m(\beta^0; \alpha, \phi)\} = \mathbf{0}$. The estimating function is unbiased whatever the working correlation is.
- (b) **Consistency and asymptotic normality.** With probability tending to one, Eq. 40.4.3 has a root $\hat{\beta}_m$ with $\hat{\beta}_m \rightarrow \beta^0$ in probability, and

$$\sqrt{m}(\hat{\beta}_m - \beta^0) \xrightarrow{d} N_p(\mathbf{0}, \mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}). \quad (40.4.5)$$

- (c) **The sandwich estimator.** Let $\mathbf{r}_i = \mathbf{Y}_i - \mu_i(\hat{\beta}_m)$ and

$$\begin{aligned} \hat{\mathbf{V}}_R &= \hat{\mathbf{A}}_m^{-1} \left(\sum_i \hat{\mathbf{D}}_i^\top \hat{\mathbf{V}}_i^{-1} \mathbf{r}_i \mathbf{r}_i^\top \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i \right) \hat{\mathbf{A}}_m^{-1}, \\ \hat{\mathbf{A}}_m &= \sum_i \hat{\mathbf{D}}_i^\top \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i, \end{aligned} \quad (40.4.6)$$

with hats denoting evaluation at $\hat{\beta}_m, \hat{\alpha}, \hat{\phi}$; $\hat{\mathbf{A}}_m$ is m times the sample version of the $\mathbf{A}_m$ of (E6). Then $m \hat{\mathbf{V}}_R \rightarrow \mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}$ in probability, and the Wald statistic of a hypothesis $\mathbf{A}^\top \beta$ of rank q , formed with $\hat{\mathbf{V}}_R$, tends to $\chi^2(q)$.

- (d) **When the model-based covariance is valid.** If the working covariance is correct, $\mathbf{V}_i = \Sigma_i^0$, then $\mathbf{B} = \mathbf{A}$ and Eq. 40.4.5 reduces to $\mathbf{A}^{-1}$, which the **model-based** estimator $\hat{\mathbf{V}}_M = (\sum_i \hat{\mathbf{D}}_i^\top \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i)^{-1}$ estimates consistently. Otherwise $\hat{\mathbf{V}}_M$ is inconsistent, in either direction.

Proof.

- (a) At $\beta = \beta^0$ the matrices $\mathbf{D}_i$ and $\mathbf{V}_i$ are deterministic — they depend on the data only through β , which is held fixed — so $E \mathbf{U}_m = \sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} E\{\mathbf{Y}_i - \mu_i(\beta^0)\} = \mathbf{0}$ by Eq. 40.4.1. Nothing about $\mathbf{R}_i$ enters, and that is the whole source of the method's robustness.
- (b) and (c). Expand $\mathbf{U}_m(\beta; \alpha)$ about β^0 at $\alpha = \hat{\alpha}$. Since $\mathbf{U}_m$ is vector-valued, no single intermediate point serves, so we use the integral form of Taylor's theorem:

$$\begin{aligned} \mathbf{0} &= \mathbf{U}_m(\hat{\beta}_m; \hat{\alpha}) = \mathbf{U}_m(\beta^0; \hat{\alpha}) + \bar{\mathbf{M}}_m(\hat{\beta}_m - \beta^0), \\ \bar{\mathbf{M}}_m &= \int_0^1 \frac{\partial \mathbf{U}_m}{\partial \beta^\top}(\beta^0 + t(\hat{\beta}_m - \beta^0)) dt. \end{aligned}$$

Three facts give the result.

The derivative. $\partial \mathbf{U}_m / \partial \beta^\top = -\sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i + \mathbf{T}_m$, where $\mathbf{T}_m$ collects the terms in which the derivative falls on $\mathbf{D}_i^\top \mathbf{V}_i^{-1}$ and therefore still multiplies $\mathbf{Y}_i - \mu_i$. Each summand of $\mathbf{T}_m$ has mean zero at β^0 and bounded variance by (E1), (E2) and (E4), so $m^{-1} \mathbf{T}_m \rightarrow \mathbf{0}$ in probability by the weak law for independent summands; and $m^{-1} \sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i \rightarrow \mathbf{A}$ by (E6). Hence $m^{-1} \partial \mathbf{U}_m / \partial \beta^\top \rightarrow -\mathbf{A}$, uniformly for β in a neighbourhood of β^0 under (E2); the convergence being uniform over that neighbourhood, $m^{-1} \bar{\mathbf{M}}_m \rightarrow -\mathbf{A}$ as well, once $\hat{\beta}_m$ is in it.

The score. $m^{-1/2} \mathbf{U}_m(\beta^0; \alpha^*)$ is $m^{-1/2}$ times a sum of m independent mean-zero vectors $\mathbf{s}_i = \mathbf{D}_i^\top \mathbf{V}_i^{-1}(\mathbf{Y}_i - \mu_i)$ with $\sum_i \text{Cov}(\mathbf{s}_i) = m\mathbf{B}_m$. Conditions (E1)–(E4) bound $E\|\mathbf{s}_i\|^4$ uniformly, which gives the Lyapunov condition, so the Lindeberg–Feller theorem applies and $m^{-1/2} \mathbf{U}_m \rightarrow N_p(\mathbf{0}, \mathbf{B})$.

Estimating α does not matter. Differentiating Eq. 40.4.3 with respect to α leaves the factor $\mathbf{Y}_i - \boldsymbol{\mu}_i$ untouched, so $\partial \mathbf{U}_m / \partial \alpha^\top$ at $\boldsymbol{\beta}^0$ is again a sum of mean-zero terms and $m^{-1} \partial \mathbf{U}_m / \partial \alpha^\top \rightarrow \mathbf{0}$. Therefore $m^{-1/2} \mathbf{U}_m(\boldsymbol{\beta}^0; \hat{\alpha}) = m^{-1/2} \mathbf{U}_m(\boldsymbol{\beta}^0; \alpha^*) + \{m^{-1} \partial \mathbf{U}_m / \partial \alpha^\top\} \sqrt{m}(\hat{\alpha} - \alpha^*) = m^{-1/2} \mathbf{U}_m(\boldsymbol{\beta}^0; \alpha^*) + o_p(1)$ by (E5).

Combining, $\sqrt{m}(\hat{\boldsymbol{\beta}}_m - \boldsymbol{\beta}^0) = \mathbf{A}^{-1} m^{-1/2} \mathbf{U}_m(\boldsymbol{\beta}^0) + o_p(1)$, which is Eq. 40.4.5. For (c), $\mathbf{r}_i \mathbf{r}_i^\top$ has mean $\boldsymbol{\Sigma}_i^0 + O(m^{-1})$ at $\hat{\boldsymbol{\beta}}_m$, and the argument of Theorem 21.4.2 with the cluster in place of the observation — the version already used for Proposition 33.4.1(b) — gives $m^{-1} \sum_i \hat{\mathbf{D}}_i^\top \hat{\mathbf{V}}_i^{-1} \mathbf{r}_i \mathbf{r}_i^\top \hat{\mathbf{V}}_i^{-1} \hat{\mathbf{D}}_i \rightarrow \mathbf{B}$. The Wald limit follows from Eq. 40.4.5 and the continuous mapping theorem.

(d) If $\mathbf{V}_i = \boldsymbol{\Sigma}_i^0$ then $\mathbf{D}_i^\top \mathbf{V}_i^{-1} \boldsymbol{\Sigma}_i^0 \mathbf{V}_i^{-1} \mathbf{D}_i = \mathbf{D}_i^\top \mathbf{V}_i^{-1} \mathbf{D}_i$ for every i , so $\mathbf{B}_m = \mathbf{A}_m$.

■

Remark (What is proved and what is assumed). The existence of a consistent root and the uniform control of the derivative are the two places where the argument leans on standard machinery rather than its own steam; both go exactly as for Theorem 34.5.1, using the concavity-free argument for estimating equations in Liang and Zeger (1986). Condition (E5) is a real assumption: moment estimators of α from Pearson residuals are $\sqrt{m}$ -consistent under (E1)–(E4), but an unstructured $\mathbf{R}$ estimated from few clusters is not. Note the notation: $\mathbf{U}_m$ is the *estimating function*, as in Chapter 38, while a hatted $\mathbf{V}$ with a letter subscript is a *covariance estimator* for $\hat{\boldsymbol{\beta}}$, as in Chapter 21; $\mathbf{V}_i$, with a cluster subscript, remains the working covariance of cluster i .

Warning (The mean model must hold for the whole cluster). Eq. 40.4.1 constrains $E(\mathbf{Y}_i)$, the mean of the whole cluster vector, and part (a) uses it in that form; what one usually has in mind is the weaker $E(Y_{ij} | \mathbf{x}_{(ij)}) = h(\mathbf{x}_{(ij)}^\top \boldsymbol{\beta})$. A *non-diagonal* $\mathbf{R}_i$ mixes observations across occasions, so unbiasedness then needs the **full-covariate conditional mean** condition $E(Y_{ij} | \mathbf{X}_i) = h(\mathbf{x}_{(ij)}^\top \boldsymbol{\beta})$: the mean at occasion j must not depend on the covariates at other occasions. With time-varying covariates and feedback — this year's investment changing next year's market value, a dose adjusted in response to last month's reading — that fails even though the occasion-by-occasion mean model is correct, and a non-diagonal working correlation is then *inconsistent* while independence GEE is not (Pepe and Anderson 1994; Diggle, Heagerty, Liang and Zeger 2002, chapter 12).

Idea. The asymptotics are in m , the number of clusters; the total sample size is irrelevant. A trial with ten thousand patients in six hospitals has six independent pieces of information about anything that varies between hospitals, and the sandwich cannot manufacture more — the lesson of Section 33.2.

40.4.3 Travel-mode choice

Example. (Four options per traveller)

Each of 210 travellers between Australian cities chose one of four modes — air, train, bus, car — and the data record, for every traveller and every mode, the terminal waiting time and a generalized cost. Take $Y_{ij} = 1$ if traveller i chose mode j , fit a logistic model with

mode indicators, waiting time and cost, and treat each traveller as a cluster of $n_i = 4$. The sample deliberately over-represents the rarer modes, so by [Theorem 35.5.1](#) the mode indicators and the intercept are shifted by the sampling design and are not population quantities; the within-traveller coefficients are unaffected, and standard errors are the point here in any case.

The four records of a traveller are anything but independent: exactly one is a 1. An independence working correlation gives the same coefficients as ordinary logistic regression, so the question is only what the standard errors should be. The ratio of the sandwich standard error to the model-based one ranges from 0.694 to 1.558 across the six coefficients: for terminal waiting time, whose coefficient is -1.0693 per ten minutes, the sandwich standard error is 1.558 times larger (0.1698 against 0.1090); for generalized cost, whose coefficient is -0.0098 per ten dollars, it is 0.694 times as large (0.0138 against 0.0199).

The sandwich is not a device for making standard errors bigger. Negative within-cluster correlation makes *within-cluster contrasts* better determined than independence would suggest, and cost is such a contrast; waiting time is confounded with the mode indicators, which the traveller's single choice constrains, and is therefore worse determined. Two further observations. The Pearson dispersion estimate is 5.155, which looks like extreme overdispersion and means nothing: Bernoulli responses carry no information about a dispersion parameter ([Proposition 40.2.1](#)(b) with $N_i = 1$). And the exchangeable working correlation estimate is -0.3015 , close to the smallest value $-1/(n_i - 1) = -1/3$ an exchangeable matrix of size four can have: there the smallest eigenvalue of $\mathbf{R}$ is $1 + 3\hat{\alpha} = 0.0956$. An almost singular structure is a bad working covariance, and independence is the sensible choice.

```

40.4.4 Small samples, and a simulation

The sandwich [Eq. 40.4.6](#) replaces Σ_i^0 by $\mathbf{r}_i \mathbf{r}_i^\top$, and the residuals are too small because $\hat{\beta}_m$ was fitted to them; the bias is of order p/m and downward, exactly as for [Theorem 21.4.2](#) and [Exercise \(C2\)](#). Two standard repairs, both used in [Example \(Coverage when the working correlation is wrong\)](#):

- **Bias-corrected residuals.** Mancl and DeRouen (2001) replace $\mathbf{r}_i$ by $(\mathbf{I} - \mathbf{H}_i)^{-1} \mathbf{r}_i$, with $\mathbf{H}_i = \mathbf{D}_i (\sum_k \mathbf{D}_k^\top \mathbf{V}_k^{-1} \mathbf{D}_k)^{-1} \mathbf{D}_i^\top \mathbf{V}_i^{-1}$ cluster i 's leverage block — the clustered analogue of the HC3 correction of [Definition 21.4.1](#). Kauermann and Carroll (2001) use $(\mathbf{I} - \mathbf{H}_i)^{-1/2}$, which corrects less.
- **A t reference.** Replace the normal quantile by t_{m-p} . With $m = 15$ and $p = 3$ this widens a 95% interval by $t_{12,0.975}/z_{0.975} = 2.179/1.960$, about eleven per cent.

Example. (Coverage when the working correlation is wrong)

Generate clusters of $n_i = 8$ binary responses from a random-intercept logistic model with $\tau = 1.5$, one covariate varying within the cluster and one fixed for the whole cluster (a treatment assigned to clusters), and fit the marginal model by GEE with an *independence* working correlation — wrong by construction. The target is the marginal cluster-level coefficient, which [Eq. 40.1.3](#) puts at 0.5748 when the conditional coefficient is 0.8. Over 600 replications at $m = 240$ the mean estimate is 0.5681: consistent for the marginal coefficient, and not for the conditional one.

The three intervals behave quite differently. The model-based interval covers 0.757 of the time and does not improve with m : it is wrong, not merely imprecise. The sandwich covers 0.913 at $m = 15$ and 0.947 at $m = 240$, and the bias-corrected sandwich with a t reference covers 0.973 at $m = 15$ — slightly conservative, which at that sample size is the right side to err on.

40.4.5 What GEE does not give

No likelihood. [Eq. 40.4.3](#) is not the derivative of anything in general, so there is no deviance, no likelihood ratio test, and no AIC or BIC. Nested mean models are compared by Wald tests built on [Eq. 40.4.6](#) or by score-type tests built on [Eq. 40.4.3](#) under the null; selection uses QIC, the quasi-likelihood analogue of AIC ([Section 40.5](#)). Reporting a “deviance” from GEE output is a category error.

No random effects and no distribution. There is nothing to predict, so if the object of interest is a cluster — which hospital is doing badly, which firm is unusually profitable — GEE has no answer and [Proposition 40.2.3](#) has no analogue; and because only the mean is modelled, the fit cannot be simulated from, cannot give a prediction interval, and cannot be checked by an envelope or posterior predictive method.

Few clusters. Everything above is asymptotic in m . Below about forty clusters the sandwich needs correcting, and below about fifteen no correction reliably saves it; a likelihood-based

Figure 40.4.1: GEE with a wrong working correlation. (a) Coverage of nominal 95% intervals for the marginal coefficient of a cluster-level covariate, against the number of clusters, for three covariance estimators. (b) The sampling distribution of $\hat{\beta}_2$ at $m = 240$, against the marginal and conditional values.

method with a covariance model from Definition 33.4.1 is then the better bet.

40.4.6 Missing data

The robustness of Eq. 40.4.3 has a sharp limit. If some responses are not observed, write $R_{ij} = 1$ when Y_{ij} is recorded, so that the estimating function is really $\sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1} (\mathbf{Y}_i - \boldsymbol{\mu}_i)$ with $\mathbf{D}_i = \text{diag}(R_{ij})$. Part (a) of Theorem 40.4.1 needs $E\{\mathbf{D}_i(\mathbf{Y}_i - \boldsymbol{\mu}_i)\} = \mathbf{0}$, a genuine restriction on the missingness.

If the data are **missing completely at random**, $\mathbf{D}_i$ is independent of $\mathbf{Y}_i$, the expectation factorizes, and everything above holds unchanged; the same is true if missingness depends only on covariates that are in the model and fully observed, because the mean model is then still correct conditionally on being observed. But if missingness depends on *previously observed responses* — a patient who was doing badly last visit is more likely to drop out — then $\mathbf{D}_i$ and $\mathbf{Y}_i - \boldsymbol{\mu}_i$ are dependent, the estimating function is biased and GEE is inconsistent. This is the **missing at random** case of Definition 41.1.1, and it is exactly the case in which a likelihood-based analysis remains valid.

That asymmetry is the strongest practical argument for the mixed-model route in longitudinal studies with dropout, and it is not widely enough known. The repair is to weight each cluster's contribution by the inverse of its estimated probability of being observed — the weighted GEE of Robins, Rotnitzky and Zhao (1995), which trades the assumption about the correlation for one about the missingness model. Chapter 41 develops the mechanisms, the ignorability theorem and the alternatives.

40.4.7 Exercises

40.4.7.1 A. Check your understanding

Exercise A1.

Show from [Eq. 40.4.3](#) that with $\mathbf{R}_i = \mathbf{I}$ the estimate $\hat{\boldsymbol{\beta}}$ does not depend on ϕ or on the cluster structure at all, and equals the ordinary generalized linear model estimate. Which quantities *do* depend on the clustering?

Exercise A2.

A trial randomizes clinics to a new protocol and measures a binary outcome on patients within clinics. The investigators want to report “the effect of the protocol on a patient’s odds of recovery”. Which method should they use, and what would a GEE analysis report instead?

40.4.7.2 B. Practice**Exercise B1.**

Take m clusters of size 2, the identity link, $V \equiv 1$, $\phi = 1$, and an exchangeable working correlation with parameter α . Show that [Eq. 40.4.3](#) reduces to weighted least squares with weight matrix $\mathbf{R}^{-1}$, $\mathbf{R} = (1 - \alpha)\mathbf{I} + \alpha\mathbf{J}$, in each cluster, and that when $\mathbf{x}_{(i1)} = \mathbf{x}_{(i2)}$ for every i the estimate does not depend on α at all. Interpret.

Solution. The estimating equation is $\sum_i \mathbf{X}_i^\top \mathbf{R}^{-1}(\mathbf{y}_i - \mathbf{X}_i \boldsymbol{\beta}) = \mathbf{0}$, which is the normal equation of generalized least squares with covariance $\mathbf{R}$. If the two rows of $\mathbf{X}_i$ are equal, $\mathbf{X}_i = \mathbf{1}\mathbf{x}_{(i)}^\top$ and $\mathbf{X}_i^\top \mathbf{R}^{-1} \mathbf{X}_i = (\mathbf{1}^\top \mathbf{R}^{-1} \mathbf{1})\mathbf{x}_{(i)}\mathbf{x}_{(i)}^\top$, $\mathbf{X}_i^\top \mathbf{R}^{-1} \mathbf{y}_i = \mathbf{x}_{(i)} \mathbf{1}^\top \mathbf{R}^{-1} \mathbf{y}_i$. For an exchangeable $\mathbf{R}$, $\mathbf{R}^{-1} \mathbf{1} = \{1/(1 + \alpha)\}\mathbf{1}$, so both sides carry the same scalar factor $1/(1 + \alpha)$ and it cancels. A cluster-constant covariate sees only the cluster mean, and reweighting a mean by an exchangeable covariance does nothing.

Exercise B2.

Let $\mathbf{G}_i$ be any $n_i \times p$ matrix depending on $\boldsymbol{\beta}$ but not on $\mathbf{Y}_i$. Show that $\sum_i \mathbf{G}_i^\top (\mathbf{Y}_i - \boldsymbol{\mu}_i)$ is an unbiased estimating function and that [Eq. 40.4.3](#) is the member with $\mathbf{G}_i = \mathbf{V}_i^{-1} \mathbf{D}_i$. Which member is optimal, in the sense of [Proposition 38.2.3](#), and why is it not available?

Solution. Unbiasedness is immediate from $E(\mathbf{Y}_i - \boldsymbol{\mu}_i) = \mathbf{0}$. The Godambe-optimal choice within this linear class is $\mathbf{G}_i = (\boldsymbol{\Sigma}_i^0)^{-1} \mathbf{D}_i$, the *true* covariance in place of the working one; [Proposition 38.2.3](#) is the same statement with $n_i = 1$. It is unavailable because $\boldsymbol{\Sigma}_i^0$ is unknown, which is precisely what makes a working correlation necessary.

40.4.7.3 C. Going deeper**Exercise C1.**

Show that if $\mathbf{V}_i = \boldsymbol{\Sigma}_i^0$ then $\mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-1} = \mathbf{A}^{-1}$ is the smallest asymptotic covariance attainable in the class of [Exercise \(B2\)](#), in the nonnegative-definite ordering. (Hint: for

any $\mathbf{G}_i$, compare $(\sum \mathbf{G}_i^\top \mathbf{D}_i)^{-1} (\sum \mathbf{G}_i^\top \Sigma_i^0 \mathbf{G}_i) (\sum \mathbf{D}_i^\top \mathbf{G}_i)^{-1}$ with $\mathbf{A}^{-1}$ using a Cauchy–Schwarz argument in the inner product $\langle \mathbf{a}, \mathbf{b} \rangle = \sum_i \mathbf{a}_i^\top \Sigma_i^0 \mathbf{b}_i$.

40.5 Working correlation

[Theorem 40.4.1](#) says the working correlation may be wrong without costing consistency. It does not say the choice is free. A wrong one costs *efficiency*, changes the small-sample behaviour of the sandwich, and — because it changes the estimate — can be turned into a diagnostic for the mean model.

40.5.1 The catalogue

The structures in use are those of [Definition 33.4.1](#), written as correlation matrices and estimated by moments rather than by likelihood. For a cluster with n_i observations at occasions $j = 1, \dots, n_i$, and Pearson residuals $r_{ij} = (y_{ij} - \hat{\mu}_{ij}) / \sqrt{V(\hat{\mu}_{ij})}$ with $\hat{\phi} = \sum_{ij} r_{ij}^2 / (n - p)$:

Structure	$(\mathbf{R}_i)_{jk}, j \neq k$	Parameters
independence	0	0
exchangeable	α	1
first-order autoregressive	$\alpha^{ j-k }$	1
q -dependent	$\alpha_{ j-k }$ if $ j - k \leq q$, else 0	q
unstructured	α_{jk}	$n(n - 1)/2$

The parameters are estimated by matching averages of residual products. Writing $N_p = \sum_i \binom{n_i}{2}$ for the within-cluster pairs and $N_a = \sum_i (n_i - 1)$ for the adjacent ones,

$$\hat{\alpha}_{\text{exch}} = \frac{1}{\hat{\phi} (N_p - p)} \sum_i \sum_{j < k} r_{ij} r_{ik}, \quad \hat{\alpha}_{\text{ar}} = \frac{1}{\hat{\phi} (N_a - p)} \sum_i \sum_{j < n_i} r_{ij} r_{i,j+1},$$

and $\hat{\alpha}_{jk} = \sum_i r_{ij} r_{ik} / (\hat{\phi} m)$, rescaled to have unit diagonal, for the unstructured case; the q -dependent estimates are lag-by-lag averages of the same kind.

The design narrows the list at once. The unstructured matrix needs a common set of occasions across clusters and costs $n(n - 1)/2$ parameters; the autoregressive structure needs an ordering, so it is for longitudinal data and not for pupils in a school; the exchangeable structure is the one a random intercept induces ([Proposition 40.2.1](#)), and is the default for clustered data with no natural order. And every estimated $\mathbf{R}_i$ must be a valid correlation matrix, which the moment estimates above do not guarantee — [Example \(Four options per traveller\)](#) showed the exchangeable estimate landing almost exactly on the boundary.

```

40.5.2 Efficiency, and where it comes from

Proposition 40.5.1 — Choosing the working correlation

In the setting of [Theorem 40.4.1](#):

- (a) **Efficiency.** The asymptotic covariance $\mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}$ of [Eq. 40.4.5](#) is minimized, in the nonnegative-definite ordering and over all unbiased estimating functions linear in $\mathbf{Y}_i - \boldsymbol{\mu}_i$, by $\mathbf{V}_i = \boldsymbol{\Sigma}_i^0$ ([Exercise \(C1\)](#)). Any other working covariance costs efficiency, but the cost depends on the covariate: it is substantial for a covariate that varies *within* clusters and negligible for one that is constant within a cluster, for which the independence choice is in fact hard to beat.
- (b) **Small samples.** The sandwich [Eq. 40.4.6](#) is biased downwards by a term of order p/m , so Wald tests built on it reject too often when m is small; the bias-corrected forms of [Section 40.4](#) and a t_{m-p} reference repair most of it. The bias grows with the number of parameters in $\mathbf{R}_i$, because $\hat{\boldsymbol{\alpha}}$ is then noisier and condition (E5) of [Theorem 40.4.1](#) is stretched.

- (c) **QIC**. Since there is no likelihood, AIC is unavailable. Pan's **quasi-likelihood information criterion** replaces the log-likelihood by the quasi-likelihood $Q(\boldsymbol{\mu}; \mathbf{y}) = \sum_{ij} \int_{y_{ij}}^{\mu_{ij}} (y_{ij} - t) / \{\phi V(t)\} dt$ of [Definition 38.2.1](#) computed under the *independence* working correlation at the fitted $\hat{\boldsymbol{\mu}}$, with ϕ the Pearson estimate of [Proposition 38.3.2](#) held fixed across the models compared, and replaces the parameter count by a sandwich-based trace:

$$\text{QIC} = -2Q(\hat{\boldsymbol{\mu}}; \mathbf{y}) + 2 \text{tr}(\hat{\boldsymbol{\Omega}}_I \hat{\mathbf{V}}_R), \quad (40.5.1)$$

where $\hat{\boldsymbol{\Omega}}_I = \sum_i \hat{\mathbf{D}}_i^\top (\hat{\mathbf{A}}_i^V)^{-1} \hat{\mathbf{D}}_i / \phi$ is the independence-model information and $\hat{\mathbf{V}}_R$ is [Eq. 40.4.6](#). If the working model is correct the trace is p and [Eq. 40.5.1](#) is the Akaike form [Definition 29.2.2](#). It is a sound criterion for choosing the *mean model*, and a weakly justified one for choosing $\mathbf{R}_i$.

Proof.

- (a) is [Exercise \(C1\)](#); the covariate-dependence is illustrated in [Example \(How much efficiency is at stake\)](#) and explained after it. (b) is the cluster version of the bias calculation in [Exercise \(C2\)](#), applied to $\hat{\mathbf{D}}_i^\top \hat{\mathbf{V}}_i^{-1} \mathbf{r}_i$ in place of $\mathbf{X}_g^\top \hat{\boldsymbol{\epsilon}}_g$. (c) is a definition; the claim that the trace equals p when the working model is correct is [Theorem 40.4.1\(d\)](#), which gives $\hat{\mathbf{V}}_R \rightarrow \mathbf{A}^{-1}$, together with $\boldsymbol{\Omega}_I = \mathbf{A}$ when $\mathbf{R}_i = \mathbf{I}$ is correct. ■

Remark (Why QIC is weak as a chooser of correlation). [Eq. 40.5.1](#) measures fit by a quasi-likelihood that ignores the correlation altogether, and penalizes by a trace that is smallest when the sandwich is closest to the model-based covariance. Changing $\mathbf{R}_i$ therefore moves QIC through the penalty almost alone, and rewards whichever structure makes the sandwich small — not whichever is right. Pan (2001) proposed it primarily for the mean model, and Hin and Wang (2009) give a variant (CIC) that drops the fit term for correlation selection. Neither has the standing AIC has for likelihoods.

Example. (How much efficiency is at stake)

Simulate 60 clusters of 6 Poisson counts with a log link, one covariate varying within the cluster and one constant within it, and generate the dependence in two ways: a shared random intercept, which makes the true correlation exchangeable, and a latent Gaussian AR(1) process with $\rho = 0.8$. Fit by GEE with each of the four working correlations and record the sampling variance of each coefficient over 400 replications.

For the **within-cluster** covariate under exchangeable truth, the efficiency of the exchangeable working correlation relative to independence is 1.789; AR(1) and unstructured reach 1.583 and 1.547. Under AR(1) truth the figures are 1.282 for AR(1), 1.183 for exchangeable and 1.160 for unstructured. Matching the truth helps, mismatching it still helps, and the gain is worth having without being dramatic.

For the **cluster-level** covariate the ranking reverses: under exchangeable truth the relative efficiencies are 0.889, 0.938 and 0.834, all below one, so independence is best of the four. The reason is [Exercise \(B1\)](#): a covariate constant within a cluster is estimated from cluster means, on which an exchangeable reweighting has no effect at all, so all a

Figure 40.5.1: Efficiency of four working correlations relative to the independence choice, for a within-cluster and a cluster-level covariate, over 400 replications with $m = 60$ clusters of $n_i = 6$ Poisson counts. (a) The true dependence is exchangeable (a shared random intercept). (b) The true dependence is a latent AR(1) process with $\rho = 0.8$. Bars above one mean more efficient than independence.

nontrivial $\mathbf{R}_i$ contributes is the noise in $\hat{\alpha}$.

40.5.3 A diagnostic hiding in the efficiency

By Theorem 40.4.1(a), every working correlation estimates the *same* β^0 , provided the mean model Eq. 40.4.1 is right. Two estimates of the same quantity differing by more than their sampling error therefore accuse the mean model, not the correlation. This is the Hausman idea, and it has real diagnostic value because the independence and exchangeable estimates weight within- and between-cluster variation differently: independence is dominated by between-cluster comparisons when clusters are large, and a nontrivial $\mathbf{R}_i$ shifts weight towards within-cluster ones.

Example. (Grunfeld's panel by GEE)

Fit the marginal version of Example (Grunfeld's firms, again) — gamma variance function $V(\mu) = \mu^2$, log link, investment on log value and log capital — to the 11 firms by GEE. The AR(1) working correlation estimates a lag-one correlation of 0.894, as one expects of annual investment figures. Yet QIC, with the dispersion held at the independence estimate of the larger model, ranks the four structures

Structure	QIC, value and capital	QIC, value only
independence	8450.1	8657.6
exchangeable	8524.2	8647.4
AR(1)	8574.1	8657.8
unstructured	8754.7	8704.1

and prefers independence. As a comparison of *mean* models the table is informative: at three of the four structures the model with capital wins, by between about 80 and 210 QIC units, and that is the comparison QIC was designed for. Under the unstructured correlation the ranking reverses, which with 11 clusters and a 20×20 matrix to estimate is a comment on the structure rather than on the model. As a comparison of structures the column mostly reports that the sandwich is smallest under independence — the remark above in numerical form.

The estimates themselves are the more interesting output. The independence fit gives $\hat{\beta}_{\text{value}} = 0.8421$ and $\hat{\beta}_{\text{capital}} = 0.3386$; the exchangeable fit gives 0.7214 and 0.2113. The gap in the first coefficient is more than its sandwich standard error of 0.1030, and the two gaps point the same way. By [Theorem 40.4.1\(a\)](#) that accuses the mean model, and two standard explanations fit equally well: firm effects correlated with the covariates, as [Example \(Grunfeld's firms, again\)](#) found, or feedback from investment to the following years' market value, which violates the full-covariate conditional mean condition and makes the exchangeable fit — not the independence one — the inconsistent member of the pair. Either way the remedy is to separate the two sources of variation. Adding the firm means of log value and log capital, as [Exercise \(C1\)](#) asks, makes the independence and exchangeable estimates agree to machine precision, at within-firm slopes 0.6142 and 0.2298, both well below the independence figures above.

```
import statsmodels.api as sm

d = sm.datasets.grunfeld.load_pandas().data.sort_values(["firm", "year"])
m, n = d["firm"].nunique(), 20
y = d["invest"].to_numpy().reshape(m, n)
lv = np.log(d["value"].to_numpy()).reshape(m, n)
lc = np.log(d["capital"].to_numpy()).reshape(m, n)

def qic(y, X, kind, phi):
    """Pan's QIC: the quasi-likelihood of the independence model at the fitted mean,
    plus a
    penalty built from the sandwich. For  $V(\mu) = \mu^2$  the quasi-likelihood is  $-y/\mu - \log \mu$ .
    The dispersion  $\phi$  is held fixed across the models compared, as in Mallows's  $C_p$ .
    """
    beta, robust, _, _ = gee(y, X, kind, family="gamma")
    mu = np.exp(X @ beta)
    Q = np.sum(-y / mu - np.log(mu)) / phi
    omega = np.einsum("mjp,mjq->pq", X, X) / phi      # independence information, log
    link
    return -2 * Q + 2 * np.trace(omega @ robust)

X_full = np.stack([np.ones((m, n)), lv, lc], axis=2)
X_small = np.stack([np.ones((m, n)), lv], axis=2)
phi_ref = gee(y, X_full, "independence", family="gamma")[2]      # from the largest
model

for name, XX in [("value + capital", X_full), ("value only", X_small)]:
    for kind in KINDS:
        print(f"{name:16s} {kind:14s} QIC {qic(y, XX, kind, phi_ref):10.2f}")
```

40.5.4 Practical advice

- **Count the clusters first.** Everything here that uses a sandwich needs m large. Below about forty clusters use a bias correction and a t reference; below about fifteen, prefer a likelihood-based model with a covariance structure chosen by REML ([Proposition 33.4.1](#)) and accept the assumptions.
- **Match the structure to the design, not to the data.** Exchangeable for unordered clusters, autoregressive for equally spaced longitudinal data, unstructured only when the occasions are common to all clusters and m is large.
- **Use independence when the covariates are time-varying, or the covariate of interest is cluster-level.** In the first case a non-diagonal $\mathbf{R}_i$ needs the full-covariate conditional mean condition of [Section 40.4](#), which feedback destroys; in the second it loses nothing ([Example \(How much efficiency is at stake\)](#)). Independence needs neither, estimates nothing extra, and cannot produce an invalid $\mathbf{R}_i$.
- **Compare structures to check the mean model.** A large difference between the independence and exchangeable estimates is a warning about $\mathbf{X}$, not about $\mathbf{R}_i$.
- **Say which covariance you report**, and never put a GEE coefficient and a GLMM coefficient in the same table as if they estimated the same thing. The first costs coverage ([Example \(Coverage when the working correlation is wrong\)](#)); the second is the commonest error in this literature.

Remark (Beyond correlations). For binary responses a correlation is an awkward measure of dependence, because the Fréchet bounds on the joint cell probability confine it to an interval that depends on the two means, while a pairwise odds ratio is free in $(0, \infty)$ whatever the means are. **Alternating logistic regressions**, due to Carey, Zeger and Diggle (1993), exploit this: they replace $\mathbf{R}_i$ by a model for the pairwise odds ratios and alternate between the mean equation [Eq. 40.4.3](#) and a logistic regression for the association, whose parameters are unconstrained and interpretable in their own right.

40.5.5 Exercises

40.5.5.1 A. Check your understanding

Exercise A1.

For each design, name the working correlation you would use and say why: (a) pupils within 300 schools, class size varying; (b) five annual measurements on each of 500 patients; (c) left and right eyes of 80 patients; (d) irregularly timed clinic visits, between two and eleven per patient, 1200 patients.

Exercise A2.

In [Example \(Grunfeld's panel by GEE\)](#), QIC prefers independence among the working correlations but the AR(1) parameter is estimated at 0.894. Are these two statements in conflict? Explain what each of them is measuring.

40.5.5.2 B. Practice

Exercise B1.

Show that the exchangeable correlation matrix $\mathbf{R} = (1 - \alpha)\mathbf{I} + \alpha\mathbf{1}\mathbf{1}^\top$ of size n has eigenvalues $1 + (n - 1)\alpha$ (once) and $1 - \alpha$ ($n - 1$ times), so that it is positive definite exactly when $-1/(n - 1) < \alpha < 1$. Verify the value $1 + 3\hat{\alpha} = 0.0956$ quoted in [Example \(Four options per traveller\)](#) from $\hat{\alpha} = -0.3015$, and say what a practitioner should do when a moment estimate falls outside the range.

Solution. $\mathbf{R} = (1 - \alpha)\mathbf{I} + \alpha\mathbf{1}\mathbf{1}^\top$; $\mathbf{1}$ is an eigenvector with eigenvalue $(1 - \alpha) + n\alpha = 1 + (n - 1)\alpha$, and any vector orthogonal to $\mathbf{1}$ has eigenvalue $1 - \alpha$. Positivity of both gives the range. With $\hat{\alpha} = -0.3015$ and $n = 4$, $1 + 3(-0.3015) = 1 - 0.9045 = 0.0955$, which matches the quoted 0.0956 to rounding. Outside the range the working covariance is not a covariance at all and the update [Eq. 40.4.4](#) can diverge; the usual remedies are to shrink $\hat{\alpha}$ towards zero, to project $\mathbf{R}$ onto the nearest correlation matrix, or — better — to use the independence structure, which is never invalid.

Exercise B2.

Formalize the diagnostic of [Example \(Grunfeld's panel by GEE\)](#). Let $\hat{\boldsymbol{\beta}}_I$ and $\hat{\boldsymbol{\beta}}_E$ be the independence and exchangeable GEE estimates. Explain why $\hat{\boldsymbol{\beta}}_I - \hat{\boldsymbol{\beta}}_E$ has mean zero to first order when the mean model is correct, and why its covariance is *not* the difference of the two covariances in general. What resampling scheme would give a usable reference distribution?

Solution. Both estimates satisfy [Eq. 40.4.5](#) with the same $\boldsymbol{\beta}^0$, so their difference is $o_p(1)$ and, after scaling, asymptotically normal with mean zero. The classical Hausman simplification $\text{Cov}(\hat{\boldsymbol{\beta}}_1 - \hat{\boldsymbol{\beta}}_2) = \text{Cov}(\hat{\boldsymbol{\beta}}_2) - \text{Cov}(\hat{\boldsymbol{\beta}}_1)$ needs one of the two to be *efficient*, which neither is here, so the covariance must be obtained from the joint asymptotic distribution of the two estimating functions or by resampling. The cluster bootstrap of [Exercise \(C1\)](#) — resample whole clusters with replacement and refit both — gives the reference distribution directly.

40.6 Summary and Notes

40.6.1 Summary

Idea.

1. A nonlinear link and a random effect do not commute, so a clustered model has two sets of coefficients. The identity and log links are the exceptions; for the probit the marginal coefficient is $\beta^C / \sqrt{1 + \tau^2}$ exactly, and for the logit it is strictly attenuated with local factor $1 - \text{Var}(P_\theta) / \{E P_\theta E(1 - P_\theta)\}$ ([Proposition 40.1.1](#)).
2. The generalized linear mixed model puts random effects in the linear predictor of a generalized linear model ([Definition 40.2.1](#)). Its marginal moments follow by conditioning: a binomial response acquires the beta-binomial overdispersion factor, and a Poisson–lognormal response acquires *exactly* the NB2 variance function

([Proposition 40.2.1](#)).

3. A cluster-level random intercept can only induce nonnegative within-cluster correlation, because two nondecreasing functions of one random variable have nonnegative covariance ([Lemma 40.2.2](#)). Data with competition inside a cluster need a different tool.
4. Predicting a random effect in a GLMM is empirical Bayes rather than BLUP, but the shrinkage survives: the posterior mode lies strictly between zero and the cluster's own estimate, with the familiar factor $\tau^2/(\tau^2 + I_i^{-1})$ to first order ([Proposition 40.2.3](#)).
5. The integrated likelihood factorizes over independent clusters. The Laplace approximation has relative error $O(n_i^{-1})$ — governed by the observations *per cluster*, not by the sample size — and adaptive Gauss–Hermite quadrature with $K = 1$ node is exactly the Laplace approximation ([Theorem 40.3.1](#)).
6. Penalized quasi-likelihood is Henderson's mixed-model equations applied to the working response, and is inconsistent: it attenuates both $\hat{\beta}$ and $\hat{\theta}$, badly for binary data in small clusters ([Proposition 40.3.2](#), [Example \(Three methods on clustered binary data\)](#)).
7. Generalized estimating equations solve $\sum_i \mathbf{D}_i^\top \mathbf{V}_i^{-1}(\mathbf{Y}_i - \boldsymbol{\mu}_i) = \mathbf{0}$ with a working correlation the analyst chooses and does not have to believe ([Definition 40.4.1](#)). The estimating function is unbiased for every working correlation, so $\hat{\beta}$ is consistent for the marginal coefficient and asymptotically normal with the sandwich covariance $\mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}$ ([Theorem 40.4.1](#)).
8. GEE gives no likelihood, no random-effect predictions and no distribution; a non-diagonal working correlation also needs the mean model to hold conditionally on the *whole* covariate history, which feedback destroys; and it fails under missingness that depends on previously observed responses — the one case in which a likelihood-based analysis still works ([Section 40.4](#)).
9. A wrong working correlation costs efficiency for covariates that vary within clusters and nothing at all for covariates fixed within a cluster; the sandwich needs a small-sample correction below about forty clusters; and QIC, the quasi-likelihood analogue of AIC, is sound for mean models and weak for correlation structures ([Proposition 40.5.1](#)).
10. Because every working correlation targets the same β^0 , a large gap between two GEE fits of the same mean model is evidence against the *mean model* ([Example \(Grunfeld's panel by GEE\)](#)).

40.6.2 Notes and sources

Coverage. The topics follow Agresti (2015, sections 9.4–9.6) and Fahrmeir, Kneib, Lang and Marx (2021, sections 7.5–7.6), but put the marginal–conditional distinction first, before either estimation method, because that is where the choice between the two traditions is actually made. Book-length treatments are Diggle, Heagerty, Liang and Zeger (2002) for longitudinal data, McCulloch, Searle and Neuhaus (2008) for the mixed-model theory, and Molenberghs and Verbeke (2005) for discrete longitudinal responses.

Marginal versus conditional. The distinction was made precise for binary data by Neuhaus, Kalbfleisch and Hauck (1991), still the clearest statement of what each coefficient means and when the two agree. The approximation factor $(1 + c^2\tau^2)^{-1/2}$ with $c = 16\sqrt{3}/(15\pi)$ is from

Zeger, Liang and Albert (1988); the constant comes from matching the logistic and normal distributions and predates its use here by a long way. The proof of [Proposition 40.1.1\(d\)](#) given above, through the derivative identity [Eq. 40.1.5](#), seems to be the shortest route to the strict inequality, and needs no assumption on the random-effect distribution beyond non-degeneracy. The median odds ratio of [Exercise \(B1\)](#) was popularized in epidemiology by Larsen and Merlo (2005).

Fitting. Breslow and Clayton (1993) introduced penalized quasi-likelihood under that name and set the pattern for GLMM software for a decade; Breslow and Lin (1995) and Lin and Breslow (1996) quantified its bias and proposed corrections. Adaptive Gauss–Hermite quadrature for this problem is due to Liu and Pierce (1994) and, for nonlinear mixed models, Pinheiro and Bates (1995), who also observed that one adaptive node reproduces the Laplace approximation. The Laplace expansion itself is classical; the form used in [Theorem 40.3.1\(b\)](#) is the one in Tierney and Kadane (1986) and Barndorff-Nielsen and Cox (1989, chapter 3). The asymptotics of the integrated likelihood quoted in [Section 40.2](#) are in McCulloch, Searle and Neuhaus (2008, chapter 14). Monte Carlo EM for this problem is Wei and Tanner (1990), with automated sample-size rules in Booth and Hobert (1999); the MCMC route with iteratively reweighted proposals is Gamerman (1997).

Estimating equations. Liang and Zeger (1986) and Zeger and Liang (1986) introduced GEE, and the pair is worth reading together: the first gives the theory, the second the practice. The conditions and the expansion in [Theorem 40.4.1](#) follow theirs, with the cluster sandwich argument taken from [Theorem 21.4.2](#) as [Section 33.2](#) already arranged it. The warning about time-varying covariates and the full-covariate conditional mean is due to Pepe and Anderson (1994), and is treated at length in Diggle, Heagerty, Liang and Zeger (2002, chapter 12). Small-sample corrections to the sandwich are due to Mancl and DeRouen (2001), Kauermann and Carroll (2001) and Fay and Graubard (2001); the first is used in [Example \(Coverage when the working correlation is wrong\)](#). QIC is Pan (2001); the criticism of it as a selector of working correlations, and the CIC variant, are in Hin and Wang (2009). Alternating logistic regressions are Carey, Zeger and Diggle (1993). The failure of GEE under missingness that depends on observed responses, and the inverse-probability-weighted repair, are from Robins, Rotnitzky and Zhao (1995).

What is new here. [Lemma 40.2.2](#) and its consequence — that a cluster-level random intercept cannot produce negative within-cluster correlation, so that the travel-mode data of [Example \(Four options per traveller\)](#) are outside the reach of any random-intercept GLMM — is elementary, and the association inequality behind it is standard, but we have not seen the two put together as a reason to prefer estimating equations. The efficiency comparison of [Example \(How much efficiency is at stake\)](#) separates within-cluster from cluster-level covariates, making the often-repeated advice “the working correlation hardly matters” precise: it hardly matters for cluster-level covariates and matters by a factor of nearly two for within-cluster ones.

Data and code. Grunfeld’s investment panel is the public-domain eleven-firm version distributed with statsmodels, also used in [Chapter 32](#) and [Chapter 33](#); its provenance is Grunfeld (1958), with the version history discussed by Kleiber and Zeileis (2010). The travel-mode choice data are the public-domain sample of 210 non-business trips between Sydney, Canberra and Melbourne from a 1987 intercity mode-choice study, also distributed with statsmodels; the sample over-represents the rarer modes, as [Example \(Four options per traveller\)](#) notes. The code in `code/ch40/` is written from the formulas in this chapter and checked against statsmodels where an equivalent fit exists; the simulations use fixed seeds.

Chapter 41

Missing Data

Every data set in this book so far has arrived complete. Real ones do not. A respondent skips the question about income, a patient stops coming to the clinic, a sensor fails for three weeks, a laboratory loses a sample. The holes are rarely scattered at random, and the software's silent default — drop every record with a hole in it — is a decision, not a neutral act.

This chapter treats the holes as data. The pattern of what is missing has a distribution of its own, and the subject turns on what that distribution may depend on. If it depends on nothing, almost any analysis survives. If it depends only on what was recorded, likelihood and Bayesian inference survive and most shortcuts do not. If it depends on what was *not* recorded, nothing in the observed data can tell you so. Those three cases organize what follows: when dropping incomplete records is safe, why single imputation lies about precision, what EM is and what it does not give you, how multiple imputation restores the uncertainty imputation destroys, and how to report a conclusion resting on an untestable assumption.

What you need. [Chapter 5](#) and [Chapter 6](#) (the linear model and least squares), [Section 7.3](#) (maximum likelihood [Theorem 7.3.1](#), the score and information [Proposition 7.4.7](#)), [Section 7.6](#) and [Section 12.6](#) (the conjugate Bayesian linear model [Theorem 7.6.2](#) and credible sets [Definition 12.6.1](#)), [Chapter 11](#) (the likelihood ratio test [Theorem 11.4.1](#)). [Section 18.6](#) ([Theorem 18.6.1](#), filling in a lost plot of a designed experiment) is the special case this chapter generalizes. [Chapter 23](#) supplies the bootstrap ([Definition 23.1.1](#)), which is one of the two honest routes to a standard error after EM; [Chapter 25](#) the habit of asking what a coefficient is meant to answer; and [Chapter 34](#) the generalized linear model ([Definition 34.2.1](#), [Theorem 34.3.1](#)), since nothing here is special to a normal response.

41.0.1 Roadmap

- [Multiple imputation](#)
- [Sensitivity analysis](#)
- [Summary and notes](#)

41.1 Missingness mechanisms

A data set with holes carries two kinds of information: the values that were recorded, and the pattern of which values were recorded at all. The second decides whether any analysis of the first means what it appears to. This section gives the pattern a probability model.

41.1.1 Notation

Write the **complete data** as an array $\mathbf{D}$ with n rows and q columns, whose i th row $\mathbf{d}_{(i)}$ holds the variables of unit i . Response and covariates sit in the same array: which is the response is a question for the analysis, not for the mechanism. Alongside it put the **missingness indicator** array $\mathbf{R}$ of the same shape, with $R_{ij} = 1$ when D_{ij} is recorded; $\mathbf{R}$ is free for this use here, as $\mathbf{H}$ was in Chapters 5 and 10.

The array $\mathbf{R}$ is always completely observed, which is what makes it data. Split $\mathbf{D}$ into recorded entries $\mathbf{D}_{\text{obs}}$ and unrecorded ones $\mathbf{D}_{\text{mis}}$. The analyst holds $(\mathbf{D}_{\text{obs}}, \mathbf{R})$; every model here describes $(\mathbf{D}, \mathbf{R})$ by the factorization

$$f(\mathbf{D}, \mathbf{R} \mid \boldsymbol{\theta}, \boldsymbol{\psi}) = f(\mathbf{D} \mid \boldsymbol{\theta}) f(\mathbf{R} \mid \mathbf{D}, \boldsymbol{\psi}). \quad (41.1.1)$$

Here $\boldsymbol{\theta}$ is the parameter the analyst cares about — a regression coefficient lives in it — and the second factor is the **missingness mechanism**. Conditioning it on the *complete* data is the essential move: it lets the probability that a value is recorded depend on the value itself, which is exactly the case that causes trouble. This is the **selection** factorization; [Section 41.6](#) uses the other one.

41.1.2 Three classes

Definition 41.1.1 — **Missing completely at random, at random, not at random**

Let $\mathbf{D}$ and $\mathbf{R}$ have the joint distribution [Eq. 41.1.1](#), and fix the realized values $\mathbf{R} = \mathbf{r}$ and $\mathbf{D}_{\text{obs}} = \mathbf{a}$. The mechanism is

- (a) **missing completely at random** (MCAR) if $f(\mathbf{r} \mid \mathbf{D}, \boldsymbol{\psi}) = f(\mathbf{r} \mid \boldsymbol{\psi})$ for every $\mathbf{D}$ and $\boldsymbol{\psi}$: the pattern is independent of the data, recorded or not;
- (b) **missing at random** (MAR) if $f(\mathbf{r} \mid \mathbf{D}, \boldsymbol{\psi})$ takes the same value for every $\mathbf{D}$ whose observed part is $\mathbf{a}$, and every $\boldsymbol{\psi}$, so that it may be written $f(\mathbf{r} \mid \mathbf{a}, \boldsymbol{\psi})$;
- (c) **missing not at random** (MNAR) otherwise.

MCAR implies MAR, and the two buy different things. Under MCAR the recorded units are a random subsample, so *every* analysis of them estimates what it would have estimated with no losses, at the price of a smaller sample. MAR says less: the recorded units are a biased subsample, but the bias is a function of recorded variables, so a method using those variables correctly can undo it.

Warning. The names have misled generations of readers. “Missing at random” does not mean the holes are haphazard; it means they are haphazard *within each configuration of the recorded values* — a strong assumption in modest language. “Missing completely at random” is the haphazard one.

Definition [Definition 41.1.1](#) states MAR at the realized $(\mathbf{r}, \mathbf{a})$; requiring it at every pattern is stronger, and the distinction is not pedantry. A Bayesian, conditioning on the data in hand, needs only the realized version; a frequentist, averaging over data sets that did not occur, needs the stronger one (Seaman, Galati, Jackson and Carlin, 2013). This chapter states the realized version and flags where the stronger one is wanted.

41.1.3 What each class looks like

Example. (A survey that asks about income)

A survey records age x for everyone and income y for those who answer. Three stories. *Completely at random:* a printing fault left the income question off one batch of forms, assembled without regard to anything, so $\Pr(R = 0 \mid x, y)$ is constant. *At random:* younger respondents skip the question more often, and among respondents of a given age, answering has nothing to do with earnings, so $\Pr(R = 0 \mid x, y) = \Pr(R = 0 \mid x)$. *Not at random:* high earners skip the question at every age, so $\Pr(R = 0 \mid x, y)$ depends on y even given x . The three are mutually exclusive descriptions of the world, and [Proposition 41.1.1](#) says the observed data cannot tell them apart.

So “the mechanism” is a property not of a variable but of the pair (variable, recorded variables). If the survey also recorded occupation, and high earners skip only because they hold occupations whose members skip, the third story becomes MAR once occupation joins $\mathbf{D}_{\text{obs}}$. Enlarging the recorded data can turn MNAR into MAR; it can never do the reverse.

Example. (A record with real gaps)

The weekly averages of the continuous Mauna Loa record of atmospheric carbon dioxide run from March 1958 to December 2001 and cover 2284 weeks, of which 59 carry no value — 2.6% of the record, in 22 runs, the longest of 18 consecutive weeks.

They are not spread evenly. Before 1970, 8.6% of weeks are missing; from 1970 on, 0.4%, and a logistic regression of $1 - R_i$ on calendar time multiplies the odds of a gap by 0.192 per decade. The mechanism depends on a variable recorded for every week, so the record is not MCAR.

Whether it is MAR given time is a question about the instrument, not about the numbers. The published rule is that a day contributes only if the analyser ran steadily for at least six hours, and a week with no such day contributes nothing. So the question is whether the analyser’s failure to deliver six steady hours is related to the concentration it would have read — plausibly not, if the failures are electrical or logistical; plausibly so, if unsettled air both disturbs the instrument and moves the reading. Nothing in [Figure 41.1.1](#) can settle that.

```
import numpy as np
import statsmodels.api as sm
```

Figure 41.1.1: The weekly Mauna Loa record. (a) The series, with a vertical rule at each missing week. (b) The fraction of weeks missing in each calendar year. The mechanism depends strongly on an observed variable, calendar time, and so is not missing completely at random.

```
co2 = sm.datasets.co2.load_pandas().data["co2"]           # one value per week, some
absent
t = co2.index.year + (co2.index.dayofyear - 0.5) / 365.25
r = (~co2.isna()).to_numpy().astype(float)               # 1 = recorded, 0 = missing
n, n_mis = len(r), int((1 - r).sum())
print(f"{n} weeks, {n_mis} missing ({100 * n_mis / n:.1f}%)")

era = (t >= 1970).astype(float)                           # one observed covariate: is
it 1970 or later?
rate_early = 1 - r[era == 0].mean()
rate_late = 1 - r[era == 1].mean()
print(f"missing before 1970: {100 * rate_early:.1f}%   from 1970 on: {100 *
rate_late:.1f}%")
```

One feature of **R** matters for computation rather than validity. A pattern is **monotone** when the columns can be ordered so that $R_{ij} = 0$ forces $R_{ik} = 0$ for $k > j$: once a unit drops out it never returns, as in longitudinal dropout. Such patterns are far easier to handle, the joint density factoring into a chain of conditionals each fitted on a nested subsample ([Exercise \(B1\)](#)).

41.1.4 Why the class cannot be read off the data

Proposition 41.1.1 — The observed data do not identify the mechanism

Let $\mathbf{d} = (d_1, d_2)$ be a unit's record, with d_1 always recorded and d_2 recorded exactly when $R = 1$. The distribution of the observed data is determined by the three pieces $f(d_1)$, $\Pr(R = 1 \mid d_1)$ and $f(d_2 \mid d_1, R = 1)$, and determines nothing else. Consequently:

- (a) for every conditional density $g(d_2 \mid d_1)$ there is exactly one joint distribution of $(\mathbf{d}, R)$ with the given observed-data distribution and with $f(d_2 \mid d_1, R = 0) = g(d_2 \mid d_1)$;

- (b) one of these choices, $g = f(\cdot \mid d_1, R = 1)$, is MAR; every other is MNAR; and all assign the observed data the same likelihood.

Proof. The observed data are (d_1, R) , with d_2 when $R = 1$. Their density is $f(d_1) \Pr(R = 0 \mid d_1)$ on $R = 0$ and $f(d_1) \Pr(R = 1 \mid d_1) f(d_2 \mid d_1, R = 1)$ on $R = 1$; only the three listed pieces enter.

- (a) Given the three pieces and a candidate g , define

$$\begin{aligned} f(d_1, d_2, R = 1) &= f(d_1) \Pr(R = 1 \mid d_1) f(d_2 \mid d_1, R = 1), \\ f(d_1, d_2, R = 0) &= f(d_1) \Pr(R = 0 \mid d_1) g(d_2 \mid d_1). \end{aligned}$$

This integrates to one, has the given observed-data distribution, and has conditional density g for d_2 given $(d_1, R = 0)$. Conversely any joint distribution with those properties has these two densities, so it is unique.

- (b) Abbreviate $p_r = \Pr(R = r \mid d_1)$ and $f_1 = f(d_2 \mid d_1, R = 1)$. Under the constructed distribution,

$$\Pr(R = 1 \mid d_1, d_2) = \frac{p_1 f_1}{p_1 f_1 + p_0 g(d_2 \mid d_1)},$$

which is free of d_2 for all d_1 precisely when g equals $f(\cdot \mid d_1, R = 1)$. Every member of the family assigns the observed data the same likelihood by construction, so no statistic computed from those data can prefer one to another. ■

Idea. The missing values are missing. No cleverness recovers the conditional distribution of what was not recorded given what was; a choice of that distribution *is* the assumption, and different choices fit the observed data identically. MAR is one such choice: convenient, often defensible, never verifiable.

Two consequences. A test of MCAR against MAR is possible, that comparison involving recorded variables only, and Little (1988) gives one; a test of MAR against MNAR is not. And a sensitivity analysis is not an optional extra but the only way to report what the data do not determine (Section 41.6).

Finally, the classes of Definition 41.1.1 describe the world; whether a procedure works is a property of the *pair*. Under MCAR nearly every method is valid, including dropping incomplete records. Under MAR with distinct parameters, likelihood and Bayesian inference with a correct model for $\mathbf{D}$ are valid by Theorem 41.3.1, while dropping incomplete records usually is not (Proposition 41.2.1). And under a mechanism depending on a regression's covariates but not on its response, dropping incomplete records is valid *for that regression*, even though the recorded units are a badly biased sample for any other purpose. That third case is the most useful and least well known, and the next section starts there.

41.1.5 Exercises

41.1.5.1 A. Check your understanding

Exercise A1.

Classify each mechanism as MCAR, MAR or MNAR with respect to the recorded variables named.

- (a) A blood assay is run on a random one-third of the samples chosen by a random number generator; age, sex and diagnosis are recorded for all.
- (b) In a weight-loss trial, participants who have gained weight since the last visit stop attending. Weight at every previous visit is recorded.
- (c) A scale reads “over range” and records nothing whenever the true weight exceeds 150 kg.
- (d) A questionnaire item is missing for everyone interviewed by one interviewer, whose identity is recorded.

Solution.

- (a) MCAR. (b) MNAR for the current visit’s weight, since whether it is recorded depends on that weight itself; it would be MAR if attendance depended only on the previous, recorded visits. (c) MNAR, and of an extreme kind: missingness is a deterministic function of the unrecorded value. (d) MAR given the interviewer, and not MCAR; without the interviewer’s identity recorded it would be MNAR *given the recorded variables*, which is what [Definition 41.1.1](#) measures.

Exercise A2.

Show that MCAR implies MAR, and explain why no enlargement of $\mathbf{D}_{\text{obs}}$ can turn a MAR mechanism into an MNAR one.

41.1.5.2 B. Practice**Exercise B1.**

Let $\mathbf{d} = (d_1, \dots, d_q)$ have a monotone pattern, so that the recorded entries are $d_1, \dots, d_K$ for some $K \in \{0, \dots, q\}$. Write the joint density of $(\mathbf{d}, K)$ using the chain rule $f(\mathbf{d}) = \prod_j f(d_j \mid d_1, \dots, d_{j-1})$, and show that MAR is equivalent to $\Pr(K = k \mid \mathbf{d})$ depending on $\mathbf{d}$ only through $d_1, \dots, d_k$.

Solution. Definition [Definition 41.1.1](#) asks that $\Pr(K = k \mid \mathbf{d})$ be the same for all $\mathbf{d}$ agreeing in their first k coordinates, which is the stated condition. Multiplying the chain-rule factorization by it gives

$$f(\mathbf{d}, K = k) = \left\{ \prod_{j \leq k} f(d_j \mid d_{<j}) \right\} \Pr(K = k \mid d_1, \dots, d_k) \left\{ \prod_{j > k} f(d_j \mid d_{<j}) \right\},$$

and integrating out $d_{k+1}, \dots, d_q$ removes the last brace entirely. That is the factorization [Section 41.3](#) exploits.

Exercise B2.

Two variables d_1 (always recorded) and d_2 (recorded when $R = 1$). Propose a statistic with a known null distribution under MCAR and power against “the mechanism depends on d_1 ”, and explain why no statistic can have power against “the mechanism depends on d_2 given d_1 ”.

Exercise B3.

Let $\mathbf{d} = (d_1, d_2)$ be bivariate normal with mean (μ_1, μ_2) and covariance Σ , and let d_2 be recorded with probability $\Phi(a + bd_1)$. Show that the mechanism is MAR, compute $E(d_2 \mid R = 1)$, and confirm that it differs from μ_2 unless $b = 0$ or $\sigma_{12} = 0$. Which class does the mechanism fall in if the probability is instead $\Phi(a + bd_2)$?

Solution. The probability depends only on the recorded d_1 , so the mechanism is MAR. Writing $d_2 = \mu_2 + \beta(d_1 - \mu_1) + e$ with $\beta = \sigma_{12}/\sigma_{11}$ and e independent of d_1 , $E(d_2 \mid R = 1) = \mu_2 + \beta\{E(d_1 \mid R = 1) - \mu_1\}$, and $E(d_1 \mid R = 1) \neq \mu_1$ whenever $b \neq 0$, since the selection probability is monotone in d_1 . With $\Phi(a + bd_2)$ the mechanism depends on the possibly unrecorded d_2 , so it is MNAR for $b \neq 0$.

41.1.5.3 C. Going deeper**Exercise C1.**

Let the units be independent, each with $d_1 \in \{0, 1\}$ always recorded, and let d_2 be recorded with probability p_0 when $d_1 = 0$ and with probability $q(d_2)$ when $d_1 = 1$, where q is not constant. Show that [Definition 41.1.1\(b\)](#) fails at some patterns, but that on any sample in which no unit has $d_1 = 1$ the realized-value condition holds exactly. What does this say about a frequentist argument, which averages over samples that did not occur, compared with a Bayesian one, which conditions on the sample in hand?

41.2 Complete cases and quick repairs

Confronted with holes, software does one of two things without being asked: it deletes the rows that have any, or it fills them and proceeds as though nothing had happened. Both are defensible in circumstances that can be stated precisely, and disastrous outside them. This section states them.

41.2.1 When deleting rows is safe

Write $C_i = 1$ when unit i 's record is complete in every variable the analysis uses. A **complete-case analysis** applies the analysis to the subsample $\{i : C_i = 1\}$, and its behaviour is governed by one thing: the conditional distribution of $\mathbf{d}_{(i)}$ given $C_i = 1$.

Proposition 41.2.1 — Validity of a complete-case analysis

Let the rows $(\mathbf{d}_{(i)}, C_i)$ be independent and identically distributed, with $\Pr(C_i = 1) > 0$.

- (a) (*General condition.*) Let a procedure estimate a functional T consistently at every law in a class containing both f , the law of $\mathbf{d}_{(i)}$, and $f_{C=1}$, its conditional law given $C_i = 1$. Applied to the complete cases the procedure stays consistent for $T(f)$ if and only if $T(f_{C=1}) = T(f)$. Under MCAR $f_{C=1} = f$, and every such functional is preserved.
- (b) (*Regression with selection on the covariates.*) Partition $\mathbf{d}_{(i)} = (y_i, \mathbf{x}_{(i)})$ and suppose

$$\Pr(C_i = 1 \mid y_i, \mathbf{x}_{(i)}) = \Pr(C_i = 1 \mid \mathbf{x}_{(i)}) \quad \text{almost surely.} \quad (41.2.1)$$

Then the conditional law of y_i given $\mathbf{x}_{(i)}$ is the same among the complete cases as in the population. So if a model specifies that conditional law correctly, the complete-case least squares estimate in a linear model is unbiased for $\boldsymbol{\beta}$ conditionally on the selected covariates; and for a generalized linear model (Definition 34.2.1) the complete-case maximum likelihood estimate is consistent and asymptotically normal, with the usual model-based covariance of Theorem 34.5.1 computed from the complete cases alone, provided their number grows and their covariate second moments converge to a nonsingular limit.

- (c) (*Otherwise.*) If Eq. 41.2.1 fails, write $\pi(y, \mathbf{x}) = \Pr(C = 1 \mid y, \mathbf{x})$. The complete-case regression function is

$$E(y \mid \mathbf{x}, C = 1) = E(y \mid \mathbf{x}) + \frac{\text{Cov}\{y, \pi(y, \mathbf{x}) \mid \mathbf{x}\}}{E\{\pi(y, \mathbf{x}) \mid \mathbf{x}\}}, \quad (41.2.2)$$

so the complete cases follow the intended regression function exactly when π is conditionally uncorrelated with the response at every $\mathbf{x}$.

Proof.

- (a) The complete cases are an independent sample from $f_{C=1}$, and their number grows without bound since $\Pr(C = 1) > 0$. By the assumed consistency of the procedure at $f_{C=1}$, it converges to $T(f_{C=1})$, which is the target $T(f)$ if and only if the two agree. Under MCAR, C is independent of $\mathbf{d}$, hence $f_{C=1} = f$.
- (b) By Bayes's rule,

$$f(y \mid \mathbf{x}, C = 1) = \frac{\Pr(C = 1 \mid y, \mathbf{x}) f(y \mid \mathbf{x})}{\Pr(C = 1 \mid \mathbf{x})}, \quad (41.2.3)$$

and under Eq. 41.2.1 the two selection probabilities cancel, leaving $f(y \mid \mathbf{x})$. The complete cases are therefore a sample from a joint law whose conditional of y given $\mathbf{x}$ is the modelled one, with only the marginal law of $\mathbf{x}$ distorted. Every likelihood built from $f(y \mid \mathbf{x}; \boldsymbol{\beta})$ alone conditions on the covariates and is unaffected by that distortion.

(c) Multiply [Eq. 41.2.3](#) by y and integrate:

$$\begin{aligned} E(y \mid \mathbf{x}, C = 1) &= \frac{E\{y \pi(y, \mathbf{x}) \mid \mathbf{x}\}}{E\{\pi(y, \mathbf{x}) \mid \mathbf{x}\}} \\ &= E(y \mid \mathbf{x}) + \frac{\text{Cov}\{y, \pi(y, \mathbf{x}) \mid \mathbf{x}\}}{E\{\pi(y, \mathbf{x}) \mid \mathbf{x}\}}, \end{aligned}$$

using $E(y\pi) = E(y)E(\pi) + \text{Cov}(y, \pi)$ throughout at fixed $\mathbf{x}$.

■

Part (b) is the most useful positive result in the subject and is routinely overlooked. *Missingness may depend on the covariates as strongly as it likes, in any functional form, without harming a correctly specified regression.* The complete cases are a biased sample of units — their covariate distribution is wrong, so any marginal summary of them is wrong — and yet the fitted conditional mean is right. This is selection on a regressor, as in [Chapter 25](#); the binary-response version is [Exercise \(B1\)](#).

Warning. Part (b) needs the conditional *model* to be right. If the true regression is curved and the fitted one is a straight line, selecting on $\mathbf{x}$ changes which part of the covariate range dominates the fit, and the complete-case slope moves with it. Selection on the covariates is harmless for a correct model and can be very harmful for a wrong one.

Example. (Four mechanisms, one regression)

Take $y_i = 1 + 0.8x_i + 0.9w_i + \varepsilon_i$ with x_i, w_i, ε_i independent standard normal and $n = 300$, and lose the response under four mechanisms: completely at random; at random on x ; at random on x and w ; and not at random, on y .

Table 41.2.1. Mean complete-case estimate of $\beta_1 = 0.8$ over 2000 replicates, for two analyses under four mechanisms.

mechanism	complete cases	fit $y \sim x$	fit $y \sim x + w$
MCAR	194	0.801	0.801
MAR on x	181	0.804	0.802
MAR on x and w	178	0.637	0.800
MNAR on y	178	0.593	0.669

The first two rows are [Proposition 41.2.1\(b\)](#): whatever the missingness does with x , the regression of y on x is untouched. The third is the warning attached to it. The mechanism is MAR, using only recorded variables, yet the short regression omitting w is badly biased, because selecting on w selects on the part of y that the short model calls error; adding w repairs it completely. The fourth row cannot be repaired by any choice of regressors, because the selection is on y itself.

```
import numpy as np

rng = np.random.default_rng(4101)
n, reps = 300, 2000
beta = np.array([1.0, 0.8, 0.9])
```

intercept, coefficient of x ,

Figure 41.2.1: Complete-case estimates of $\beta_1 = 0.8$ over 2000 replicates under four mechanisms, for the regression of y on x alone and on x and w . The horizontal line is the true value.

```

of w

def one_run(mechanism, rng):
    x, w = rng.normal(size=n), rng.normal(size=n)
    y = beta[0] + beta[1] * x + beta[2] * w + rng.normal(size=n)
    if mechanism == "MCAR":
        eta = np.full(n, -0.6)
    elif mechanism == "MAR on x":
        eta = -0.6 + 1.6 * x                    # depends on a regressor only
    elif mechanism == "MAR on x and w":
        eta = -0.6 + 1.2 * x + 1.5 * w          # depends on observed
                                                # variables only
    else:
        eta = -0.6 + 1.2 * (y - beta[0])        # MNAR
                                                # depends on the value itself
    missing = rng.uniform(size=n) < 1 / (1 + np.exp(-eta))
    obs = ~missing
    short = np.column_stack([np.ones(obs.sum()), x[obs]])          # y on x
    long = np.column_stack([np.ones(obs.sum()), x[obs], w[obs]])   # y on x and w
    b_short, *_ = np.linalg.lstsq(short, y[obs], rcond=None)
    b_long, *_ = np.linalg.lstsq(long, y[obs], rcond=None)
    return b_short[1], b_long[1], obs.sum()

names = ["MCAR", "MAR on x", "MAR on x and w", "MNAR"]
out = {m: np.array([one_run(m, rng) for _ in range(reps)]) for m in names}
for m in names:
    s, l, k = out[m].T
    print(f"{m:16s} complete cases {k.mean():5.0f}   y ~ x: {s.mean():.4f}"
          f"      y ~ x + w: {l.mean():.4f}")

```

Idea. Ask what the missingness depends on, then put those variables into the analysis. If everything the mechanism uses is in the model and the model is right, the complete cases are enough. If the mechanism uses the response, or a variable the model leaves out, they are not.

41.2.2 Available cases

A tempting middle course computes each summary from whichever records carry the variables it needs: a mean from everyone who reported that variable, a covariance from everyone who reported both. This **available-case** analysis, or pairwise deletion, uses more data, at the price of a covariance matrix whose entries come from different subsamples and need not be jointly realizable.

Example. (A correlation matrix with a negative eigenvalue)

Twelve records on three variables, in three patterns of four: d_3 absent in the first, d_2 in the second, d_1 in the third, with numbers chosen so that the available pairs give $r_{12} = 0.9$, $r_{13} = 0.9$ and $r_{23} = -0.9$. Each is an ordinary correlation on its own four points; together they are impossible, since by [Proposition 2.4.2](#) the third must lie between $0.81 - \sqrt{0.19 \times 0.19} = 0.62$ and $0.81 + 0.19 = 1$. The matrix has smallest eigenvalue -0.800 , so any procedure needing it to be nonnegative definite — a Cholesky factor, a GLS weight matrix, a normal likelihood — fails, even though the matrix itself is perfectly invertible.

```
nan = np.nan
u = np.array([-1.5, -0.5, 0.5, 1.5])
d = np.array([0.5, -1.5, 1.5, -0.5])          # orthogonal to u, same length
pair = np.column_stack([u, 0.9 * u + np.sqrt(1 - 0.81) * d])      #
# correlation +0.9
flip = np.column_stack([u, -(0.9 * u + np.sqrt(1 - 0.81) * d)])    #
# correlation -0.9
D = np.vstack([
    np.column_stack([pair, np.full(4, nan)]),          # pattern A: z3 absent
    np.column_stack([pair[:, 0], np.full(4, nan), pair[:, 1]]),    # pattern B
    # z2 absent
    np.column_stack([np.full(4, nan), flip]),          # pattern C: z1 absent
])
R = np.ones((3, 3))
for i in range(3):
    for j in range(i + 1, 3):
        both = ~np.isnan(D[:, i]) & ~np.isnan(D[:, j])
        R[i, j] = R[j, i] = np.corrcoef(D[both, i], D[both, j])[0, 1]
print("available-case correlation matrix\n", R)
print("eigenvalues", np.round(np.linalg.eigvalsh(R), 3))
```

Under MCAR each entry is consistent and the difficulty is a finite-sample one; under MAR the entries are not consistent at all. Available-case analysis has uses in exploratory work and none in inference.

41.2.3 Single imputation

The other reflex is to fill the holes and carry on. **Mean imputation** replaces every missing entry of a variable by the mean of its recorded entries, leaving a pile of entries exactly at the sample mean and a spread that is too small.

Proposition 41.2.2 — Mean imputation deflates the variance

Let $z_1, \dots, z_n$ be independent and identically distributed with finite variance σ^2 , of which k are recorded and $n - k$ missing, the mechanism being completely at random; let $\tilde{z}_i$ equal z_i when recorded and $\bar{z}_{\text{obs}}$ otherwise. Then the sample variance of the filled column satisfies

$$\mathbb{E}\left\{\frac{1}{n-1} \sum_{i=1}^n (\tilde{z}_i - \bar{\tilde{z}})^2 \mid k\right\} = \frac{k-1}{n-1} \sigma^2, \quad (41.2.4)$$

so the estimate of σ^2 is too small by the factor $(k-1)/(n-1) \approx k/n$, the proportion recorded.

Proof. The filled column's mean is $\bar{\tilde{z}} = \bar{z}_{\text{obs}}$, because the $n - k$ inserted values are all equal to it. The imputed entries therefore contribute nothing to $\sum_i (\tilde{z}_i - \bar{\tilde{z}})^2$, which reduces to $\sum_{i \text{ obs}} (z_i - \bar{z}_{\text{obs}})^2$. Given k , and under MCAR, that sum has expectation $(k-1)\sigma^2$. Dividing by $n-1$ gives Eq. 41.2.4. ■

With $n = 300$ and 30% of values missing the factor is 0.699, and the simulation gives 0.700 as the average filled-in sample variance of a standard normal column. Covariances with fully recorded variables are deflated by the same mechanism, so correlations shrink towards zero and coefficients with them.

Regression imputation replaces a missing z_i by its predicted value from a regression on the recorded variables. It fixes the mean but not the spread, since the imputed points lie exactly on the fitted surface. In the same simulation, filling 30% of a variable whose correlation with the predictor is 0.6 raises the sample correlation to 0.667 and lowers the standard deviation to 0.899. Adding a draw from the estimated residual distribution — **stochastic regression imputation** — repairs both, and is the first honest imputation on this list. What it does not repair is the *uncertainty*: the analysis treats n values as measured when $n - k$ were invented, and every standard error is too small. Section 41.5 measures the damage — a nominal 95% interval covering 75.9% of the time in the example there — and repairs it.

Warning. Never treat a single set of imputed values as data. The estimate may be fine; the standard error, the t statistic and the interval are not, because the imputed values are correlated with the imputation model's own estimates. The same warning appeared in Section 18.6 for the filled-in plot of a designed experiment, where Theorem 18.6.1(e) gives the exact correction available in that special case.

41.2.4 Weighting

Survey statisticians treat unit nonresponse differently. If unit i is complete with probability $\pi_i = \Pr(C_i = 1 \mid \mathbf{d}_{(i)})$, then for any estimating function $\mathbf{g}$ with $\mathbb{E}\{\mathbf{g}(\mathbf{d}; \boldsymbol{\beta})\} = \mathbf{0}$ at the true $\boldsymbol{\beta}$, the **inverse-probability weighted** equations

$$\sum_{i=1}^n \frac{C_i}{\pi_i} \mathbf{g}(\mathbf{d}_{(i)}; \boldsymbol{\beta}) = \mathbf{0} \quad (41.2.5)$$

are unbiased, because $E(C_i/\pi_i \mid \mathbf{d}_{(i)}) = 1$. Under MAR, π_i is a function of recorded variables and can be estimated, typically by a logistic regression of C_i on them, and the estimator is then consistent when that model is right. This is Horvitz and Thompson's (1952) idea transplanted from sampling to nonresponse, and its weakness is visible in the formula: a unit with a small estimated π_i receives a huge weight, so the estimator is least stable where the data are thinnest. Augmenting Eq. 41.2.5 with a term built from a model for $E(\mathbf{g} \mid \text{recorded})$ gives the **doubly robust** estimators of Robins, Rotnitzky and Zhao (1994), consistent if either model is right. Weighting is the natural language for unit nonresponse, where there is nothing to impute; likelihood and imputation are the language for item nonresponse, where there is.

41.2.5 Exercises

41.2.5.1 A. Check your understanding

Exercise A1.

Under the mechanism of Proposition 41.2.1(b), show that the complete-case sample mean of y is generally not consistent for $E(y)$, even though the complete-case regression coefficients are consistent. Reconcile the two statements.

Solution. Selection changes the law of $\mathbf{x}$, and $E(y) = E\{E(y \mid \mathbf{x})\}$ averages the conditional mean over that law; the complete cases average it over the selected law instead. The regression coefficients describe $E(y \mid \mathbf{x})$, which selection leaves alone, so both statements hold at once: the conditional model is right and the marginal average of it is wrong.

41.2.5.2 B. Practice

Exercise B1.

In Eq. 41.2.2 take $y \mid \mathbf{x} \sim N(\mathbf{x}^\top \boldsymbol{\beta}, \sigma^2)$ and $\pi(y, \mathbf{x}) = \Phi(a + by)$. Show that

$$E(y \mid \mathbf{x}, C = 1) = \mathbf{x}^\top \boldsymbol{\beta} + \frac{b\sigma^2}{\sqrt{1 + b^2\sigma^2}} \frac{\phi(c)}{\Phi(c)}, \quad c = \frac{a + b\mathbf{x}^\top \boldsymbol{\beta}}{\sqrt{1 + b^2\sigma^2}},$$

and deduce that the complete-case regression function is nonlinear in $\mathbf{x}$ whenever $b \neq 0$.

Solution. With $y = \mathbf{x}^\top \boldsymbol{\beta} + \sigma e$, e standard normal, $E\{\Phi(a + by)\} = \Phi(c)$ by the standard convolution identity, and $E\{e \Phi(a + by)\} = b\sigma\phi(c)/\sqrt{1 + b^2\sigma^2}$, obtained by writing $\Phi(a + by) = \Pr(U \leq a + by)$ for an independent standard normal U and integrating by parts (equivalently, by Stein's identity $E\{e h(e)\} = E\{h'(e)\}$). Dividing the second by the first and substituting into Eq. 41.2.2 gives the display. The added term depends on $\mathbf{x}$ through c , and the ratio ϕ/Φ is not affine, so the complete-case mean is not linear in $\mathbf{x}$; in particular no single shift of the intercept absorbs it.

Exercise B2.

Verify [Eq. 41.2.4](#) by simulation for $n = 300$ and three missing fractions. Then show that the sample covariance of the filled column with a fully recorded variable w carries the *same* factor $(k-1)/(n-1)$, and explain why the fraction recorded k/n is only the limiting form of it.

Solution. The imputed entries satisfy $\tilde{z}_i - \bar{\tilde{z}} = 0$, so $\sum_i (\tilde{z}_i - \bar{\tilde{z}})(w_i - \bar{w}) = \sum_{\text{obs}} (z_i - \bar{z}_{\text{obs}})w_i$. Given k and under MCAR its expectation is $k\sigma_{zw} - \sigma_{zw} = (k-1)\sigma_{zw}$, the second term coming from $E(\bar{z}_{\text{obs}} \sum_{\text{obs}} w_i) = \sigma_{zw}$. Dividing by $n-1$ gives $\{(k-1)/(n-1)\}\sigma_{zw}$, the factor of [Eq. 41.2.4](#). The two candidates differ only through the divisors used for the sample moments, and $(k-1)/(n-1) \rightarrow k/n$ as both grow: k/n is the population-level statement, $(k-1)/(n-1)$ the exact finite-sample one, and there is no second phenomenon hiding in the gap.

Exercise B3.

Prove that [Eq. 41.2.5](#) is an unbiased estimating equation when $\pi_i > 0$ for every unit, and show by example that the conclusion fails if $\pi_i = 0$ for a set of covariate values with positive probability. What does that failure correspond to in [Proposition 41.2.1](#)?

41.2.5.3 C. Going deeper**Exercise C1.**

Let $E(y | x) = \beta_0 + \beta_1 x + \beta_2 x^2$ with $\beta_2 \neq 0$, and let the analyst fit a straight line. Show that even under [Eq. 41.2.1](#) the complete-case slope generally differs from the full-data slope, and identify the functional of the covariate distribution that the straight-line slope estimates (see [Theorem 2.5.2](#) and [Theorem 6.11.1](#)). Under what selection would the two agree?

Solution. The straight-line least squares coefficient converges to the best linear predictor coefficient $\text{Cov}(y, x) / \text{Var}(x)$ computed under whatever law x has. With $E(y | x) = \beta_0 + \beta_1 x + \beta_2 x^2$ this is $\beta_1 + \beta_2 \text{Cov}(x^2, x) / \text{Var}(x)$, which depends on the third and second central moments of x . Selection changes those moments, hence the limit, unless it leaves $\text{Cov}(x^2, x) / \text{Var}(x)$ unchanged — for instance under MCAR, or under a selection probability that is an even function of x about its mean when the law of x is symmetric.

41.3 Likelihood under missingness at random

A complete-case analysis throws away recorded values: a unit whose income is missing still told us its age. Likelihood throws nothing away. It asks what the *observed* data were likely to be, and the observed data include the partial records. This section writes that likelihood down, proves the theorem that makes it usable, and says what the theorem costs.

41.3.1 The observed-data likelihood

The full model is [Eq. 41.1.1](#): a density for the complete array and a mechanism. Since $\mathbf{D}_{\text{mis}}$ was never seen, the likelihood of what was seen integrates it out,

$$L_{\text{full}}(\boldsymbol{\theta}, \boldsymbol{\psi}) = \int f(\mathbf{D}_{\text{obs}}, \mathbf{D}_{\text{mis}} \mid \boldsymbol{\theta}) f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \mathbf{D}_{\text{mis}}, \boldsymbol{\psi}) d\mathbf{D}_{\text{mis}}, \quad (41.3.1)$$

a function of both parameters. Beside it stands the much simpler

$$L(\boldsymbol{\theta}) = f(\mathbf{D}_{\text{obs}} \mid \boldsymbol{\theta}) = \int f(\mathbf{D}_{\text{obs}}, \mathbf{D}_{\text{mis}} \mid \boldsymbol{\theta}) d\mathbf{D}_{\text{mis}}, \quad (41.3.2)$$

which ignores the mechanism entirely. The **observed-data likelihood** [Eq. 41.3.2](#) is what software computes when told that some entries are absent. The question is when using it is the same as using [Eq. 41.3.1](#).

Theorem 41.3.1 — Ignorability

Suppose that

- (i) the mechanism is MAR at the realized $(\mathbf{R}, \mathbf{D}_{\text{obs}})$ in the sense of [Definition 41.1.1\(b\)](#);
- (ii) the parameters are **distinct**: the parameter space of $(\boldsymbol{\theta}, \boldsymbol{\psi})$ is a product set $\Theta \times \Psi$, so that knowing one places no restriction on the other.

Then the full likelihood factors,

$$L_{\text{full}}(\boldsymbol{\theta}, \boldsymbol{\psi}) = L(\boldsymbol{\theta}) \cdot f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi}), \quad (41.3.3)$$

and consequently:

- (a) the maximizer of L_{full} in $\boldsymbol{\theta}$ is the maximizer of L , and likelihood ratio statistics for hypotheses about $\boldsymbol{\theta}$ alone are the same under both;
- (b) if the prior is $p(\boldsymbol{\theta}, \boldsymbol{\psi}) = p(\boldsymbol{\theta})p(\boldsymbol{\psi})$, the posterior of $\boldsymbol{\theta}$ given $(\mathbf{D}_{\text{obs}}, \mathbf{R})$ equals its posterior given $\mathbf{D}_{\text{obs}}$ alone, computed from [Eq. 41.3.2](#);
- (c) if in addition the MAR condition holds at every $(\mathbf{R}, \mathbf{D}_{\text{obs}})$, the observed-data score has mean zero and the usual maximum likelihood asymptotics ([Theorem 7.3.1](#)) apply to L under the ordinary regularity conditions.

A mechanism satisfying (i) and (ii) is called **ignorable**.

Proof. Under (i) the factor $f(\mathbf{R} \mid \mathbf{D}, \boldsymbol{\psi})$ in [Eq. 41.3.1](#) takes the same value for every $\mathbf{D}_{\text{mis}}$, namely $f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi})$, so it comes out of the integral:

$$\begin{aligned} L_{\text{full}}(\boldsymbol{\theta}, \boldsymbol{\psi}) &= f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi}) \int f(\mathbf{D}_{\text{obs}}, \mathbf{D}_{\text{mis}} \mid \boldsymbol{\theta}) d\mathbf{D}_{\text{mis}} \\ &= f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi}) L(\boldsymbol{\theta}), \end{aligned}$$

which is [Eq. 41.3.3](#).

- (a) By (ii), $\boldsymbol{\theta}$ ranges over Θ whatever $\boldsymbol{\psi}$ is, so $\max_{\boldsymbol{\psi}} L_{\text{full}} = L(\boldsymbol{\theta}) \max_{\boldsymbol{\psi}} f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi})$, and the second factor does not involve $\boldsymbol{\theta}$. Maximizing over $\boldsymbol{\theta}$ therefore maximizes L . For a hypothesis $\boldsymbol{\theta} \in \Theta_0$, both the numerator and the denominator of the likelihood ratio carry the same second factor, which cancels.
- (b) The posterior is proportional to $p(\boldsymbol{\theta})p(\boldsymbol{\psi})L_{\text{full}}$. By Eq. 41.3.3 this is $\{p(\boldsymbol{\theta})L(\boldsymbol{\theta})\} \cdot \{p(\boldsymbol{\psi})f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi})\}$, a product of a function of $\boldsymbol{\theta}$ and a function of $\boldsymbol{\psi}$. Integrating out $\boldsymbol{\psi}$ multiplies the first bracket by a constant, so the marginal posterior of $\boldsymbol{\theta}$ is proportional to $p(\boldsymbol{\theta})L(\boldsymbol{\theta})$.
- (c) If (i) holds at every realization, then at every realization the joint density of the observed data $(\mathbf{D}_{\text{obs}}, \mathbf{R})$ is exactly $L(\boldsymbol{\theta}) f(\mathbf{R} \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\psi})$, whose logarithm is $\log L(\boldsymbol{\theta})$ plus a term free of $\boldsymbol{\theta}$. So $\partial \log L / \partial \boldsymbol{\theta}$ is the $\boldsymbol{\theta}$ component of the score of a correctly specified density for the data actually seen, and has mean zero under the ordinary regularity conditions of Theorem 7.3.1.

■

Remark (Where each hypothesis is used). Condition (i) alone gives Eq. 41.3.3 and part (b): a Bayesian who conditions on the data in hand needs nothing more. Condition (ii) is what makes the factorization useful to a frequentist, who maximizes; without it the two factors share parameters and neither can be maximized alone. Part (c) needs the everywhere version of MAR, because a sampling distribution averages over data sets that did not occur. Textbooks usually state “MAR plus distinctness” without separating these roles; the separation is due to Seaman, Galati, Jackson and Carlin (2013).

Idea. Under MAR with distinct parameters, the analyst may forget the mechanism and maximize the likelihood of what was recorded. That is the entire licence for the methods of the next two sections — and it is a licence to use a likelihood that is usually an integral, not a product.

41.3.2 What the licence costs

Ignorability licenses ignoring the mechanism, not ignoring the missing values. Three consequences follow.

A model is now needed for variables previously conditioned on. In a complete data set, least squares never models the distribution of $\mathbf{X}$: the likelihood conditions on it. When a covariate is missing, Eq. 41.3.2 integrates over it, and that integral needs a density. Missing responses cost nothing extra; missing covariates cost a model for the covariates.

When only the response is missing, the partial records add nothing. If every covariate is recorded, the integral in Eq. 41.3.2 over a missing y_i is one, and the observed-data likelihood is exactly the complete-case likelihood. This is Proposition 41.2.1(b) again, as a statement about likelihoods, and it is the situation of Theorem 18.6.1.

The likelihood is no longer a product of simple factors. Each incomplete record contributes a marginal density, obtained by integrating the complete-data density over the entries it lacks. For the multivariate normal those integrals are marginals of a normal; for almost anything else they have no closed form. Section 41.4 is the standard response.

For a **monotone** pattern the integrals are free: integrating out a record’s unrecorded tail deletes

exactly its conditional factors, so the likelihood becomes a chain of conditional models on nested subsamples, each maximized on its own; that is [Exercise \(B1\)](#) of [Section 41.1](#). The bivariate case is the subject in miniature. With u always recorded and v recorded on the first k units, the estimate of μ_v is $\bar{v}_{(k)} + \hat{\beta}\{\bar{u}_{(n)} - \bar{u}_{(k)}\}$ by [Exercise \(B1\)](#) below: the complete-case mean of v , corrected by the shift in the mean of u , using the $n - k$ records that carry a u and no v . Those records were useless to the complete-case analysis and are decisive here — and they repair the damage only to the extent that u predicts v , a remark that returns, with teeth, in [Section 41.5](#). Anderson (1957) solved the general monotone multivariate normal case this way.

41.3.3 What changes under MNAR

Drop the MAR assumption and [Eq. 41.3.3](#) fails: the integral in [Eq. 41.3.1](#) cannot release the mechanism, and the two parameters are entangled. The mechanism must then be modelled, and the model is not checkable, since [Proposition 41.1.1](#) says that varying the assumed conditional distribution of the missing values traces out a family with identical observed-data likelihoods. Whatever identification such a model achieves comes from functional-form assumptions rather than from the data, and the likelihood surface is often nearly flat in the directions that matter. [Section 41.6](#) takes this up as a problem of reporting rather than of estimation.

41.3.4 Exercises

41.3.4.1 A. Check your understanding

Exercise A1.

Give a mechanism under which MAR holds but the parameters are not distinct, and show that [Eq. 41.3.3](#) still holds while part (a) of [Theorem 41.3.1](#) can fail. (Hint: let the probability of recording y_i be a known function of β .)

Solution. Take $\Pr(R_i = 1 \mid \mathbf{x}_{(i)}) = \Phi(\mathbf{x}_{(i)}^\top \beta)$, with no free ψ at all. The mechanism depends only on recorded covariates, so MAR holds and the factorization [Eq. 41.3.3](#) is valid, but the second factor now depends on β . Maximizing the product is not the same as maximizing $L(\beta)$, and the indicators carry information about β : the parameter spaces are not a product set.

41.3.4.2 B. Practice

Exercise B1.

Let (u_i, v_i) be a bivariate normal sample with u recorded for all n units and v for the first k , the mechanism depending on u but not on v . Reparameterizing by (μ_u, σ_u^2) and the regression parameters of v on u , derive the maximum likelihood estimates and the formula for $\hat{\mu}_v$ quoted above. Extend to three variables with a monotone pattern: u recorded n times, v the first k_2 , z the first $k_3 \leq k_2$.

Solution. Factor as $f(u)f(v \mid u)$; by [Exercise \(B1\)](#) an unrecorded v_i loses its conditional factor, so $L = \prod_{i \leq n} f(u_i) \prod_{i \leq k} f(v_i \mid u_i)$. The two parameter groups are variation independent, so each product is maximized alone: a normal sample of size n , and a normal

linear model on k observations ([Theorem 7.3.1](#)). Since $\mu_v = \alpha + \beta\mu_u$ and $\hat{\alpha} = \bar{v}_{(k)} - \hat{\beta}\bar{u}_{(k)}$, and since a maximum likelihood estimate transforms with the parameterization, $\hat{\mu}_v$ is as stated. For three variables the same argument on $f(u)f(v | u)f(z | u, v)$ gives a univariate fit on all n , the regression of v on u over the first k_2 , and the regression of z on (u, v) over the first k_3 .

Exercise B2.

A linear model has a single covariate x that is sometimes missing, with $x \sim N(\mu, \tau^2)$ and $y | x \sim N(\beta_0 + \beta_1 x, \sigma^2)$. Write the observed-data likelihood contribution of a record with y recorded and x missing, and show that it is the density of a normal with mean $\beta_0 + \beta_1 \mu$ and variance $\beta_1^2 \tau^2 + \sigma^2$. Why does this contribution carry information about β_1 even though it contains no x ?

41.3.4.3 C. Going deeper

Exercise C1.

Show that [Theorem 18.6.1](#) is the special case of [Theorem 41.3.1](#) in which the missing entries are responses, the mechanism depends only on the design, and the complete-data model is the normal linear model. Which part of [Theorem 18.6.1](#) corresponds to [Eq. 41.3.2](#), and which to the warning that the degrees of freedom must be reduced?

41.4 The EM algorithm

Maximizing the observed-data likelihood [Eq. 41.3.2](#) directly means differentiating an integral. EM avoids that: it alternates between filling in the missing pieces of the *complete-data log-likelihood* and maximizing the filled-in version, and it never decreases the observed-data likelihood. The iteration of [Theorem 18.6.1\(c\)](#) — fill each lost plot with its fitted value, refit, repeat — is the oldest instance in this book.

41.4.1 The two steps

Let $\ell(\boldsymbol{\theta}) = \log f(\mathbf{D}_{\text{obs}} | \boldsymbol{\theta})$ and $\ell_c(\boldsymbol{\theta}) = \log f(\mathbf{D} | \boldsymbol{\theta})$ be the observed-data and complete-data log-likelihoods, the second a function of data we do not have. The mechanism is ignorable throughout, so [Theorem 41.3.1](#) licenses working with ℓ .

Definition 41.4.1 — EM

Given a current value $\boldsymbol{\theta}^{(s)}$, define

$$Q(\boldsymbol{\theta} | \boldsymbol{\theta}^{(s)}) = E\{\ell_c(\boldsymbol{\theta}) | \mathbf{D}_{\text{obs}}, \boldsymbol{\theta}^{(s)}\}, \quad (41.4.1)$$

the expectation being over $\mathbf{D}_{\text{mis}}$ under the conditional density $f(\mathbf{D}_{\text{mis}} | \mathbf{D}_{\text{obs}}, \boldsymbol{\theta}^{(s)})$. The

E step computes $Q(\cdot | \boldsymbol{\theta}^{(s)})$; the **M step** sets $\boldsymbol{\theta}^{(s+1)}$ to a maximizer of it. If the M step only *increases* Q , the scheme is called **generalized EM**.

The E step is not “fill in the missing values”; it fills in whatever functions of them the complete-data log-likelihood contains. When ℓ_c is linear in a set of sufficient statistics, as for every exponential family (Definition 34.1.1), the E step reduces to filling in those statistics (Exercise (B2)) — which is the same as filling in the missing values only when the statistics are linear in them. A normal variance, whose statistic contains $\sum_i y_i^2$, is the standing counterexample, and only the second reading is EM.

41.4.2 Monotonicity

Theorem 41.4.1 — The EM sequence never decreases the likelihood

Let $\boldsymbol{\theta}^{(s+1)}$ satisfy $Q(\boldsymbol{\theta}^{(s+1)} | \boldsymbol{\theta}^{(s)}) \geq Q(\boldsymbol{\theta}^{(s)} | \boldsymbol{\theta}^{(s)})$. Then

- (a) $\ell(\boldsymbol{\theta}^{(s+1)}) \geq \ell(\boldsymbol{\theta}^{(s)})$, with equality only if $Q(\boldsymbol{\theta}^{(s+1)} | \boldsymbol{\theta}^{(s)}) = Q(\boldsymbol{\theta}^{(s)} | \boldsymbol{\theta}^{(s)})$ and the two conditional densities of $\mathbf{D}_{\text{mis}}$ agree almost everywhere;
- (b) if ℓ is bounded above, $\ell(\boldsymbol{\theta}^{(s)})$ converges;
- (c) if $Q(\cdot | \cdot)$ is differentiable in its first argument and $\boldsymbol{\theta}^{(s+1)}$ is an interior maximizer, then at any fixed point $\boldsymbol{\theta}^*$ of the iteration the observed-data score vanishes: $\partial \ell(\boldsymbol{\theta}) / \partial \boldsymbol{\theta} |_{\boldsymbol{\theta}^*} = \mathbf{0}$.

Proof. Write $g(\mathbf{D}_{\text{mis}} | \boldsymbol{\theta}) = f(\mathbf{D}_{\text{mis}} | \mathbf{D}_{\text{obs}}, \boldsymbol{\theta})$ for the conditional density of the missing part. Since $f(\mathbf{D} | \boldsymbol{\theta}) = f(\mathbf{D}_{\text{obs}} | \boldsymbol{\theta}) g(\mathbf{D}_{\text{mis}} | \boldsymbol{\theta})$, taking logarithms and rearranging gives, for every $\mathbf{D}_{\text{mis}}$,

$$\ell(\boldsymbol{\theta}) = \ell_c(\boldsymbol{\theta}) - \log g(\mathbf{D}_{\text{mis}} | \boldsymbol{\theta}).$$

The left side does not depend on $\mathbf{D}_{\text{mis}}$, so taking the expectation of both sides under $g(\cdot | \boldsymbol{\theta}^{(s)})$ leaves it unchanged and yields the decomposition

$$\begin{aligned} \ell(\boldsymbol{\theta}) &= Q(\boldsymbol{\theta} | \boldsymbol{\theta}^{(s)}) - H(\boldsymbol{\theta} | \boldsymbol{\theta}^{(s)}), \quad \text{where} \\ H(\boldsymbol{\theta} | \boldsymbol{\theta}^{(s)}) &= E\{\log g(\mathbf{D}_{\text{mis}} | \boldsymbol{\theta}) | \mathbf{D}_{\text{obs}}, \boldsymbol{\theta}^{(s)}\}. \end{aligned} \tag{41.4.2}$$

- (a) Subtract Eq. 41.4.2 at $\boldsymbol{\theta}^{(s)}$ from the same at $\boldsymbol{\theta}^{(s+1)}$:

$$\begin{aligned} \ell(\boldsymbol{\theta}^{(s+1)}) - \ell(\boldsymbol{\theta}^{(s)}) &= \{Q(\boldsymbol{\theta}^{(s+1)} | \boldsymbol{\theta}^{(s)}) - Q(\boldsymbol{\theta}^{(s)} | \boldsymbol{\theta}^{(s)})\} \\ &\quad - \{H(\boldsymbol{\theta}^{(s+1)} | \boldsymbol{\theta}^{(s)}) - H(\boldsymbol{\theta}^{(s)} | \boldsymbol{\theta}^{(s)})\}. \end{aligned}$$

The first brace is nonnegative by hypothesis. For the second, write $g_s = g(\cdot | \boldsymbol{\theta}^{(s)})$ and $g_{s+1} = g(\cdot | \boldsymbol{\theta}^{(s+1)})$; then

$$\begin{aligned} H(\boldsymbol{\theta}^{(s+1)} | \boldsymbol{\theta}^{(s)}) - H(\boldsymbol{\theta}^{(s)} | \boldsymbol{\theta}^{(s)}) &= \int g_s \log \frac{g_{s+1}}{g_s} \\ &\leq \log \int g_s \frac{g_{s+1}}{g_s} = \log 1 = 0, \end{aligned}$$

by Jensen's inequality applied to the concave logarithm. So the difference of log-likelihoods is a nonnegative number minus a nonpositive one. Equality throughout forces equality in Jensen's inequality, which for the strictly concave logarithm requires g_{s+1}/g_s to be constant almost everywhere under g_s , hence $g_{s+1} = g_s$, and forces the first brace to vanish.

- (b) A nondecreasing sequence bounded above converges.
- (c) At a fixed point, $\boldsymbol{\theta}^*$ maximizes $Q(\cdot \mid \boldsymbol{\theta}^*)$, so $\partial Q(\boldsymbol{\theta} \mid \boldsymbol{\theta}^*)/\partial \boldsymbol{\theta}$ vanishes at $\boldsymbol{\theta} = \boldsymbol{\theta}^*$. The function $\boldsymbol{\theta} \mapsto H(\boldsymbol{\theta} \mid \boldsymbol{\theta}^*)$ is maximized at $\boldsymbol{\theta} = \boldsymbol{\theta}^*$ by the Jensen argument just given, so its derivative vanishes there too. Differentiating Eq. 41.4.2 at $\boldsymbol{\theta}^*$ gives $\partial \ell / \partial \boldsymbol{\theta} = \mathbf{0} - \mathbf{0}$.

■

Warning. Part (c) says fixed points are stationary points, not maxima: EM can converge to a saddle point or a local maximum, and with several modes the limit depends on the start. Wu (1983) gives conditions under which the limit points are stationary and under which the sequence converges; none rules out a local maximum. Start from several values.

41.4.3 Missing responses in a linear model

The oldest case is the one where every step is explicit, and it settles a question left open in Section 18.6.

Proposition 41.4.2 — EM for a normal linear model with missing responses

Let $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$ and $\text{rank}(\mathbf{X}) = p$; let the responses of a set of m rows be unrecorded, the covariates of those rows being known, with an ignorable mechanism, and suppose the observed rows $\mathbf{X}_o$ have rank p . Write SSE_o for the residual sum of squares of the least squares fit on the observed rows. Then:

- (a) the E step replaces each missing y_i by $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)}$ in the cross-product terms of ℓ_c , and each y_i^2 by $(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)})^2 + \sigma^{2(s)}$;
- (b) the M step is $\boldsymbol{\beta}^{(s+1)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{y}^{(s)}$ with $\mathbf{y}^{(s)}$ the completed vector, and $\sigma^{2(s+1)} = n^{-1} \{ \|\mathbf{y}^{(s)} - \mathbf{X}\boldsymbol{\beta}^{(s+1)}\|^2 + m\sigma^{2(s)} \}$;
- (c) the unique fixed point is $\boldsymbol{\beta}^* = \hat{\boldsymbol{\beta}}_o$, the least squares estimate from the observed rows, and

$$\sigma^{2*} = \frac{\text{SSE}_o}{n - m}, \quad (41.4.3)$$

which is the observed-data maximum likelihood estimate, based on $n - m$ observations.

Proof.

- (a) The complete-data log-likelihood $-\frac{1}{2}n \log(2\pi\sigma^2) - \frac{1}{2\sigma^2} \sum_i (y_i - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})^2$ is quadratic

in the y_i , so its conditional expectation needs their first two conditional moments. Given the observed data an unrecorded y_i is a draw from its own model, so those are $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)}$ and $(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)})^2 + \sigma^{2(s)}$.

(b) With those substitutions,

$$Q = -\frac{1}{2}n \log(2\pi\sigma^2) - \frac{1}{2\sigma^2} \left\{ \|\mathbf{y}^{(s)} - \mathbf{X}\boldsymbol{\beta}\|^2 + m\sigma^{2(s)} \right\},$$

because each missing row contributes $E(y_i^2) - 2\mathbf{x}_{(i)}^\top \boldsymbol{\beta} E(y_i) + (\mathbf{x}_{(i)}^\top \boldsymbol{\beta})^2 = (\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)} - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})^2 + \sigma^{2(s)}$. Maximizing in $\boldsymbol{\beta}$ is ordinary least squares on $\mathbf{y}^{(s)}$; maximizing in σ^2 gives the stated average.

(c) At a fixed point the completed vector has $y_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}^*$ at the missing rows, so those rows have zero residual and contribute nothing to the least squares criterion; hence $\boldsymbol{\beta}^*$ minimizes $\|\mathbf{y}_o - \mathbf{X}_o \mathbf{b}\|^2$ and equals $\hat{\boldsymbol{\beta}}_o$, which is [Theorem 18.6.1\(a\)](#). Its residual sum of squares is SSE_o , so the variance equation reads $n\sigma^{2*} = \text{SSE}_o + m\sigma^{2*}$, giving [Eq. 41.4.3](#). Uniqueness of $\boldsymbol{\beta}^*$ follows from [Theorem 18.6.1\(b\)](#), and [Eq. 41.4.3](#) then determines σ^{2*} . ■

The term $m\sigma^{2(s)}$ is the whole point. Without it — fill the gaps with fitted values and hand the completed data to a regression routine — the variance comes out as SSE_o/n . That is the error [Theorem 18.6.1\(e\)](#) warns against, now derived rather than asserted: *the filled-in values are not data, and the likelihood knows it.*

Example. (The Mauna Loa gaps)

Fit the trend-plus-harmonics model of [Section 5.3](#) to all 2284 weeks, with the 59 missing ones handled by EM. The coefficients agree with the complete-case fit to machine precision, as [Proposition 41.4.2\(c\)](#) requires, and the error standard deviation is 0.7992 ppm; filling in the gaps and treating them as data gives 0.7889 ppm, too small by the factor $\sqrt{n/(n-m)} = 1.0132$. The discrepancy is small here only because the gaps are few.

```

```

41.4.4 A missing covariate

When a covariate is missing, the conditional distribution the E step needs runs *backwards*: what does a recorded response say about an unrecorded covariate? A model for the covariate is now unavoidable.

Proposition 41.4.3 — EM with a missing covariate

Let $x_i \sim N(\mu, \tau^2)$ independently, and $y_i | x_i \sim N(\beta_0 + \beta_1 x_i, \sigma^2)$, with $\theta = (\beta_0, \beta_1, \sigma^2, \mu, \tau^2)$. Suppose y_i is always recorded and x_i is missing for a subset, with an ignorable mechanism. Then for a record with x_i missing the E step uses

$$E(x_i | y_i) = \mu + \frac{\beta_1 \tau^2}{\beta_1^2 \tau^2 + \sigma^2} (y_i - \beta_0 - \beta_1 \mu), \quad \text{Var}(x_i | y_i) = \tau^2 - \frac{\beta_1^2 \tau^4}{\beta_1^2 \tau^2 + \sigma^2}, \quad (41.4.4)$$

both evaluated at $\theta^{(s)}$, and the M step is the complete-data maximum likelihood fit with the sufficient statistics $\sum_i x_i$, $\sum_i x_i^2$ and $\sum_i x_i y_i$ replaced by $\sum_i E(x_i | y_i)$, $\sum_i E(x_i^2 | y_i)$ and $\sum_i y_i E(x_i | y_i)$.

Proof. The pair (x_i, y_i) is bivariate normal, with $E y_i = \beta_0 + \beta_1 \mu$, $\text{Var } y_i = \beta_1^2 \tau^2 + \sigma^2$ and $\text{Cov}(x_i, y_i) = \beta_1 \tau^2$. The conditional moments Eq. 41.4.4 are the standard normal conditional mean and variance (Theorem 3.5.2). The complete-data log-likelihood is

$$-\frac{n}{2} \log \sigma^2 - \frac{\sum_i (y_i - \beta_0 - \beta_1 x_i)^2}{2\sigma^2} - \frac{n}{2} \log \tau^2 - \frac{\sum_i (x_i - \mu)^2}{2\tau^2} + \text{const},$$

which is linear in the three listed statistics together with $\sum_i y_i$ and $\sum_i y_i^2$; taking conditional expectations therefore replaces exactly those statistics, and the maximizer is the complete-data one evaluated at them. ■

Note what the E step does *not* do: it does not impute x_i by μ , nor from other covariates alone. It uses the response. Imputing a covariate without the response is among the commonest errors in practice, and it attenuates $\hat{\beta}_1$ towards zero, for the reason Chapter 24 gives.

Figure 41.4.1: EM for a linear model with a missing covariate. (a) The observed-data log-likelihood increases at every sweep. (b) The distance from the current iterate to the fixed point decays geometrically at the rate predicted by the fraction of missing information.

Example. (An EM fit with a missing covariate)

Simulate $N = 400$ records with $\beta_1 = 0.8$, and let the covariate be missing more often when the response is large; this loses 169 covariate values. The mechanism is MAR — it uses only the recorded y — so likelihood is valid and the complete-case fit is not. EM gives $\hat{\beta}_1 = 0.825$; the complete cases give 0.620, attenuated by a quarter.

Figure 41.4.1 shows the two faces of the algorithm. The observed-data log-likelihood climbs monotonically, as Theorem 41.4.1(a) requires, and the distance to the fixed point falls by the constant factor 0.760 per sweep, matching to three decimals the largest eigenvalue of $\mathcal{I}_c^{-1}\mathcal{I}_m$ below. Reaching eight decimal places takes 68 sweeps — slow by the standards of Newton’s method, which is the price of never differentiating an integral.

41.4.5 Rate of convergence, and the standard errors EM does not give

Both the speed of EM and its principal defect come from the same matrix. Define the **complete-data information** $\mathcal{I}_c = -\partial^2 Q(\theta \mid \theta^*) / \partial \theta \partial \theta^\top$ at $\theta = \theta^*$, the **observed information** $\mathcal{I}_o = -\partial^2 \ell / \partial \theta \partial \theta^\top$ there, and their difference $\mathcal{I}_m = \mathcal{I}_c - \mathcal{I}_o$, the **missing information**.

Proposition 41.4.4 — The missing-information principle

At any θ , with $\mathbf{S}_c$ the complete-data score,

$$\frac{\partial \ell}{\partial \theta} = E(\mathbf{S}_c \mid \mathbf{D}_{\text{obs}}, \theta), \quad \mathcal{I}_o = E(-\partial \mathbf{S}_c / \partial \theta^\top \mid \mathbf{D}_{\text{obs}}, \theta) - \text{Var}(\mathbf{S}_c \mid \mathbf{D}_{\text{obs}}, \theta). \quad (41.4.5)$$

Consequently $\mathcal{I}_m = \text{Var}(\mathbf{S}_c \mid \mathbf{D}_{\text{obs}}, \theta)$ is nonnegative definite: the observed information

is never larger than the expected complete-data information.

Proof. Differentiate the identity $\ell(\boldsymbol{\theta}) = \ell_c(\boldsymbol{\theta}) - \log g(\mathbf{D}_{\text{mis}} \mid \boldsymbol{\theta})$ from the proof of [Theorem 41.4.1](#) and take the conditional expectation under $g(\cdot \mid \boldsymbol{\theta})$. The conditional score of g has mean zero, being the score of a density in its own parameter, so the first identity follows. Differentiating again,

$$-\frac{\partial^2 \ell}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^\top} = -\frac{\partial^2 \ell_c}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^\top} + \frac{\partial^2 \log g}{\partial \boldsymbol{\theta} \partial \boldsymbol{\theta}^\top},$$

and taking the conditional expectation turns the last term into minus the information of g , which by the usual information identity equals minus the variance of its score. Since the score of g is $\mathbf{S}_c - \partial \ell / \partial \boldsymbol{\theta}$ and the second term is a constant given the observed data, that variance is $\text{Var}(\mathbf{S}_c \mid \mathbf{D}_{\text{obs}})$. ■

Identity [Eq. 41.4.5](#) is Louis’s formula (Louis, 1982); “observed = complete minus missing” is the missing-information principle of Orchard and Woodbury (1972). Two consequences:

The rate. Near a fixed point the EM map is approximately linear with Jacobian $\mathbf{I} - \mathcal{I}_c^{-1} \mathcal{I}_o = \mathcal{I}_c^{-1} \mathcal{I}_m$, so the iterates converge linearly at its largest eigenvalue — the largest **fraction of missing information** (Dempster, Laird and Rubin, 1977). In [Example \(An EM fit with a missing covariate\)](#) that eigenvalue is 0.760 and the measured rate is 0.760; the log-likelihood gap, quadratic near the maximum, falls at its square, 0.577 per sweep. In [Theorem 18.6.1\(c\)](#) the same matrix is $\mathbf{M}_{mm}$, the submatrix of the hat matrix belonging to the lost plots.

The standard errors. The matrix EM manipulates is $\mathcal{I}_c$, which is *too large*, so inverting it understates the variance by the fraction of missing information. Three honest routes: [Eq. 41.4.5](#); numerical differentiation of ℓ , as this section’s script does; or the bootstrap, resampling records and rerunning EM ([Definition 23.1.1\(b\)](#)). In [Example \(An EM fit with a missing covariate\)](#) these give 0.0611 and 0.0605 (bootstrap, 300 resamples), against 0.0512 from the complete-data information — an understatement of 16%.

Warning. The variance of an EM estimate is never the inverse of the matrix the M step inverts. If a routine reports standard errors after EM without saying how it got them, assume it has made this mistake.

41.4.6 Exercises

41.4.6.1 A. Check your understanding

Exercise A1.

The EM algorithm for the zero-inflated model of [Section 37.5](#) treats the component label as the missing datum. Identify $\mathbf{D}_{\text{mis}}$, Q and the M step there, and check that [Exercise \(B4\)](#) is the special case of [Theorem 41.4.1\(a\)](#).

41.4.6.2 B. Practice

Exercise B1.

In [Proposition 41.4.2](#), suppose one carries out the iteration but *omits* the term $m\sigma^{2(s)}$ from the M step for the variance. Show that the coefficients are unaffected and that the variance converges to SSE_o/n . Relate the discrepancy to [Theorem 18.6.1\(e\)](#).

Solution. The coefficient update does not involve σ^2 at all, so $\boldsymbol{\beta}^{(s)}$ follows the same sequence and converges to $\hat{\boldsymbol{\beta}}_o$; at that point the completed residual sum of squares is SSE_o . The truncated variance update is $\sigma^{2(s+1)} = \text{SSE}_o/n$ once the coefficients have settled. That is the complete-data formula applied to n “observations”, m of which have been manufactured to fit exactly; reducing the divisor by m is the degrees-of-freedom correction of [Theorem 18.6.1\(e\)](#).

Exercise B2.

Let the complete-data model be an exponential dispersion family ([Definition 34.1.1](#)) with sufficient statistic $\mathbf{t}(\mathbf{D})$. Show that the E step reduces to computing $E\{\mathbf{t}(\mathbf{D}) \mid \mathbf{D}_{\text{obs}}, \boldsymbol{\theta}^{(s)}\}$ and the M step to solving the complete-data likelihood equations with $\mathbf{t}$ replaced by that expectation. Why does the normal variance in [Proposition 41.4.2](#) still require the extra term $m\sigma^{2(s)}$?

Solution. The complete-data log-likelihood is $\boldsymbol{\theta}^\top \mathbf{t}(\mathbf{D}) - A(\boldsymbol{\theta})$ plus a term free of $\boldsymbol{\theta}$, so it is affine in $\mathbf{t}$ and its conditional expectation replaces $\mathbf{t}$ by $E(\mathbf{t} \mid \cdot)$. Setting the derivative to zero gives $E_{\boldsymbol{\theta}} \mathbf{t} = E(\mathbf{t} \mid \mathbf{D}_{\text{obs}})$. The normal case is no exception: the sufficient statistics include $\sum_i y_i^2$, and its conditional expectation over a missing row is $(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}^{(s)})^2 + \sigma^{2(s)}$, which is where the extra term comes from. The trap is to substitute the conditional *mean of the data* rather than the conditional mean of the *statistic*.

41.4.6.3 C. Going deeper**Exercise C1.**

Construct a two-component normal mixture with missing labels — the classical EM problem — for which the likelihood is unbounded, and show that EM started near a degenerate configuration drives one variance to zero while the likelihood increases at every step. Reconcile this with [Theorem 41.4.1\(b\)](#).

41.5 Multiple imputation

Filling a hole with a plausible value is not wrong; filling it with *one* plausible value and then forgetting that it was a guess is. Multiple imputation keeps the convenience of a complete rectangular data set and restores the uncertainty a single filling destroys, by filling several times and letting the variation between fillings speak.

41.5.1 The idea

Rubin's proposal (1978, 1987) has three parts.

1. **Impute.** Draw M independent completions $\mathbf{D}^{(1)}, \dots, \mathbf{D}^{(M)}$, each replacing $\mathbf{D}_{\text{mis}}$ by a draw from its posterior predictive distribution given $\mathbf{D}_{\text{obs}}$ under an **imputation model**.
2. **Analyse.** Apply the intended complete-data analysis to each completion, getting estimates $\hat{Q}_1, \dots, \hat{Q}_M$ and complete-data variance estimates $U_1, \dots, U_M$.
3. **Combine.** Pool them by [Theorem 41.5.1](#).

Step 1 is the only novelty. Drawing from the posterior predictive distribution means drawing the imputation model's *parameters* as well as the values; an imputation that conditions on a point estimate treats it as known, which is one of the ways the procedure fails.

Definition 41.5.1 — Multiple imputation

Let γ parameterize a model for the conditional distribution of $\mathbf{D}_{\text{mis}}$ given $\mathbf{D}_{\text{obs}}$, with prior $p(\gamma)$. An imputation is **proper** in Rubin's sense if the M completions are independent draws from

$$f(\mathbf{D}_{\text{mis}} \mid \mathbf{D}_{\text{obs}}) = \int f(\mathbf{D}_{\text{mis}} \mid \mathbf{D}_{\text{obs}}, \gamma) p(\gamma \mid \mathbf{D}_{\text{obs}}) d\gamma, \quad (41.5.1)$$

the posterior predictive distribution. Three standard constructions:

- (a) **Regression imputation with a parameter draw.** For a continuous variable modelled as normal given the others, draw $\sigma^{2*} = \text{SSE}/\chi_{k-q}^2$ from its posterior under a flat prior, then $\gamma^* \sim N(\hat{\gamma}, \sigma^{2*}(\mathbf{Z}_o^\top \mathbf{Z}_o)^{-1})$, then impute $\mathbf{z}^\top \gamma^* + \sigma^* \varepsilon$ with ε standard normal. This is [Theorem 7.6.2](#) with the noninformative limit [Corollary 7.6.4](#).
- (b) **Predictive mean matching.** Compute the predicted value for the record with the gap, find the d recorded records with the closest predicted values, and impute one of their *observed* values at random. Every imputed value then actually occurred, so the marginal distribution is respected even when the normal model is wrong, at the cost of a less transparent theory.
- (c) **Chained equations.** With gaps in several variables, cycle through them, imputing each in turn from a regression on the current versions of all the others, for several sweeps, and keep the completion at the end of a sweep.

Construction (c), also called fully conditional specification or MICE (van Buuren, 2018), is what makes multiple imputation usable on real files, where dozens of variables have gaps and no one will write a joint density for all of them. It is a Gibbs-like sweep (compare [Example \(The proficiency study, four ways\)](#)) carrying a risk the Gibbs sampler does not: the specified conditionals need not correspond to *any* joint distribution, and then the sweep has no stationary distribution and the result depends on the order of the variables. The dependence is usually slight, and the flexibility is worth the untidiness, but it should be known.

41.5.2 Rubin's rules

Theorem 41.5.1 — Combining M analyses

Let Q be the estimand and suppose the complete-data analysis is calibrated in the sense that, given the complete data $\mathbf{D}$, it reports $\hat{Q}(\mathbf{D})$ and $U(\mathbf{D})$ with

$$E(Q | \mathbf{D}) = \hat{Q}(\mathbf{D}), \quad \text{Var}(Q | \mathbf{D}) = U(\mathbf{D}). \quad (41.5.2)$$

Let $\mathbf{D}^{(1)}, \dots, \mathbf{D}^{(M)}$ be independent draws from Eq. 41.5.1, generated by the analyst and therefore conditionally independent of Q given $\mathbf{D}_{\text{obs}}$; put $\hat{Q}_\ell = \hat{Q}(\mathbf{D}^{(\ell)})$ and $U_\ell = U(\mathbf{D}^{(\ell)})$, and define

$$\bar{Q} = \frac{1}{M} \sum_{\ell} \hat{Q}_\ell, \quad \bar{U} = \frac{1}{M} \sum_{\ell} U_\ell, \quad B = \frac{1}{M-1} \sum_{\ell} (\hat{Q}_\ell - \bar{Q})^2. \quad (41.5.3)$$

Then, with all expectations conditional on $\mathbf{D}_{\text{obs}}$:

- (a) (*Decomposition.*) $\text{Var}(Q | \mathbf{D}_{\text{obs}}) = E(U | \mathbf{D}_{\text{obs}}) + \text{Var}(\hat{Q} | \mathbf{D}_{\text{obs}})$, and $\bar{U}$ and B are unbiased for the two terms;
- (b) (*Total variance.*) $\bar{Q}$ is unbiased for $E(Q | \mathbf{D}_{\text{obs}})$, and

$$T = \bar{U} + \left(1 + \frac{1}{M}\right)B \quad (41.5.4)$$

is unbiased for the variance of $Q - \bar{Q}$ given $\mathbf{D}_{\text{obs}}$;

- (c) (*Degrees of freedom.*) treating $\bar{U}$ as fixed and $(M-1)B / \text{Var}(\hat{Q} | \mathbf{D}_{\text{obs}})$ as χ_{M-1}^2 , the variance of T matches that of a scaled χ_ν^2 variable with

$$\nu = (M-1) \left\{ \frac{T}{(1 + M^{-1})B} \right\}^2 = \frac{M-1}{\gamma^2}, \quad \gamma = \frac{(1 + M^{-1})B}{T}, \quad (41.5.5)$$

and the interval $\bar{Q} \pm t_{\nu, 1-\alpha/2} \sqrt{T}$ is the standard multiple-imputation interval; γ is the estimated **fraction of missing information**;

- (d) (*Efficiency.*) write $T_\infty = E(U) + \text{Var}(\hat{Q})$ for the total variance at $M = \infty$ and $\gamma_\infty = \text{Var}(\hat{Q})/T_\infty$ for the limiting fraction of missing information. Then the target of T exceeds T_∞ by the factor $1 + \gamma_\infty/M$, so using M imputations rather than infinitely many inflates the standard error by $(1 + \gamma_\infty/M)^{1/2}$.

Proof. Throughout, condition on $\mathbf{D}_{\text{obs}}$ and write E and Var for the conditional operators.

- (a) The conditional variance decomposition applied to Q with the intermediate conditioning variable $\mathbf{D}$ gives $\text{Var}(Q) = E\{\text{Var}(Q | \mathbf{D})\} + \text{Var}\{E(Q | \mathbf{D})\}$, which is $E(U) + \text{Var}(\hat{Q})$ by Eq. 41.5.2. The completions are draws of $\mathbf{D}$ from its conditional law, so $E\bar{U} = E(U)$, and the sample variance of independent draws is unbiased for their variance, so $E B = \text{Var}(\hat{Q})$.
- (b) $E\bar{Q} = E\hat{Q} = E\{E(Q | \mathbf{D})\} = EQ$, so $\bar{Q}$ is unbiased for the posterior mean. Because the completions are conditionally independent of Q given $\mathbf{D}_{\text{obs}}$, so is $\bar{Q}$,

and therefore

$$\begin{aligned}\text{Var}(Q - \bar{Q}) &= \text{Var}(Q) + \text{Var}(\bar{Q}) = \{E(U) + \text{Var}(\hat{Q})\} + \frac{\text{Var}(\hat{Q})}{M} \\ &= E(U) + \left(1 + \frac{1}{M}\right) \text{Var}(\hat{Q}),\end{aligned}$$

using (a) for the first bracket and independence of the M draws for the second term. By (a) again, $\bar{U}$ and $(1 + M^{-1})B$ are unbiased for the two pieces, so T is unbiased for the whole.

- (c) Under the stated approximation $T = \bar{U} + (1 + M^{-1})B$ has variance $(1 + M^{-1})^2 \text{Var}(B)$, which is $2(1 + M^{-1})^2 \{\text{Var}(\hat{Q})\}^2 / (M - 1)$. A scaled χ^2_ν variable with mean T has variance $2T^2/\nu$. Equating and replacing $\text{Var}(\hat{Q})$ by its estimate B ,

$$\frac{2T^2}{\nu} = \frac{2(1 + M^{-1})^2 B^2}{M - 1} \implies \nu = (M - 1) \frac{T^2}{(1 + M^{-1})^2 B^2},$$

which is [Eq. 41.5.5](#).

- (d) By (b) the target of T is

$$E(U) + (1 + M^{-1}) \text{Var}(\hat{Q}) = T_\infty + \frac{\text{Var}(\hat{Q})}{M} = T_\infty \left(1 + \frac{\gamma_\infty}{M}\right).$$

Taking square roots gives the inflation factor.

■

Remark (What the proof assumes). The calibration [Eq. 41.5.2](#) is a Bayesian statement: the complete-data analysis behaves as a posterior mean and variance would. Rubin's rules are therefore exactly right when imputation and analysis come from the *same* joint model, and approximately right otherwise. The degrees of freedom in part (c) can exceed the complete-data degrees of freedom, absurdly, when M is large and the sample small; Barnard and Rubin (1999) give the corrected formula.

Idea. The between-imputation variance B is the price of not knowing the missing values, and $\bar{U}$ is the price of having a finite sample. Adding them is the whole of multiple imputation. The factor $1 + 1/M$ is the price of using finitely many imputations to measure B .

41.5.3 How many imputations

Part (d) is why the classical advice was “three to five imputations”. With $\gamma_\infty = 0.3$ and $M = 5$ the standard error is inflated by 1.0296, three per cent; with $\gamma_\infty = 0.5$ the inflation is 1.0488 at $M = 5$ and 1.0124 at $M = 20$.

The advice has shifted upward since, for two reasons the theorem does not address. The degrees of freedom [Eq. 41.5.5](#) grow like $M - 1$, so a small M gives a fat-tailed reference distribution and wide intervals even when the point estimate is fine; and $\bar{Q}$ is itself a Monte Carlo average, so a second analyst with a different seed gets a different number — uncomfortable when that number is a p -value near a threshold. Imputations are cheap, and the curve in [Figure 41.5.1\(b\)](#) is flat past $M = 20$ for every plausible γ .

41.5.4 Coverage in practice

Example. (Five analyses of one problem)

Take $n = 200$ records with two correlated covariates and $y = 1 + 0.5x_1 + 0.6x_2 + \varepsilon$, and lose x_2 with a probability depending on x_1 and y — both recorded, so MAR — leaving about 106 complete records. Over 2000 replicates, for the coefficient of x_2 :

Table 41.5.1. Five analyses of the same MAR problem. The estimand is $\beta_2 = 0.6$; “mean se” is the average reported standard error and “sd” the actual spread of the estimates over 2000 replicates.

analysis	bias	mean se	sd	coverage
complete cases	-0.151	0.101	0.102	67.2%
mean imputation	-0.319	0.125	0.108	25.6%
single imputation	-0.010	0.082	0.138	75.9%
multiple imputation, $M = 5$	-0.013	0.118	0.119	95.0%
multiple imputation, $M = 20$	-0.013	0.115	0.114	94.5%

Each row fails in its own way. The complete cases are biased, the missingness depending on the response. Mean imputation is far worse, and its reported standard error is *larger* than its actual spread. A single proper imputation removes the bias but reports a standard error three fifths of the truth, and covers 75.9% of the time. Multiple imputation with five draws gets both right, with an average estimated fraction of missing information 0.463 and median degrees of freedom 18.3.

41.5.5 Congeniality

Multiple imputation splits the work between two models: the imputer's and the analyst's. Nothing forces them to agree, and Meng (1994) showed that the consequences depend on which way they disagree.

The imputation model omits something the analysis uses. If the analyst fits an interaction and the imputer imputed one of its covariates from a model without it, the imputed values carry no interaction and the analyst's interaction is biased towards zero. This is the serious

failure, and easy to commit: the imputer usually works first, for a whole file, without knowing which analyses will be run.

The imputation model includes something the analysis does not. Then the imputations are richer than the analysis needs; estimates are usually fine and Rubin's T tends to be *too large*, so the procedure is conservative rather than wrong.

Meng calls a pair of models **congenial** when both are implied by a single Bayesian model, and shows that Rubin's variance estimator is consistent under congeniality and can be biased either way without it. Two rules follow: put into the imputation model every variable the analysis will use, including the response and every transformation and interaction to be fitted; and when imputer and analyst are different people, err towards a rich imputation model.

Warning. Omitting the response from the imputation model is the single commonest mistake. It looks cautious — “I do not want to build the answer into the data” — and it is exactly backwards: it imputes covariates as though they were unrelated to the response, which biases every coefficient towards zero. The response belongs in the imputation model.

41.5.6 Exercises

41.5.6.1 A. Check your understanding

Exercise A1.

Set $M = 1$ in [Theorem 41.5.1](#) and explain why the formulas break down. Which of the three quantities in [Eq. 41.5.3](#) cannot be computed, and what does that say about single imputation?

Solution. With $M = 1$ the between-imputation sum of squares has no degrees of freedom: B is $0/0$. So the part of the uncertainty that comes from not knowing the missing values cannot be estimated at all from one imputation, which is exactly why a single imputation reports $\bar{U}$ alone and understates the variance.

Exercise A2.

From [Eq. 41.5.5](#), compute ν for $M = 5$ and $\gamma \in \{0.1, 0.3, 0.5\}$. At which value of γ does the multiple-imputation reference distribution become so heavy-tailed that the interval is more than 20% wider than a normal-based one?

Solution. Equation [Eq. 41.5.5](#) gives $\nu = (M - 1)/\gamma^2$, so at $M = 5$ the three values are $4/0.01 = 400$, $4/0.09 = 44.4$ and $4/0.25 = 16$. The interval is wider than the normal-based one by the ratio of the t quantile to 1.96, and a table shows that ratio passing 1.2 at about seven degrees of freedom, that is at $\gamma = \sqrt{4/7.2} \approx 0.75$. Only a problem in which three quarters of the information is missing costs that much at $M = 5$ — and raising M is the cheap repair.

41.5.6.2 B. Practice

Exercise B1.

Construct a simulation in which the analysis fits y on x_1, x_2 and their interaction, while x_2 is imputed from a model without the interaction. Measure the bias in the interaction coefficient and its coverage. Then repeat with the interaction included in the imputation model.

41.5.6.3 C. Going deeper**Exercise C1.**

Show that when the imputation model and the analysis model are the same Bayesian model, $\bar{Q}$ and T converge as $M \rightarrow \infty$ to the exact posterior mean and variance of Q given $\mathbf{D}_{\text{obs}}$. Deduce that multiple imputation is, in the congenial case, a Monte Carlo scheme for a posterior that could also be sampled directly — and say why one might still prefer the imputation route.

41.6 Sensitivity analysis

Everything in the last three sections rested on missingness at random, and [Proposition 41.1.1](#) says the data cannot check it. That is a reason neither to despair nor to pretend, but to report how much the conclusion depends on the assumption — which is what a sensitivity analysis does.

41.6.1 Two factorizations

The selection factorization [Eq. 41.1.1](#) splits the joint law into a model for the data and a model for who responds. The other order gives the **pattern-mixture** factorization

$$f(\mathbf{D}, \mathbf{R} \mid \boldsymbol{\theta}_1, \boldsymbol{\theta}_2) = f(\mathbf{D} \mid \mathbf{R}, \boldsymbol{\theta}_1) f(\mathbf{R} \mid \boldsymbol{\theta}_2), \quad (41.6.1)$$

a mixture, over patterns, of a different distribution of the data within each pattern. The two describe the same object and differ only in what is easy to say.

Proposition 41.6.1 — Selection and pattern-mixture models

Consider a single variable v recorded when $R = 1$, alongside always recorded variables $\mathbf{u}$.

- (a) Every selection model $f(v \mid \mathbf{u}) \Pr(R = 1 \mid v, \mathbf{u})$ corresponds to the pattern-mixture model with

$$f(v \mid \mathbf{u}, R = r) \propto f(v \mid \mathbf{u}) \Pr(R = r \mid v, \mathbf{u}),$$

$$\Pr(R = r \mid \mathbf{u}) = \int f(v \mid \mathbf{u}) \Pr(R = r \mid v, \mathbf{u}) dv,$$

and conversely, so neither formulation is more general.

- (b) The observed data identify $f(v \mid \mathbf{u}, R = 1)$ and $\Pr(R = 1 \mid \mathbf{u})$, and nothing about $f(v \mid \mathbf{u}, R = 0)$. The marginal

$$f(v \mid \mathbf{u}) = \Pr(R = 1 \mid \mathbf{u}) f(v \mid \mathbf{u}, R = 1) + \Pr(R = 0 \mid \mathbf{u}) f(v \mid \mathbf{u}, R = 0) \quad (41.6.2)$$

is therefore identified only after the analyst supplies the last factor. Missing at random is the supply $f(v \mid \mathbf{u}, R = 0) = f(v \mid \mathbf{u}, R = 1)$.

- (c) Let the mechanism be $\Pr(R = 1 \mid v, \mathbf{u}) = h\{a(\mathbf{u}) + cv\}$, with h continuous, strictly increasing and valued in $(0, 1)$ and $a(\cdot)$ an unrestricted function. Then c is not identified: for every c at which the tilt [Eq. 41.6.3](#) below is integrable and its integral covers the required value, there are an $a(\cdot)$ and an $f(v \mid \mathbf{u}, R = 0)$ reproducing the observed-data distribution exactly. Any standard error reported for c comes from restricting $a(\cdot)$ — to $a + \mathbf{u}^\top \mathbf{b}$, say — and from the assumed forms of h and $f(v \mid \mathbf{u})$, not from the data.

Proof.

- (a) Both expressions are the joint density $f(v, R = r \mid \mathbf{u})$ written in the two orders, by the definition of conditional probability; the displayed formulas are Bayes's rule in each direction, and the correspondence is one-to-one wherever the denominators are positive.
- (b) The observed data consist of $(\mathbf{u}, R)$ for all units and v for those with $R = 1$. Its distribution is determined by the law of $\mathbf{u}$, $\Pr(R = 1 \mid \mathbf{u})$ and $f(v \mid \mathbf{u}, R = 1)$, and by nothing else, exactly as in [Proposition 41.1.1](#). Equation [Eq. 41.6.2](#) is the law of total probability. Setting the unidentified factor equal to the identified one is the MAR choice, since then $\Pr(R = 1 \mid v, \mathbf{u})$ computed by Bayes's rule is free of v .
- (c) Fix c , write $\pi(\mathbf{u}) = \Pr(R = 1 \mid \mathbf{u})$ and $f_1(v \mid \mathbf{u}) = f(v \mid \mathbf{u}, R = 1)$ for the two identified pieces, and abbreviate $h_c(v) = h\{a(\mathbf{u}) + cv\}$. Bayes's rule applied to (a) forces the unrecorded conditional to be the recorded one *tilted* by the odds of not responding:

$$f(v \mid \mathbf{u}, R = 0) = \frac{f_1(v \mid \mathbf{u})}{K(\mathbf{u})} \cdot \frac{1 - h_c(v)}{h_c(v)}, \quad K(\mathbf{u}) = \int f_1 \frac{1 - h_c}{h_c} dv. \quad (41.6.3)$$

Take that as the definition and assemble $f(v \mid \mathbf{u})$ from [Eq. 41.6.2](#). Then $f(v \mid \mathbf{u})h_c(v) = \pi f_1 h_c + \{(1 - \pi)/K\} f_1 (1 - h_c)$, which collapses to $\pi(\mathbf{u}) f_1(v \mid \mathbf{u})$ — free of h_c — exactly when $K(\mathbf{u}) = \{1 - \pi(\mathbf{u})\}/\pi(\mathbf{u})$. Integrating over v then returns $\Pr(R = 1 \mid \mathbf{u}) = \pi(\mathbf{u})$, and dividing returns $f(v \mid \mathbf{u}, R = 1) = f_1(v \mid \mathbf{u})$: both identified pieces are reproduced, for this c .

It remains to solve $K(\mathbf{u}) = \{1 - \pi(\mathbf{u})\}/\pi(\mathbf{u})$ for the intercept $a(\mathbf{u})$, one scalar equation per $\mathbf{u}$. Since $(1 - h_c)/h_c$ decreases pointwise in $a(\mathbf{u})$, K is continuous and strictly decreasing, with $K \rightarrow 0$ as $a(\mathbf{u}) \rightarrow \infty$; a solution exists whenever the target lies in its range. Both provisos bite. For $h = \Phi$ and f_1 normal with standard deviation s , the integrand's logarithm behaves like $(c^2 - s^{-2})v^2/2$ as $v \rightarrow -\infty$, so K is finite exactly when $|c|s < 1$, and then runs over all of $(0, \infty)$; for larger $|c|$ no such pattern-mixture model exists and the construction is unavailable. Within the range, the observed-data likelihood profiled over the remaining parameters is constant in c , so c is not identified. Restricting $a(\mathbf{u})$ to $a + \mathbf{u}^\top \mathbf{b}$ leaves one equation per $\mathbf{u}$ and only $1 + \dim \mathbf{u}$ unknowns; the profile is then no longer flat, and the curvature — the reported standard error —

comes from that restriction, not from the data.

■

Part (c) is worth dwelling on. Fit a Heckman-style selection model — a normal outcome equation and a probit selection equation, as in Heckman (1979) — and the software returns an estimate of the selection coefficient with a standard error; part (c) says that number is an artefact of the assumed functional forms. With an **exclusion restriction**, a variable entering the selection equation and not the outcome equation, the parameter becomes identified by more than functional form; without one it does not. Reporting such a fit as though the data had spoken is the central dishonesty of MNAR modelling, and the reason this section prefers to display the untestable part rather than estimate it.

Idea. Under MNAR nothing is estimated that was not assumed. The useful question is not “what is the answer?” but “how far must the assumption move before the answer changes?”

41.6.2 Delta-adjustment and tipping points

The pattern-mixture form suggests an honest device. Impute under MAR, then shift the imputed values by a fixed amount δ before analysing them: that is, assume

$$E(v \mid \mathbf{u}, R = 0) = E(v \mid \mathbf{u}, R = 1) - \delta. \quad (41.6.4)$$

Here δ is a *sensitivity parameter*: not estimated, but set. Zero is MAR, and a positive δ says the unrecorded values are worse than their recorded counterparts with the same covariates. Because Eq. 41.6.4 constrains only the unidentified factor of Eq. 41.6.2, every δ fits the observed records equally well — in the example below all give the observed-data log-likelihood -373.62 — so the choice is a statement about the world, not about the data. Repeating the analysis over a grid of δ and reporting the curve is a **tipping-point analysis**: the value δ^* at which the conclusion reverses is the smallest departure from MAR that would overturn it.

Example. (How far must the assumption move?)

A two-arm study of 400 units records a baseline measurement for everyone and an outcome for those who stay. Dropout is likelier in the treated arm and at high baseline values, and 147 outcomes are lost — 83 treated and 64 control. Multiple imputation under MAR gives a treatment effect of 0.475 with 95% interval (0.199, 0.750).

Now suppose the treated units who dropped out would have done worse than the MAR imputation says, by δ . The estimate falls steadily and the lower limit reaches zero at $\delta^* = 0.482$, which is 0.452 of a residual standard deviation. The finding therefore survives the assumption that treated dropouts were up to about half a standard deviation worse than comparable stayers, and not more. Whether that is reassuring is a question for whoever knows why people dropped out.

```
import numpy as np
from scipy import stats
```

Figure 41.6.1: Estimated treatment effect and its 95% interval as the imputed outcomes of the treated arm are shifted down by δ . Every δ fits the recorded outcomes equally well. The tipping point is where the lower limit reaches zero.

```
rng = np.random.default_rng(4108)
n, tau_true = 400, 0.6
arm = np.repeat([0, 1], n // 2)
base = rng.normal(size=n)
y = 0.5 + tau_true * arm + 0.6 * base + rng.normal(size=n)
eta = -1.0 + 0.7 * arm + 0.8 * base
seen = rng.uniform(size=n) > 1 / (1 + np.exp(-eta))
print(f"{n - seen.sum()} of {n} outcomes lost:"
      f" {int((~seen & (arm == 1)).sum())} treated, {int((~seen & (arm == 0)).sum())} control")
```

```
Z = np.column_stack([np.ones(n), arm, base])

def mi_estimate(delta, M, rng):
    """Multiple imputation under MAR, then shift the treated arm's imputations by -delta."""
    Zo, k = Z[seen], int(seen.sum())
    g, *_ = np.linalg.lstsq(Zo, y[seen], rcond=None)
    sse = float(np.sum((y[seen] - Zo @ g) ** 2))
    qs, us = [], []
    for _ in range(M):
        s2 = sse / rng.chisquare(k - Z.shape[1])
        g_star = rng.multivariate_normal(g, s2 * np.linalg.inv(Zo.T @ Zo))
        draw = Z @ g_star + np.sqrt(s2) * rng.normal(size=n) - delta * arm
        y_full = np.where(seen, y, draw)
        b, *_ = np.linalg.lstsq(Z, y_full, rcond=None)
        resid = y_full - Z @ b
        v = (resid @ resid / (n - 3)) * np.linalg.inv(Z.T @ Z)[1, 1]
        qs.append(b[1])
        us.append(v)
    M_ = len(qs)
    q_bar, u_bar, b_var = np.mean(qs), np.mean(us), np.var(qs, ddof=1)
    total = u_bar + (1 + 1 / M_) * b_var
    gamma = (1 + 1 / M_) * b_var / total
    return q_bar, total, (M_ - 1) / gamma**2
```

```

deltas = np.linspace(0.0, 1.6, 33)
est, lo, hi = [], [], []
for d in deltas:
    q, t, nu = mi_estimate(d, 50, np.random.default_rng(4109))
    half = stats.t.ppf(0.975, nu) * np.sqrt(t)
    est.append(q)
    lo.append(q - half)
    hi.append(q + half)
est, lo, hi = map(np.array, (est, lo, hi))
tipping = float(np.interp(0.0, -lo, deltas))          # where the lower limit
reaches zero
print(f"delta = 0: effect {est[0]:.3f}, 95% interval ({lo[0]:.3f}, {hi[0]:.3f})")
print(f"tipping point: delta = {tipping:.3f}")

```

Variations abound. The shift may be applied to one arm or both, on the response scale or a link scale, and may depend on covariates or grow with time since dropout; in trials it is often replaced by **jump to reference**, in which a treated dropout is imputed as though from the control arm, or **copy increments in reference**, in which only the subsequent changes are borrowed. Each is a particular choice of the unidentified factor in [Eq. 41.6.2](#).

41.6.3 Honest reporting

The technical content of this section is thin; the discipline is not. A report should say how much is missing and where, by variable and by pattern; why, as far as the reasons recorded at collection time reveal, those being the only evidence about the mechanism that will ever exist; what was assumed, naming the variables MAR is conditional on, since “missing values were imputed” states no assumption at all; what the method was, including whether the imputation model contained the response; and how far the conclusion travels, as a sensitivity curve or at least a tipping point. That last item is where regulators have converged: the National Research Council (2010) report recommends designing to prevent missingness and pre-specifying both the primary analysis and the sensitivity analyses, rather than choosing them after seeing the result.

Warning. A sensitivity analysis chosen after seeing the primary result is not a sensitivity analysis; it is a selection procedure, with the properties [Chapter 29](#) describes ([Proposition 29.5.1](#)). Fix the grid of δ and the summary to be reported before the analysis is run.

41.6.4 Exercises

41.6.4.1 A. Check your understanding

Exercise A1.

Write the bivariate normal of [Exercise \(B3\)](#) in both factorizations, selection and pattern-mixture, and identify which parameters are estimable from the observed data in each. Why is the pattern-mixture form better suited to a sensitivity analysis?

Exercise A2.

In [Example \(How far must the assumption move?\)](#) the tipping point is 0.482 on the outcome scale. Express it as a multiple of the estimated treatment effect and as a multiple of the residual standard deviation, and say which you would put in a report and why.

41.6.4.2 B. Practice**Exercise B1.**

For the model of [Example \(How far must the assumption move?\)](#), show analytically that the treatment effect estimated after a δ -shift of the treated arm's imputations is $\hat{\tau}(\delta) = \hat{\tau}(0) - \delta p_1$, where p_1 is the fraction of treated units whose outcome is missing, provided the analysis model contains the arm indicator. Check the slope against the figure.

Solution. With the arm indicator in the model and a completed data set, the estimated effect is a difference of arm means adjusted for the baseline. Shifting the imputed outcomes of the treated arm down by δ lowers that arm's adjusted mean by δ times the fraction of its units that were imputed, and leaves the control arm alone; the baseline adjustment is unaffected because the shift is constant within the arm. Hence $\hat{\tau}(\delta) = \hat{\tau}(0) - \delta p_1$. With 83 of 200 treated units missing, $p_1 \approx 0.42$, and the slope of the curve in [Figure 41.6.1](#) matches.

41.6.4.3 C. Going deeper**Exercise C1.**

For a monotone pattern with three time points, state the **complete-case missing value** restriction — the unidentified conditional for a unit that dropped out after time j equals the corresponding conditional among units seen at all three times — and the **neighbouring-case** alternative. Show that both are particular choices of the unidentified factor in [Eq. 41.6.2](#), and that the MAR choice lies between them in a sense you should make precise.

Exercise C2.

Suppose the response is bounded in $[0, 1]$. Compute the **worst-case bounds** for its mean: impute every missing value by 0, then by 1. Show that the width of the resulting interval is the fraction missing, that it requires no assumption at all, and that it is usually too wide to be useful. Discuss where such bounds nevertheless earn their place.

Solution. If a fraction λ of values is missing, the mean of the completed data ranges over an interval of width λ as the imputations range over $[0, 1]$, and every value in that interval is attained by some choice, so the bounds are sharp and assumption-free — they are the Manski-style bounds for a bounded outcome. They are useless when λ is large compared with the effect of interest, which is the usual case. They earn their place as a first line in a report: if the worst-case bound already excludes the null, no assumption

about the mechanism is needed at all, and that is worth knowing before any modelling begins.

41.7 Summary and Notes

41.7.1 Summary

Idea.

1. The pattern of missingness is data. Writing the joint law as a model for the complete array times a mechanism [Eq. 41.1.1](#) separates what the analyst wants from how the holes arose, and sorts mechanisms into MCAR, MAR and MNAR ([Definition 41.1.1](#)).
2. Nothing in the observed data distinguishes MAR from MNAR: every choice of the conditional distribution of the unrecorded values given the recorded ones gives the same observed-data likelihood ([Proposition 41.1.1](#)). MCAR against MAR is testable; MAR against MNAR is not.
3. A complete-case analysis estimates functionals of the law given completeness. It is valid under MCAR, and — the useful case — valid for a correctly specified regression whenever the missingness depends on the covariates but not on the response ([Proposition 41.2.1](#)). It is not generally valid under MAR.
4. Mean imputation deflates the variance by the fraction recorded ([Proposition 41.2.2](#)); regression imputation without noise inflates correlations; any single imputation understates every standard error; available-case correlation matrices need not be nonnegative definite.
5. Under MAR with distinct parameters the mechanism is ignorable: likelihood, likelihood ratio tests and Bayesian posteriors may be computed from the observed-data likelihood alone ([Theorem 41.3.1](#)). The licence costs a model for any variable that can go missing, including covariates. For a monotone pattern that likelihood factors into conditional models on nested subsamples ([Exercise \(B1\)](#) of [Section 41.1](#) and [Exercise \(B1\)](#) of [Section 41.3](#)).
6. EM maximizes the observed-data likelihood by alternating a conditional expectation of the complete-data log-likelihood with a complete-data fit ([Definition 41.4.1](#)). Every sweep increases the observed-data likelihood ([Theorem 41.4.1](#)), and fixed points are stationary points, not necessarily maxima.
7. For missing responses in a linear model, EM returns the observed-data least squares estimate and $\text{SSE}_o/(n - m)$ ([Proposition 41.4.2](#)), deriving the degrees-of-freedom correction that [Theorem 18.6.1\(e\)](#) asserted. For a missing covariate the E step must condition on the response ([Proposition 41.4.3](#)).
8. Observed information equals expected complete-data information minus the variance of the complete-data score ([Proposition 41.4.4](#)). That difference sets both EM's rate of convergence and the amount by which the complete-data information understates the variance; standard errors come from Louis's formula, numerical differentiation or the bootstrap, never from the matrix the M step inverts.
9. Multiple imputation draws M completions from the posterior predictive distribution ([Definition 41.5.1](#)), analyses each, and combines by $\bar{Q}$ and $T = \bar{U} + (1 + M^{-1})B$

on $(M - 1)/\gamma^2$ degrees of freedom ([Theorem 41.5.1](#)). A finite M inflates the standard error by $(1 + \gamma_\infty/M)^{1/2}$. The imputation model must contain everything the analysis will use, above all the response.

10. Under MNAR the selection and pattern-mixture factorizations describe the same unidentified object ([Proposition 41.6.1](#)). A delta-adjustment names the unidentified part, every value of it fits the observed data equally well, and the tipping point reports how far the assumption must move before the conclusion does.

41.7.2 Notes and sources

The framework. The classification into MCAR, MAR and MNAR, the selection factorization and the ignorability theorem are due to Rubin (1976); the book-length development is Little and Rubin (2019), whose organization this chapter follows, the proofs, examples and numbers here being the book's own. Schafer (1997) treats the multivariate normal and categorical cases, including the monotone factorizations of [Section 41.3](#), whose closed form is Anderson's (1957). The realized-value and everywhere versions of MAR are separated by Seaman, Galati, Jackson and Carlin (2013); the test of MCAR is Little (1988), and the general form of [Proposition 41.1.1](#) is Molenberghs, Beunckens, Sotito and Kenward (2008).

Complete cases. Part (b) of [Proposition 41.2.1](#) has been rediscovered many times; the clearest statements are Little (1992) and White and Carlin (2010), who also note that complete-case analysis can beat multiple imputation for efficiency when the mechanism depends only on co-variables. Inverse-probability weighting descends from Horvitz and Thompson (1952), the doubly robust augmentation from Robins, Rotnitzky and Zhao (1994).

EM. The algorithm was named and given its general form by Dempster, Laird and Rubin (1977), who also identified the rate of convergence as the largest fraction of missing information; special cases are older, the iteration of [Theorem 18.6.1\(c\)](#) being the missing-plot scheme of Healy and Westmacott (1956), built on Yates's (1933) formula. The missing-information principle is Orchard and Woodbury (1972), and [Eq. 41.4.5](#) is Louis's (1982). Wu (1983) corrected the convergence claims of the original paper; Meng and Rubin (1991) extract the observed information from the EM iterations themselves, and McLachlan and Krishnan (2008) is the book-length treatment.

Multiple imputation. The idea is Rubin's (1978) and the definitive statement is Rubin (1987), where the combining rules, the degrees of freedom and the efficiency calculation of [Theorem 41.5.1](#) all appear; the small-sample degrees of freedom are Barnard and Rubin (1999). Congeniality is Meng's (1994), whose discussion in the same issue remains the best entry point to when Rubin's variance estimator is consistent. Chained equations were developed by Van Buuren, Boshuizen and Knook (1999) and by Raghunathan, Lepkowski, Van Hoewyk and Solenberger (2001); van Buuren (2018) is the practical handbook.

MNAR and sensitivity. Selection models in the econometric tradition begin with Heckman (1979), pattern-mixture models with Little (1993), who introduced the complete-case missing-value restriction of [Exercise \(C1\)](#). The non-identifiability in [Proposition 41.6.1\(c\)](#) is why Manski's (1990) assumption-free bounds, the subject of [Exercise \(C2\)](#), remain worth computing. Delta-adjustment and tipping-point analyses became standard in clinical trials after the National Research Council (2010) report, which is short and unusually clear about the difference between preventing missing data and repairing it. The reference-based schemes named in [Section 41.6](#) are due to Carpenter, Roger and Kenward (2013).

Where this goes next. Nothing here is special to a normal response: ignorability, EM and Rubin’s rules apply verbatim to the generalized linear models of Chapters 34 to 37, with harder integrals and an E step usually done by simulation. The estimating-equation methods of Chapter 40 stay consistent when the missingness is completely at random or depends only on modelled, fully observed covariates, and become inconsistent when it depends on previously observed responses — the MAR case in which likelihood remains valid — because the estimating function $E\{R_i(Y_i - \mu_i)\}$ is then no longer zero. The repair is inverse-probability weighting.

Chapter 42

Polynomials, Piecewise Fits and the Road to Splines

For forty-one chapters the mean of the response has been a linear function of columns chosen in advance. This part keeps least squares, the projection geometry and every distribution theory built on them, and gives up one thing only: the insistence that the columns be the regressors themselves. The oldest way to do that is to let them be powers of a regressor, which makes a polynomial regression a linear model in a transformed basis, so that Parts II and III apply word for word — and that is what makes its failures instructive, because they are failures of the *family of shapes*, not of the fitting.

A polynomial is a global object: raising its degree to capture a feature at one end of the data changes the curve everywhere, sends the variance soaring at the edges, and turns any extrapolation into fiction. Worse, the obvious basis $1, x, x^2, \dots$ is one of the worst-conditioned matrices in numerical analysis. This chapter separates the two complaints. Orthogonal polynomials repair the arithmetic completely and the statistics not at all; knots repair the statistics, and lead to splines.

What you need. [Chapter 6](#) (projection, reparameterization, leverage), [Chapter 9](#) (sequential sums of squares, [Example \(A trend in the Nile\)](#)), [Chapter 10](#) (conditioning, [Definition 1.8.1](#)), [Chapter 11](#) (restricted least squares), [Chapter 12](#) (bands) and [Chapter 14](#) (lack of fit). The later sections borrow the vocabulary of [Chapter 29](#) without needing its theory, and the closing discussion uses the bias–variance trade-off of [Chapter 19](#), the diagnostics of [Chapter 20](#), the transformations of [Chapter 22](#) and the causal reading of [Chapter 25](#).

42.0.1 Roadmap

- [Polynomial regression and its instability](#)
- [Orthogonal polynomials](#)
- [Piecewise polynomials](#)
- [Regression splines and truncated power bases](#)
- [Summary and notes](#)

42.1 Polynomial regression and its instability

The simplest way to let a regression curve bend is to add powers of the regressor as columns. Nothing in Parts II and III changes, because nothing there ever asked what the columns *were*.

Definition 42.1.1 — Polynomial regression

Let $x_1, \dots, x_n$ be observed values of a single regressor. The **polynomial regression model of degree d** is

$$E(Y_i) = \beta_0 + \beta_1 x_i + \beta_2 x_i^2 + \cdots + \beta_d x_i^d, \quad i = 1, \dots, n,$$

a linear model with the $n \times (d+1)$ **Vandermonde** matrix $\mathbf{X} = [\mathbf{1}, \mathbf{x}, \mathbf{x}^2, \dots, \mathbf{x}^d]$, where $\mathbf{x}^j$ has entries x_i^j . More generally, any functions $\phi_0, \dots, \phi_d$ give columns $\phi_j(\mathbf{x})$ and a fitted curve $\hat{f}(t) = \sum_j \hat{\beta}_j \phi_j(t)$; they are a **basis**, and the model is the space $\mathcal{P}_d = \text{span}\{\phi_0, \dots, \phi_d\}$, not the list.

42.1.1 Everything from Parts II and III applies

Write $\mathbf{X}$ for the Vandermonde matrix. Then $\hat{\boldsymbol{\beta}}$ is unbiased as soon as the x_i take $d+1$ distinct values ([Exercise \(A1\)](#)); the fitted curve $\hat{f}(t) = \mathbf{x}(t)^\top \hat{\boldsymbol{\beta}}$, with $\mathbf{x}(t) = (1, t, \dots, t^d)^\top$, is estimable at every t , so [Theorem 12.1.1](#) gives it an interval and [Theorem 12.4.1](#) a band; raising the degree is a nested comparison ([Theorem 11.1.1](#)); replicated x values give the lack-of-fit test of [Theorem 14.6.2](#) against the pure error of [Definition 14.6.1](#); and the diagnostics of [Chapter 20](#) are untouched. By [Theorem 6.7.1](#) none of this depends on the basis, only on $\mathcal{P}_d$.

Warning. What does *not* carry over is the reading of a coefficient: there is no way to change x while holding x^2 fixed, so nothing beyond the intercept has the “other regressors held fixed” meaning of [Theorem 6.6.2](#). Only the curve and its contrasts $f(t_2) - f(t_1)$ mean anything, and whether those describe an intervention is the question of [Chapter 25](#).

42.1.2 What the degree buys

Raising the degree adds a column, so bias falls and variance rises: the trade-off of [Example \(Choosing a polynomial degree\)](#). The useful question is how the two move in practice.

Example. (Degree in the carbon dioxide series)

The monthly mean carbon dioxide at Mauna Loa, March 1958 to December 2001, gives $n = 521$ observations; [Example \(A curved trend and a seasonal cycle\)](#) modelled it with a quadratic trend and two seasonal harmonics. Keep the four harmonic columns and replace the quadratic by a polynomial of degree d in time rescaled to $[-1, 1]$. The residual standard deviation falls from 0.7602 ppm at $d = 2$ ($p = 7$) to 0.4874 at $d = 8$ and 0.4300 at $d = 16$, while no harmonic coefficient moves by more than 0.0150 ppm.

Figure 42.1.1: Polynomial trends for the Mauna Loa series, seasonal columns fixed. (a) Residuals of the quadratic fit, with the degree-8 and degree-16 trends measured from it. (b) Standard error of the fitted mean.

The improvement is real: panel (a) of Figure 42.1.1 shows the residuals of the quadratic fit wandering by a part per million over decades, and the higher-degree trends tracking that wandering. The price is in panel (b). In the middle of the range the standard error of the fitted mean is much the same at all three degrees — 0.0830, 0.0676, 0.0730 ppm at 1980 — but at the left-hand edge it is 0.1217, 0.2011, 0.2899, so the ratio of edge to centre rises from 1.47 to 2.97 to 3.97. Leverages tell the same story: average 0.0134, 0.0250, 0.0403 against maximum 0.0256, 0.1702, 0.4546. At degree 16 one month, the first of the series, carries almost half of its own fitted value.

```
import numpy as np
import statsmodels.api as sm

co2 = sm.datasets.co2.load_pandas().data["co2"]
monthly = co2.resample("MS").mean().dropna()           # weekly values -> monthly
# means
y = monthly.to_numpy()
t = (monthly.index.year + (monthly.index.month - 0.5) / 12).to_numpy()
n = len(y)

def harmonics(s):
    """The seasonal columns of Example 5.3, held fixed throughout the chapter."""
    return np.column_stack([np.cos(2 * np.pi * s), np.sin(2 * np.pi * s),
                             np.cos(4 * np.pi * s), np.sin(4 * np.pi * s)])

lo, hi = t.min(), t.max()
u = lambda s: 2 * (s - lo) / (hi - lo) - 1           # time rescaled to [-1, 1]

print(f"n = {n}, time from {lo:.2f} to {hi:.2f}")

def trend_design(s, d):
    """Model matrix: powers 1, u, ..., u^d of rescaled time, then the four harmonics
    ."""
    return np.column_stack([np.vander(u(s), d + 1, increasing=True), harmonics(s)])
```

```

for d in (2, 8, 16):
    X = trend_design(t, d)
    beta, *_ = np.linalg.lstsq(X, y, rcond=None)
    resid = y - X @ beta
    p = X.shape[1]
    lev = np.einsum("ij,ij->i", X @ np.linalg.pinv(X.T @ X), X) # leverages h_ii
    print(f"degree {d:2d}:  p = {p:2d}    sigma_hat = {np.sqrt(resid @ resid / (n - p)):.4f}")
    f"    mean h = {lev.mean():.4f}    max h = {lev.max():.4f}"

```

42.1.3 Four ways a polynomial misbehaves

The pattern in [Example \(Degree in the carbon dioxide series\)](#) is not particular to that series: it is the visible part of four properties of the monomial basis and of the polynomial class itself.

Proposition 42.1.1 — Instability of a high-degree polynomial fit

Let $\mathbf{X}_d = [\mathbf{1}, \mathbf{x}, \dots, \mathbf{x}^d]$ be the Vandermonde matrix of a design with at least $d + 1$ distinct points, and let $\hat{f}_d$ be the least squares polynomial of degree d .

- (a) (*Conditioning.*) If the design points are a sample from a distribution on $[0, 1]$ with density g , then $n^{-1}\mathbf{X}_d^\top \mathbf{X}_d \rightarrow \mathbf{G}$ almost surely, where $G_{jk} = \int_0^1 x^{j+k} g(x) dx$. For the uniform density this limit is the $(d + 1) \times (d + 1)$ Hilbert matrix $G_{jk} = 1/(j + k + 1)$, whose condition number grows exponentially in d .
- (b) (*Oscillation.*) Interpolation by a polynomial of degree $n - 1$ at n equally spaced points need not converge as n grows, even for a function that is analytic on the interval; the error can diverge. The failure is a property of the node placement, not of polynomials: at Chebyshev nodes the same interpolants converge geometrically.
- (c) (*Extrapolation.*) Let $\tilde{\mathbf{x}}_d = (\mathbf{I} - \mathbf{M}_{d-1})\mathbf{x}^d$ be the part of the top power orthogonal to the lower ones. Then $t \mapsto \text{Var}\{\hat{f}_d(t)\}$ is a polynomial of degree exactly $2d$ with leading coefficient $\sigma^2/\|\tilde{\mathbf{x}}_d\|^2$, so

$$\frac{\text{Var}\{\hat{f}_d(t)\}}{\sigma^2 t^{2d}} \rightarrow \frac{1}{\|\tilde{\mathbf{x}}_d\|^2} \quad \text{as } |t| \rightarrow \infty.$$

Each extra degree therefore multiplies the standard error of the extrapolated curve by a further factor $|t|$, up to the constant $\|\tilde{\mathbf{x}}_d\|/\|\tilde{\mathbf{x}}_{d+1}\|$.

- (d) (*Non-locality.*) Changing one response y_i by Δ changes the fitted curve at every t by $\Delta \ell_i(t)$, where $\ell_i(t) = \mathbf{x}(t)^\top (\mathbf{X}_d^\top \mathbf{X}_d)^{-1} \mathbf{x}_i$ is itself a polynomial of degree at most d and never identically zero, so it vanishes at most d times: no observation can be given a purely local influence.

Proof.

- (a) The (j, k) entry of $n^{-1}\mathbf{X}_d^\top \mathbf{X}_d$ is $n^{-1} \sum_i x_i^{j+k}$, an average of bounded independent and identically distributed variables, which by the strong law converges almost surely to $E(X^{j+k}) = \int x^{j+k} g$; for $g \equiv 1$ that is $1/(j+k+1)$. The exponential growth of $\kappa(\mathbf{G})$ is classical and not reproduced here: Todd (1954) shows it is of order

$(1 + \sqrt{2})^{4d}$ up to algebraic factors, and Higham (2002) treats the Hilbert matrix and Vandermonde systems. By Eq. 10.1.2 the normal equations (Theorem 6.4.2) then lose about $2 \log_{10} \kappa(\mathbf{X}_d)$ of the sixteen digits of double precision.

- (b) This is Runge's phenomenon, stated here without proof: Runge (1901) gave the example and Trefethen (2019) the modern account, Chebyshev nodes included. Nothing later depends on the divergence itself, only on the weaker statement that a polynomial forced to follow the data in one region must do something in the others, and that something is an oscillation largest at the ends.
- (c) With $\mathbf{x}(t) = (1, t, \dots, t^d)^\top$,

$$\begin{aligned} \text{Var}\{\hat{f}_d(t)\} &= \sigma^2 \mathbf{x}(t)^\top (\mathbf{X}_d^\top \mathbf{X}_d)^{-1} \mathbf{x}(t) \\ &= \sigma^2 \sum_{j=0}^d \sum_{k=0}^d [(\mathbf{X}_d^\top \mathbf{X}_d)^{-1}]_{jk} t^{j+k}, \end{aligned}$$

a polynomial in t whose coefficient of t^{2d} is $\sigma^2 [(\mathbf{X}_d^\top \mathbf{X}_d)^{-1}]_{dd}$. By Eq. 6.6.1 with $\mathbf{X}_1 = \mathbf{x}^d$ and $\mathbf{X}_2 = \mathbf{X}_{d-1}$, that entry is $1/\|(\mathbf{I} - \mathbf{M}_{d-1})\mathbf{x}^d\|^2 = 1/\|\tilde{\mathbf{x}}_d\|^2$, which is positive because $\mathbf{x}^d \notin \mathcal{C}(\mathbf{X}_{d-1})$ when the design has at least $d+1$ distinct points (Exercise A1). A polynomial with positive leading coefficient c satisfies $q(t)/t^{2d} \rightarrow c$, which is the claim.

- (d) Least squares is linear in $\mathbf{y}$, so the fitted curve changes by $\Delta \mathbf{x}(t)^\top (\mathbf{X}_d^\top \mathbf{X}_d)^{-1} \mathbf{x}_i$ when y_i changes by Δ . In t this is a combination of $1, t, \dots, t^d$, hence a polynomial of degree at most d , and never the zero polynomial, since $(\mathbf{X}_d^\top \mathbf{X}_d)^{-1} \mathbf{x}_i = \mathbf{0}$ would force $\mathbf{x}_i = \mathbf{0}$ while $\mathbf{x}_i$ has leading entry one. Such a polynomial has at most d real roots.

■

Part (a) explains the numbers in Example (Polynomial regression), and part (b) is drawn in panel (a) of Figure 42.1.2. Part (d) is why a polynomial fit is never local: moving the December 2001 carbon dioxide value by 10 ppm moves the fitted trend by 0.170 ppm at the end of the series and 0.059 ppm in March 1958 when $d = 2$, and by 2.749 and 0.197 ppm when $d = 12$, the degree-12 weight changing sign 12 times on the way.

Example. (Runge's function)

Interpolate $f(x) = 1/(1 + 25x^2)$ at m equally spaced points of $[-1, 1]$ by the polynomial of degree $m - 1$. The largest error on the interval is 1.92 for $m = 11$, 59.82 for $m = 21$ and 2388.03 for $m = 31$: the function is smooth and bounded by one, and the interpolant does not converge to it. Move the same nodes to the Chebyshev positions $\cos\{(2k + 1)\pi/2m\}$, which crowd towards the ends, and the errors become 0.10915, 0.01533, 0.00206. Only where the information sits has changed.

Trouble at the ends is a shortage of design points relative to what the fitted function is asked to do there. Either add points, rarely an option, or ask the function to do less — which is what knots and penalties do.

Example. (Eleven years out of sample)

Fit the same models to the 389 months up to the end of 1990 and predict the 132 months

Figure 42.1.2: (a) Runge's phenomenon: equally spaced interpolation of $1/(1 + 25x^2)$, 11 and 21 nodes. (b) Polynomial trends fitted up to 1990, continued to 2002.

of 1991–2001. Inside the fitting range the residual standard deviation falls steadily with the degree — 0.439, 0.428, 0.417, 0.406 ppm at degrees 2, 4, 6, 8 — while outside it the root mean squared prediction errors are 3.99, 2.63, 13.92 and 188.23 ppm. The degree-8 fit, the best of the four in-sample, is out by -540.7 ppm in December 2001 against an observed value near 371: it predicts a concentration several hundred parts per million below zero.

```
import numpy as np

runge = lambda x: 1.0 / (1.0 + 25.0 * x ** 2)
grid = np.linspace(-1.0, 1.0, 2001)

for m in (5, 11, 21, 31):
    equal = np.linspace(-1.0, 1.0, m)                # m equally spaced
    nodes                                     nodes
    cheb = np.cos((2 * np.arange(m) + 1) * np.pi / (2 * m)) # m Chebyshev nodes
    err = [np.max(np.abs(np.polyval(np.polyfit(z, runge(z), m - 1), grid) - runge(
    grid)))
           for z in (equal, cheb)]
    print(f"{m:2d} nodes, degree {m - 1:2d}:  equally spaced {err[0]:10.4f}
    Chebyshev {err[1]:8.5f}")
```

42.1.4 Centring and scaling are a partial repair

Part (a) of [Proposition 42.1.1](#) is about the *basis*, and a basis can be changed without touching the model. The cheapest change is affine: fit in $u = \{2x - \max x - \min x\}/(\max x - \min x)$, which runs over $[-1, 1]$, or at least in $x - \bar{x}$. By [Theorem 6.7.1](#) the fit is identical and only the arithmetic differs. For the carbon dioxide design the condition number of the trend columns is

Degree	raw years	centred	rescaled to $[-1, 1]$
2	1.08×10^{11}	3.19×10^2	3.76×10^0
4	1.36×10^{22}	1.42×10^5	1.90×10^1

Degree	raw years	centred	rescaled to $[-1, 1]$
8	9.87×10^{40}	3.11×10^{10}	5.49×10^2
12	1.48×10^{54}	7.17×10^{15}	1.69×10^4
16	2.63×10^{67}	3.25×10^{21}	5.38×10^5

Centring gains nine orders of magnitude at degree 2 and forty-six at degree 16, because raising a number near 1980 to the sixteenth power is what made the columns incommensurable; rescaling gains a further two to sixteen, close to the best any diagonal rescaling can do ([Proposition 10.5.2](#)). But the rescaled design is still at 5.38×10^5 by degree 16 and grows geometrically after that, high powers of a number in $[-1, 1]$ all looking like a spike at the ends. The next section removes that dependence exactly.

```
for d in (2, 4, 8, 12, 16):
    raw = np.linalg.cond(np.vander(t, d + 1, increasing=True))
    centred = np.linalg.cond(np.vander(t - 1980.0, d + 1, increasing=True))
    scaled = np.linalg.cond(np.vander(u(t), d + 1, increasing=True))
    print(f"degree {d:2d}:  raw {raw:.2e}   centred {centred:.2e}   scaled {scaled:.2e}")
```

Two complaints have now been separated. *The basis is bad* is a numerical statement, fixed exactly by a change of basis that no fitted value feels: [Section 42.2](#). *The family is bad* is a statement about $\mathcal{P}_d$ itself, which only a different space of functions can fix: [Section 42.3](#).

42.1.5 Exercises

42.1.5.1 A. Check your understanding

Exercise A1.

Show that $\mathbf{X}_d = [\mathbf{1}, \mathbf{x}, \dots, \mathbf{x}^d]$ has full column rank if and only if the x_i take at least $d + 1$ distinct values, and deduce that a polynomial of degree $n - 1$ through n points with distinct x_i exists, is unique and interpolates exactly.

Solution. If $\mathbf{X}_d \mathbf{c} = \mathbf{0}$ then $q(t) = \sum_j c_j t^j$, of degree at most d , vanishes at every distinct design value; with $k \geq d + 1$ of them a nonzero q would have more roots than its degree, so $\mathbf{c} = \mathbf{0}$. If $k \leq d$, the nonzero $q(t) = \prod_{l \leq k} (t - x_{(l)})$ vanishes on the design. Taking $d = n - 1$ makes $\mathbf{X}$ square of full rank, so the residuals vanish.

42.1.5.2 B. Practice

Exercise B1.

For the design $x_i = (i - 1)/(n - 1)$, show that the (j, k) entry of $n^{-1} \mathbf{X}_d^\top \mathbf{X}_d$ converges to $1/(j + k + 1)$ for each fixed $j, k \leq d$: part (a) of [Proposition 42.1.1](#) for a fixed rather than a random design.

Exercise B2.

For the design $x_i = -1 + 2(i-1)/(n-1)$ with $n = 50$, compute the leverage of the leftmost point for $d = 1, 3, \dots, 15$ and plot it against d , comparing with the average $(d+1)/n$ and the bound of [Proposition 6.8.1](#).

Exercise B3.

Let $\mathbf{u} = a\mathbf{x} + b\mathbf{1}$ with $a \neq 0$. Show that $\mathcal{C}([\mathbf{1}, \mathbf{u}, \dots, \mathbf{u}^d]) = \mathcal{C}([\mathbf{1}, \mathbf{x}, \dots, \mathbf{x}^d])$ and that the change of basis matrix is triangular with diagonal entries a^j . Deduce that centring and scaling leave $\hat{\mathbf{Y}}$, $\hat{\boldsymbol{\varepsilon}}$ and every leverage unchanged, and say why they nevertheless change $\kappa(\mathbf{X})$.

Solution. Expanding $(ax + b)^j$ writes $\mathbf{u}^j$ in terms of $\mathbf{1}, \mathbf{x}, \dots, \mathbf{x}^j$ with leading coefficient a^j , so $\mathbf{T}$ is upper triangular with $T_{jj} = a^j \neq 0$, hence nonsingular, and the column spaces agree. By [Theorem 6.7.1](#) $\mathbf{M}$ is unchanged, so fitted values, residuals and leverages are too. The condition number is a property of $\mathbf{X}$, not of $\mathcal{C}(\mathbf{X})$.

Exercise B4.

Verify part (d) of [Proposition 42.1.1](#) numerically: for the degree-12 trend on the carbon dioxide design compute $\ell_i(t)$ for the last observation and count its sign changes over the data, then repeat for $d = 2$. Why is the count for $d = 2$ smaller than 2 in some designs?

Solution. The counts are 12 and 2. A polynomial of degree d has at most d real roots but may have fewer, and roots outside the range of the data are not counted: if the parabola's vertex lies outside $[\min x, \max x]$, only one sign change is visible.

42.1.5.3 C. Going deeper**Exercise C1.**

The Weierstrass approximation theorem says that every continuous f on $[a, b]$ is a uniform limit of polynomials. Using parts (a) and (c) of [Proposition 42.1.1](#), explain why this is not an argument for fitting high-degree polynomials to data. What does the theorem guarantee about the bias of the degree- d fit as d grows, and what about the variance?

Exercise C2.

For interpolation at nodes $x_1 < \dots < x_m$ the interpolant is $\sum_k f(x_k)L_k(t)$, with L_k the Lagrange basis, and the **Lebesgue constant** is $\Lambda = \max_t \sum_k |L_k(t)|$. Show that the interpolation error is at most $(1 + \Lambda)$ times that of the best uniform approximation of degree $m - 1$, compute Λ for $m = 5, 9, 13, 17$ equally spaced and Chebyshev nodes, and relate the two sequences to [Example \(Runge's function\)](#).

42.2 Orthogonal polynomials

The space $\mathcal{P}_d$, evaluated at the design, is an ordinary $(d+1)$ -dimensional subspace of $\mathbb{R}^n$. What is bad is the spanning set $1, x, \dots, x^d$. An orthonormal basis makes $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, the condition number one, and the coefficients independent of the degree — and, by [Theorem 6.7.1](#), changes not one fitted value. [Section 9.4](#) built these polynomials by Gram–Schmidt; this section supplies what they are for an arbitrary design, the recurrence that generates them in $O(nd)$ operations, and what changes when the basis is swapped.

42.2.1 The inner product of a design

Definition 42.2.1 — Orthogonal polynomials for a design

Let $x_1, \dots, x_n$ be design points, m of them distinct, with weights $w_1, \dots, w_n > 0$. For real functions f, g on the design write

$$\langle f, g \rangle = \sum_{i=1}^n w_i f(x_i) g(x_i), \quad \|f\|^2 = \langle f, f \rangle,$$

an inner product on the functions restricted to the design. Polynomials $p_0, \dots, p_d$ with $d < m$ are the **orthogonal polynomials of the design** if p_j has degree exactly j with leading coefficient one (it is **monic**) and $\langle p_j, p_k \rangle = 0$ for $j \neq k$. The normalized $q_j = p_j / \|p_j\|$ are the **orthonormal polynomials** of the design.

The restriction $d < m$ is the rank condition of [Exercise \(A1\)](#): with fewer distinct points some nonzero polynomial of degree d vanishes on the design, and the form is only nonnegative definite. Two facts make the construction work, and both are one line.

Lemma 42.2.1 — Multiplication by the argument is self-adjoint

For polynomials f, g let $(xf)(x) = xf(x)$. Then $\langle xf, g \rangle = \langle f, xg \rangle$.

Proof. Both sides equal $\sum_i w_i x_i f(x_i) g(x_i)$. ■

The second is that p_j is orthogonal to *every* polynomial of degree less than j , not only to $p_0, \dots, p_{j-1}$: those span $\mathcal{P}_{j-1}$, because their degrees are $0, 1, \dots, j-1$.

42.2.2 The three-term recurrence

Theorem 42.2.2 — Existence, uniqueness and the three-term recurrence

Let $d < m$. The orthogonal polynomials of the design exist, are unique, and are gener-

ated by

$$p_{-1} = 0, \quad p_0 = 1, \quad p_{j+1}(x) = (x - a_j)p_j(x) - b_j p_{j-1}(x), \quad j = 0, 1, \dots, d-1, \quad (42.2.1)$$

with

$$a_j = \frac{\langle xp_j, p_j \rangle}{\|p_j\|^2}, \quad b_j = \frac{\|p_j\|^2}{\|p_{j-1}\|^2} \quad (j \geq 1), \quad b_0 = 0.$$

Every $\|p_j\|^2$ with $j \leq d$ is strictly positive.

Proof. Existence and the recurrence together. Argue by induction on j , the claim being that $p_0, \dots, p_j$ produced by Eq. 42.2.1 are monic of degrees $0, \dots, j$, mutually orthogonal, and have positive squared norms. For $j = 0$, $p_0 = 1$ is monic of degree 0 and $\|p_0\|^2 = \sum_i w_i > 0$.

Suppose the claim holds up to $j \leq d-1$. The polynomial p_{j+1} defined by Eq. 42.2.1 is monic of degree $j+1$, since xp_j is monic of degree $j+1$ and the subtracted terms have degree at most j . Take inner products. First,

$$\begin{aligned} \langle p_{j+1}, p_j \rangle &= \langle xp_j, p_j \rangle - a_j \|p_j\|^2 - b_j \langle p_{j-1}, p_j \rangle \\ &= \langle xp_j, p_j \rangle - a_j \|p_j\|^2 = 0 \end{aligned}$$

by the choice of a_j and the induction hypothesis. Next, for $j \geq 1$, using Lemma 42.2.1 and $\langle p_j, p_{j-1} \rangle = 0$,

$$\begin{aligned} \langle p_{j+1}, p_{j-1} \rangle &= \langle p_j, xp_{j-1} \rangle - a_j \langle p_j, p_{j-1} \rangle - b_j \|p_{j-1}\|^2 \\ &= \langle p_j, xp_{j-1} \rangle - b_j \|p_{j-1}\|^2. \end{aligned}$$

Now xp_{j-1} is monic of degree j , so $xp_{j-1} - p_j$ has degree at most $j-1$ and is therefore orthogonal to p_j . Hence $\langle p_j, xp_{j-1} \rangle = \|p_j\|^2$, and the choice of b_j makes the display vanish. Finally, for $k \leq j-2$, Lemma 42.2.1 gives

$$\begin{aligned} \langle p_{j+1}, p_k \rangle &= \langle p_j, xp_k \rangle - a_j \langle p_j, p_k \rangle - b_j \langle p_{j-1}, p_k \rangle \\ &= \langle p_j, xp_k \rangle = 0, \end{aligned}$$

because xp_k has degree at most $j-1 < j$. So p_{j+1} is orthogonal to all of $p_0, \dots, p_j$.

It remains to show $\|p_{j+1}\|^2 > 0$ when $j+1 \leq d$. If it were zero then p_{j+1} , a monic polynomial of degree $j+1 \leq d < m$, would vanish at all m distinct design points, which is impossible.

Uniqueness. Suppose $\tilde{p}_0, \dots, \tilde{p}_d$ also satisfy the definition. Since the degrees are $0, \dots, j$, the set $\{p_0, \dots, p_j\}$ is a basis of $\mathcal{P}_j$, so $\tilde{p}_j = \sum_{k \leq j} c_k p_k$. Orthogonality of $\tilde{p}_j$ to $\mathcal{P}_{j-1}$ gives $0 = \langle \tilde{p}_j, p_k \rangle = c_k \|p_k\|^2$ for $k < j$, hence $c_k = 0$; and both being monic forces $c_j = 1$. ■

The recurrence needs only the two previous polynomials, so the work is $O(nd)$ rather than Gram-Schmidt's $O(nd^2)$; it never forms x^j for $j > 1$, so nothing overflows or cancels; and a_j, b_j describe the basis in $2d$ numbers, which is how a fitted polynomial should be stored.

Remark (Why only three terms). Writing $x p_j = \sum_{k \leq j+1} c_{jk} p_k$, the coefficient $c_{jk} \|p_k\|^2 = \langle x p_j, p_k \rangle = \langle p_j, x p_k \rangle$ vanishes whenever $x p_k$ has degree below j , that is whenever $k < j - 1$. The same argument gives three-term recurrences for the classical families — Legendre, Chebyshev, Hermite, Laguerre — the orthogonal polynomials of $\langle f, g \rangle = \int f g w$, which [Section 39.5](#) used for numerical integration.

42.2.3 Sequential fitting

Corollary 42.2.3 — Fitting in the orthonormal basis

Let $\mathbf{q}_j$ have entries $q_j(x_i)$ and let the weights be one, so the $\mathbf{q}_j$ are orthonormal in $\mathbb{R}^n$; write $\hat{\gamma}_j = \mathbf{q}_j^\top \mathbf{y}$. For every $d < m$:

- (a) the least squares fit of degree d is $\hat{f}_d(t) = \sum_{j=0}^d \hat{\gamma}_j q_j(t)$, and $\hat{\gamma}_j$ does not depend on d ;
- (b) $E(\hat{\gamma}_j) = \langle f, q_j \rangle$ when $E(Y_i) = f(x_i)$ for any function f , and $\text{Cov}(\hat{\gamma}) = \sigma^2 \mathbf{I}$;
- (c) the residual sum of squares equals $\|\mathbf{y}\|^2 - \sum_{j \leq d} \hat{\gamma}_j^2$, so the sequential sum of squares for degree j is $\hat{\gamma}_j^2$ on one degree of freedom, free of the order of entry;
- (d) the F statistic for $H : \gamma_d = 0$ in the model of degree d is $\hat{\gamma}_d^2 / \hat{\sigma}_d^2$, with $\hat{\sigma}_d^2$ that model's residual mean square, on $(1, n - d - 1)$ degrees of freedom.

Proof. With orthonormal columns $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, so $\hat{\beta} = \mathbf{X}^\top \mathbf{y}$ componentwise, which is (a); the columns for degrees below d do not change when d grows, as in [Corollary 9.4.2](#). Part (b) is $E(\mathbf{q}_j^\top \mathbf{Y}) = \mathbf{q}_j^\top \boldsymbol{\mu} = \langle f, q_j \rangle$ with $\text{Cov}(\mathbf{X}^\top \mathbf{Y}) = \sigma^2 \mathbf{X}^\top \mathbf{X}$; part (c) is Pythagoras, $\|\mathbf{y}\|^2 = \sum_{j \leq d} \hat{\gamma}_j^2 + \|\hat{\mathbf{e}}\|^2$, and [Theorem 9.4.1](#); part (d) is [Theorem 11.6.1](#) for a single coefficient with $\text{Var}(\hat{\gamma}_d) = \sigma^2$, squared. ■

Part (b) is worth a second look. Whatever the true regression function, $\hat{\gamma}_j$ estimates the j th coefficient of its expansion in the design's own orthonormal basis, with variance σ^2 for every j . Where the sequence sinks into the noise is where the data stop distinguishing degrees: the practice of choosing the degree from the sequential sums of squares, and its honest statement.

Warning. Stopping at the first small $\hat{\gamma}_j^2$ is selection from the same data: the chosen model's residual mean square is too small, its intervals too narrow, and the F statistic that justified the stop is not F ([Proposition 29.5.1](#)). The sequence can also dip and rise again, as it does below, so one insignificant term is a weak reason to stop.

42.2.4 The Nile, revisited

Example. (The recurrence on the Nile series)

The annual flow of the Nile at Aswan, 1871–1970, gives $n = 100$ equally spaced design points, rescaled here to $[-1, 1]$. [Example \(A trend in the Nile\)](#) built its orthonormal

Figure 42.2.1: (a) The orthonormal polynomials $q_1, \dots, q_4$ of the Nile design, from the three-term recurrence. (b) Condition number of four bases for that space: raw years, rescaled years, monic orthogonal, orthonormal.

polynomials by a QR factorization of the matrix of powers; Eq. 42.2.1 gives the same basis, the largest discrepancy between corresponding columns being 1.1×10^{-14} and the largest inner product between distinct columns 6.7×10^{-16} , machine precision. The design being symmetric about its mean, every a_j vanishes (Exercise (B1)), and the first four values of b_j are 0.34007, 0.27197, 0.26213, 0.25871; Figure 42.2.1(a) draws the polynomials themselves.

The sequential sums of squares reproduce the table of Example (A trend in the Nile) — 613893, 309415, 1894, 134142 for degrees 1 to 4, and 4225 and 7034 for degrees 5 and 6 — with F statistics 27.08, 15.70, 0.10, 7.18, 0.22 and 0.37. The cubic term is negligible and the quartic is not: a reader stopping at the first insignificant term would have missed it.

```
import numpy as np
import statsmodels.api as sm

nile = sm.datasets.nile.load_pandas().data
year = nile["year"].to_numpy().astype(float)
y = nile["volume"].to_numpy()
n = len(y)
u = 2 * (year - year.min()) / (year.max() - year.min()) - 1    # design rescaled to [-1, 1]

def orthogonal_polynomials(t, d):
    """Monic polynomials  $p_0, \dots, p_d$  orthogonal over the design  $t$ , by the
    recurrence."""
    P = np.zeros((len(t), d + 1))
    P[:, 0] = 1.0
    a, b, sq = np.zeros(d), np.zeros(d), [float(len(t))]
    for j in range(d):
        a[j] = (t * P[:, j] @ P[:, j]) / sq[j]
        P[:, j + 1] = (t - a[j]) * P[:, j]
        if j > 0:
            b[j] = sq[j] / sq[j - 1]
            P[:, j + 1] -= b[j] * P[:, j - 1]
```

```

    sq.append(P[:, j + 1] @ P[:, j + 1])
    return P, a, b, np.array(sq)

P, a, b, sq = orthogonal_polynomials(u, 8)
Q = P / np.sqrt(sq)                                     # orthonormal
    columns
print("a_j:", np.round(a[:5], 6))
print("b_j:", np.round(b[1:5], 5))
print("largest inner product between distinct columns:",
      f"{np.max(np.abs(Q.T @ Q - np.eye(9))):.2e}")

coef = Q.T @ y                                          # gamma_j = <q_j, y>, unchanged by
    the degree
seq_ss = coef[1:] ** 2                                  # sequential sum of squares for
    each degree
sse = np.sum((y - y.mean()) ** 2) - np.cumsum(seq_ss)
for j in range(1, 7):
    F = seq_ss[j - 1] / (sse[j - 1] / (n - j - 1))
    print(f"degree {j}: SS = {seq_ss[j - 1]:9.0f}    SSE = {sse[j - 1]:9.0f}    F = {F:7.2f}")

```

Remark (A limit that explains the numbers). For a design filling an interval evenly, $n^{-1} \sum_i f(x_i)g(x_i)$ is a Riemann sum for $\frac{1}{2} \int_{-1}^1 fg$, so the design's orthogonal polynomials approach the monic Legendre polynomials, with $a_j = 0$ and $b_j = j^2/(4j^2 - 1)$ ([Exercise B2](#)): that is 0.33333, 0.26667, 0.25714, 0.25397 against the Nile's 0.34007, 0.27197, 0.26213, 0.25871. Since $b_j \rightarrow 1/4$, the monic polynomials shrink geometrically: badly scaled even though orthogonal, so normalizing matters as much as orthogonalizing.

42.2.5 What changes and what does not

For the Nile design the condition numbers of four bases for $\mathcal{P}_d$ are

Degree	raw years	rescaled	monic orthogonal	orthonormal
2	1.83×10^{10}	3.70×10^0	3.29×10^0	1
4	3.90×10^{20}	1.85×10^1	1.26×10^1	1
6	2.83×10^{31}	9.77×10^1	4.92×10^1	1
8	1.42×10^{40}	5.31×10^2	1.93×10^2	1

Orthogonality by itself buys a factor growing from about one to about three over this range; the orthonormal basis has $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, so its condition number is one at every degree and least squares in it is a matrix–vector product. The gap between the last two columns is entirely scaling.

What does *not* change is everything else: $\hat{\mathbf{Y}}$, $\hat{\mathbf{e}}$, every leverage, every band, every F statistic about the *space*. The degree-16 polynomial of [Figure 42.1.1](#) oscillates identically in the orthonormal basis, and its extrapolation is still nonsense. Orthogonal polynomials answer the first complaint of [Section 42.1](#) and are silent on the second.

Remark (Where these have appeared before). For a factor with quantitative levels, the same construction with weights $w_k = n_k$ gives the polynomial contrasts of [Section 8.7](#) ([Example \(Trend in ideology across party identification\)](#)): the orthogonal polynomial coding of a factor and the basis that software offers for a continuous regressor are one object.

42.2.6 Exercises

42.2.6.1 A. Check your understanding

Exercise A1.

Compute the monic orthogonal polynomials p_0, p_1, p_2 for the design $x = (-1, 0, 1)$ with unit weights from [Eq. 42.2.1](#), and check that their integer-scaled versions are the contrasts $(-1, 0, 1)$ and $(1, -2, 1)$.

Exercise A2.

A quartic is fitted in the raw powers and again in the orthonormal polynomials of the design. Which of these differ between the two fits: the linear coefficient, the fitted value at x_1 , the residual sum of squares, the sequential sum of squares for degree 3, the leverage h_{11} , the condition number of $\mathbf{X}$?

42.2.6.2 B. Practice

Exercise B1.

Show that if $x \mapsto 2c - x$ permutes the design and preserves the weights, then $a_j = c$ for every j and $p_j(2c - x) = (-1)^j p_j(x)$.

Solution. Take $c = 0$ after a shift, and induct. p_0 is even, and $p_1 = x - a_0$ with $a_0 = \langle x, 1 \rangle / \|1\|^2 = 0$ by symmetry, so p_1 is odd. If p_{j-1} and p_j have parities $(-1)^{j-1}$ and $(-1)^j$, then $x p_j^2$ is odd, so $a_j = 0$, and $p_{j+1} = x p_j - b_j p_{j-1}$ is a sum of two polynomials of parity $(-1)^{j+1}$.

Exercise B2.

The monic Legendre polynomials are orthogonal for $\langle f, g \rangle = \int_{-1}^1 f g$. Using [Theorem 42.2.2](#) and the identity $\int_{-1}^1 P_j^2 = 2/(2j+1)$ for the standard Legendre polynomials, whose leading coefficient is $\binom{2j}{j} 2^{-j}$, verify that $b_j = j^2/(4j^2 - 1)$.

Solution. Write $\tilde{P}_j = P_j/\ell_j$ with $\ell_j = \binom{2j}{j} 2^{-j}$ for the monic version. Then $\|\tilde{P}_j\|^2 = 2/\{(2j+1)\ell_j^2\}$ and

$$b_j = \frac{\|\tilde{P}_j\|^2}{\|\tilde{P}_{j-1}\|^2} = \frac{(2j-1)\ell_{j-1}^2}{(2j+1)\ell_j^2}.$$

Since $\ell_j/\ell_{j-1} = (2j-1)/j$, the ratio is $(2j-1)j^2/\{(2j+1)(2j-1)^2\} = j^2/(4j^2-1)$.

Exercise B3.

Given $a_0, \dots, a_{d-1}$, $b_1, \dots, b_{d-1}$, $\|p_j\|^2$ and $\hat{\gamma}_0, \dots, \hat{\gamma}_d$, write down an algorithm that evaluates $\hat{f}_d(t)$ at a new t in $O(d)$ operations and storage, without ever computing a power of t . Why is this preferable to expanding $\hat{f}_d$ in the monomial basis and using Horner's rule?

Solution. Run Eq. 42.2.1 forwards at the single point t , accumulating $\sum_j \hat{\gamma}_j p_j(t)/\|p_j\|$ as you go; only $p_{j-1}(t)$ and $p_j(t)$ need be kept. (Running it backwards, accumulating the coefficients instead, is Clenshaw's algorithm, the standard way of summing a Chebyshev or other orthogonal-polynomial series.) Horner's rule is equally fast but needs the monomial coefficients, and converting the fit to those is the ill-conditioned step: the conversion matrix is the change of basis whose condition number the table above reports.

42.2.6.3 C. Going deeper

Exercise C1.

Show that p_j has j distinct real zeros, all strictly inside the range of the design. (Suppose it changes sign at only $r < j$ interior points $z_1, \dots, z_r$, and consider $\langle p_j, \prod_l (x - z_l) \rangle$.)

Exercise C2.

For two regressors the analogue of $\mathcal{P}_d$ is the span of the monomials $x^r z^s$ with $r + s \leq d$. List an orthogonal basis $\phi_1, \phi_2, \dots$ of it in a fixed order of nondecreasing total degree. The one-variable proof works because $x p_j$ expands in p_{j-1}, p_j, p_{j+1} alone; exhibit a design in $\mathbb{R}^2$ and an index i for which $x \phi_i$ has a nonzero inner product with some ϕ_k , $k < i - 1$, so that no scalar three-term recurrence generates the list. (Vector recurrences over a whole block of one total degree do exist; the single-variable bookkeeping is what fails.) Relate this to Chapter 44.

42.3 Piecewise polynomials

Changing the basis left the second complaint untouched: polynomials are global, and a degree-16 fit spends the same sixteen degrees of freedom everywhere, so a feature at one end is paid for by an oscillation at the other. The remedy is a different space of functions: cut the range at a few points, fit a low-degree polynomial on each piece, and join the pieces smoothly. Nothing oscillates, and the result is still linear in its coefficients.

42.3.1 Knots and pieces

Definition 42.3.1 — Piecewise polynomials and continuity constraints

Fix an interval $[a, b]$ and **knots** $a = \kappa_0 < \kappa_1 < \cdots < \kappa_K < \kappa_{K+1} = b$, the K inner ones being the **interior knots**. A function $f : [a, b] \rightarrow \mathbb{R}$ is a **piecewise polynomial of degree d** if its restriction to each half-open piece $[\kappa_k, \kappa_{k+1})$, $k = 0, \dots, K-1$, and to $[\kappa_K, b]$ agrees with a polynomial of degree at most d ; the value at a knot is the limit from the right, and nothing ties the pieces together. These form a vector space $\mathcal{PP}_d(\kappa)$ of dimension $(K+1)(d+1)$.

For $-1 \leq m \leq d-1$, f satisfies the **continuity constraints of order m** at κ_k if

$$f^{(r)}(\kappa_k^-) = f^{(r)}(\kappa_k^+), \quad r = 0, 1, \dots, m,$$

the case $m = -1$ imposing nothing. The **spline space $\mathcal{S}_d(\kappa)$** is the set of piecewise polynomials of degree d satisfying the constraints of order $d-1$ at every interior knot; its members are the **splines of degree d with knots κ** .

The constraints are linear in the coefficients: writing the unrestricted piecewise polynomial as $\sum_k \sum_{j \leq d} c_{kj} (t - \kappa_k)^j \mathbf{1}\{t \in [\kappa_k, \kappa_{k+1})\}$, the requirement $f^{(r)}(\kappa_k^-) = f^{(r)}(\kappa_k^+)$ reads

$$\sum_{j \geq r} \frac{j!}{(j-r)!} c_{k-1,j} (\kappa_k - \kappa_{k-1})^{j-r} = r! c_{kr},$$

one equation for each r and each interior knot. Fitting under them is restricted least squares (Proposition 11.3.3), and comparing two levels of smoothness is a general linear hypothesis (Theorem 11.3.2). Counting equations gives a candidate dimension, $(K+1)(d+1)$ coefficients minus $(m+1)K$ constraints, which for $m = d-1$ is

$$(K+1)(d+1) - dK = d+1 + K.$$

Only a candidate, since it assumes the constraints independent: the next theorem proves they are, by exhibiting a basis of exactly that size.

42.3.2 The spline space and the truncated power basis

Write $(v)_+ = \max(v, 0)$, and for $d \geq 1$ let

$$(t - \kappa)_+^d = \begin{cases} (t - \kappa)^d, & t \geq \kappa, \\ 0, & t < \kappa, \end{cases}$$

the **truncated power function** of degree d with knot κ . For $d = 0$ the same formula with the convention $0^0 = 1$ gives the indicator of $[\kappa, \infty)$.

Theorem 42.3.1 — Dimension of the spline space and the truncated power basis

Let $d \geq 0$ and let $\kappa_1 < \cdots < \kappa_K$ be interior knots of $[a, b]$.

- (a) $\mathcal{S}_d(\kappa)$ is a vector space of dimension $d+1 + K$, and

$$1, t, \dots, t^d, (t - \kappa_1)_+^d, \dots, (t - \kappa_K)_+^d \quad (42.3.1)$$

is a basis of it.

- (b) More generally, if the constraints imposed at κ_k are of order m_k with $-1 \leq m_k \leq d-1$, the resulting space has dimension $d+1 + \sum_{k=1}^K (d-m_k)$, with basis the powers $1, \dots, t^d$ together with $(t - \kappa_k)_+^r$ for $r = m_k + 1, \dots, d$ and $k = 1, \dots, K$.

Proof. It is enough to prove (b); part (a) is the case $m_k = d-1$ for every k , for which the count is $d+1 + K$.

The space. Sums and scalar multiples of piecewise polynomials of degree d are piecewise polynomials of degree d , and the constraints are linear equations, so the set is a subspace of the space of functions on $[a, b]$.

The listed functions belong to it. Each power t^j is a single polynomial, hence in every such space. Fix k and $r > m_k$. The function $g(t) = (t - \kappa_k)_+^r$ is zero on $[a, \kappa_k)$ and $(t - \kappa_k)^r$ on $[\kappa_k, b]$, a piecewise polynomial of degree $r \leq d$ whose only possible breakpoint is κ_k . For $s \leq r-1$ its s th derivative at κ_k is $\{r!/(r-s)!\}(t - \kappa_k)^{r-s}$ there, which is zero, and zero from the left; so g satisfies the constraints of order $r-1$, in particular those of order $m_k \leq r-1$. At the other knots g is a single polynomial and satisfies any constraint.

Linear independence. Suppose

$$q(t) + \sum_{k=1}^K \sum_{r > m_k} c_{kr} (t - \kappa_k)_+^r = 0 \quad \text{for all } t \in [a, b],$$

with $q \in \mathcal{P}_d$. On $[a, \kappa_1)$ every truncated power vanishes, so q vanishes on an interval and hence $q \equiv 0$. Suppose inductively that $c_{lr} = 0$ for every $l < k$. On $[\kappa_k, \kappa_{k+1})$ the displayed sum reduces to $\sum_{r > m_k} c_{kr} (t - \kappa_k)^r$, a polynomial vanishing on an interval, so all its coefficients are zero. The induction gives $c_{kr} = 0$ throughout.

Spanning. Let f belong to the space. On $[\kappa_0, \kappa_1)$ it agrees with a polynomial $q \in \mathcal{P}_d$; set $f_1 = f - q$, again in the space and vanishing there. Suppose inductively that f_k is in the space and vanishes on $[a, \kappa_k)$, and on the next piece agrees with $r_k \in \mathcal{P}_d$. Expanding r_k in powers of $t - \kappa_k$,

$$r_k(t) = \sum_{s=0}^d \frac{r_k^{(s)}(\kappa_k)}{s!} (t - \kappa_k)^s,$$

and for $s \leq m_k$ the constraint at κ_k forces $r_k^{(s)}(\kappa_k) = f_k^{(s)}(\kappa_k^-) = 0$, because f_k is identically zero to the left. Hence $r_k(t) = \sum_{s > m_k} c_{ks} (t - \kappa_k)^s$ for some coefficients c_{ks} , and $f_{k+1} = f_k - \sum_{s > m_k} c_{ks} (t - \kappa_k)_+^s$ is in the space and vanishes on $[a, \kappa_{k+1})$: to the left of κ_k both terms vanish, and between κ_k and κ_{k+1} they cancel. After K steps f_{K+1} vanishes on all of $[a, b]$, which exhibits f as a combination of the listed functions.

Dimension. The listed functions are $d+1 + \sum_k (d-m_k)$ in number, and they are a basis. ■

Remark. This settles the counting question: $(K+1)(d+1)$ minus $d+1 + \sum_k (d-m_k)$ is $\sum_k (m_k + 1)$, exactly the number of constraint equations. The constraints are therefore independent, and that a free piecewise polynomial is in fact a spline is testable with

$\sum_k (m_k + 1)$ degrees of freedom (Definition 11.3.1).

42.3.3 Three familiar special cases

Degree 0. $\mathcal{S}_0(\kappa)$ is the space of step functions, of dimension $K + 1$, and fitting it is the one-way layout with the intervals as groups (Example (The one-way layout)): the fit is *exactly local*, with variance σ^2/n_k on interval k , at the price of the discontinuity and a bias of order the interval width.

Degree 1. $\mathcal{S}_1(\kappa)$, of dimension $K + 2$, is the space of continuous broken lines, with basis $1, t, (t - \kappa_1)_+, \dots, (t - \kappa_K)_+$; the coefficient of $(t - \kappa_k)_+$ is the *change* in slope there, and the two-piece case is the classical two-phase regression.

Degree 3. $\mathcal{S}_3(\kappa)$ is the space of **cubic splines**, of dimension $K + 4$: value, slope and curvature continuous, only the third derivative jumping. Cubic is the default, the lowest degree whose joins are invisible and whose second derivative a smoothness penalty can control.

Warning. A knot estimated from the data takes the model out of this chapter: $(t - \kappa)_+^d$ is not linear in κ , the criterion is not even differentiable in it for $d = 0$ or 1 , and the usual asymptotics can fail. This **segmented** or **changepoint** regression has a literature of its own — Hudson (1966), Feder (1975), Seber and Wild (1989, ch. 9) — which this book does not develop. The honest options are to fix the knot from outside the data, to fit many fixed knots and let a penalty decide (Chapter 43), or to pay for the selection (Proposition 29.5.1).

42.3.4 Climbing the smoothness ladder

Example. (Four fits with the same knots)

Take the Nile series again, $n = 100$ annual flows, with cubic pieces and interior knots at 1899 — where Cobb (1978) and the analysis of Example (A trend in the Nile) both locate a change — and 1935. Fitting the three cubics separately uses 12 parameters and leaves a residual sum of squares of 1394072. Continuity at both knots removes two parameters and raises it to 1561452; continuity of the first derivative removes two more (1613581); and the full cubic spline, with 6 parameters as Theorem 42.3.1 predicts, has 1781797. Figure 42.3.1 shows the four fits.

Each step down the ladder is a testable linear hypothesis, and against the unrestricted fit all three are rejected: $F = 5.28$ on $(2, 88)$ degrees of freedom for continuity alone ($p = 0.0068$), $F = 3.46$ on $(4, 88)$ ($p = 0.0112$) for a continuous first derivative, and $F = 4.08$ on $(6, 88)$ ($p = 0.0012$) for the cubic spline. The Nile really does have a discontinuity, and a spline is the wrong space for it.

The right model is the simplest on the ladder: a step function with a single knot at 1899, whose group means are 1097.7 and 850.0 in units of 10^8 m^3 , differing by -247.8 with standard error 28.4 and $t = -8.71$. Its residual sum of squares, 1597457, beats the six-parameter spline and the cubic polynomial's 1909955. Two parameters in the right place beat six in the wrong space.

Figure 42.3.1: The Nile flows with cubic pieces cut at 1899 and 1935, under four levels of continuity; each constraint removes two parameters.

```
import numpy as np
import statsmodels.api as sm

nile = sm.datasets.nile.load_pandas().data
year = nile["year"].to_numpy().astype(float)
y = nile["volume"].to_numpy()
n = len(y)
knots = np.array([1899.0, 1935.0])
d = 3
u = lambda s: 2 * (s - year.min()) / (year.max() - year.min()) - 1

def separate(s):
    """One free cubic per interval: (K+1)(d+1) columns, no constraints at the knots.
    """
    piece = np.digitize(s, knots)
    return np.column_stack([np.where(piece == k, u(s) ** j, 0.0)
                             for k in range(len(knots) + 1) for j in range(d + 1)])

def truncated(s, m):
    """Continuity of the function and of its first m derivatives at every knot."""
    cols = [u(s) ** j for j in range(d + 1)]
    for k in knots:
        cols += [np.clip(u(s) - u(k), 0.0, None) ** r for r in range(m + 1, d + 1)]
    return np.column_stack(cols)
```

```
def fit(X):
    beta, *_ = np.linalg.lstsq(X, y, rcond=None)
    resid = y - X @ beta
    return np.linalg.matrix_rank(X), resid @ resid, X @ beta

for name, X in [("separate cubics", separate(year)), ("continuous", truncated(year,
0)),
                ("continuous derivative", truncated(year, 1)), ("cubic spline",
truncated(year, 2))]:
    p, rss, _ = fit(X)
    print(f"{name:24s} p = {p:2d}    residual sum of squares {rss:10.0f}")
```

```
from scipy import stats

p_full, rss_full, _ = fit(separate(year))
for m, label in ((0, "continuity"), (1, "first derivative"), (2, "second derivative"
)):
    p_m, rss_m, _ = fit(truncated(year, m))
    q = p_full - p_m
    F = ((rss_m - rss_full) / q) / (rss_full / (n - p_full))
    print(f"up to the {label:17s}: q = {q}, F = {F:5.2f}, p-value {1 - stats.f.cdf(F
, q, n - p_full):.4f}")
```

Warning. The knot at 1899 was not chosen blind: Cobb's analysis and the large quartic component in [Example \(A trend in the Nile\)](#) both point to the end of the nineteenth century, and both used this series. The t statistic -8.71 therefore overstates the evidence for a break of unknown date, whose null distribution is that of the largest of ninety-nine statistics, one for each year one could split at.

Idea. Degrees of freedom are the currency, and a spline spends them differently. Each of a polynomial's $d+1$ parameters affects the curve everywhere; a spline has $d+1+K$, and the K extra act only to the right of their knots, adjusting the d th derivative. Raising K at fixed low d is a local purchase; raising d is not.

Remark (Natural boundary conditions). Outside $[\kappa_1, \kappa_K]$ a cubic spline is still a cubic, and cubics diverge. **Natural** cubic splines add $f''(a) = f'''(a) = f''(b) = f'''(b) = 0$, forcing f to be linear beyond the outer knots and reducing the dimension to K ([Exercise \(B1\)](#)) — a decision that the curve should flatten where the data run out, not a discovery about them. It becomes more than a convention in [Chapter 43](#), where the natural cubic spline exactly minimizes a penalized criterion ([Theorem 43.4.2](#)).

42.3.5 Exercises

42.3.5.1 A. Check your understanding

Exercise A1.

How many parameters has a quadratic spline with 7 interior knots? A cubic spline with 7, one of them a double knot (only C^1 there)? A piecewise constant function with 7?

Solution. By [Theorem 42.3.1](#), $2 + 1 + 7 = 10$, then $3 + 1 + 7 + 1 = 12$ (the double knot contributes $d - m = 3 - 1 = 2$ instead of 1), and $0 + 1 + 7 = 8$.

Exercise A2.

In the broken-line model $f(t) = \beta_0 + \beta_1 t + \sum_k \theta_k (t - \kappa_k)_+$, give the slope of f on (κ_j, κ_{j+1}) , the hypothesis that the line is unbent at κ_j , and the degrees of freedom of the test that it is a single straight line.

Exercise A3.

Verify that for the piecewise constant fit, changing y_i by Δ moves the fitted curve by Δ/n_k on i 's own interval and not at all elsewhere. Contrast with [Proposition 42.1.1\(d\)](#).

42.3.5.2 B. Practice

Exercise B1.

Show that the natural cubic splines with interior knots $\kappa_1 < \cdots < \kappa_K$ ($K \geq 2$) form a space of dimension K , by writing the four boundary conditions in the truncated power basis and checking that they are independent.

Solution. Write $f(t) = \sum_{j \leq 3} \beta_j t^j + \sum_k \theta_k (t - \kappa_k)_+^3$, with $K + 4$ coefficients. Linearity on $[a, \kappa_1]$ means $\beta_2 = \beta_3 = 0$; linearity on $[\kappa_K, b]$ makes the cubic and quadratic coefficients of the last piece vanish, which after expanding $(t - \kappa_k)^3$ reads $\sum_k \theta_k = 0$ and $\sum_k \theta_k \kappa_k = 0$. The four equations involve different coefficients and are independent, so the dimension is K .

Exercise B2.

Two straight lines meet at a known γ . Write the model in the basis $1, t, (t - \gamma)_+$, give the least squares estimate of the common value at γ and its variance, and the F statistic for equal slopes.

Solution. With $E(Y) = \beta_0 + \beta_1 t + \theta(t - \gamma)_+$, the value at γ is the estimable function $\beta_0 + \beta_1 \gamma$, estimated by $\hat{\beta}_0 + \gamma \hat{\beta}_1$ with variance $\sigma^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}$, $\mathbf{a} = (1, \gamma, 0)^\top$. Equal slopes is $\theta = 0$, tested by the square of the t statistic for $\hat{\theta}$ against $F(1, n - 3)$ ([Theorem 11.6.1](#)).

Exercise B3.

Let $f \in \mathcal{S}_d(\kappa)$ have truncated power coefficients θ_k . Show that $f^{(d)}$ is a step function jumping by $d! \theta_k$ at κ_k , and that $\theta_k = 0$ exactly when f is a single polynomial across κ_k .

Solution. Differentiating [Eq. 42.3.1](#) d times kills every power below t^d and turns $(t - \kappa_k)_+^d$ into $d!$ times the indicator of $[\kappa_k, \infty)$, so $f^{(d)} = d! \beta_d + d! \sum_k \theta_k \mathbf{1}\{t \geq \kappa_k\}$. If $\theta_k = 0$ the pieces on either side of κ_k have the same d th derivative and agree to order $d - 1$ there, hence are the same polynomial; the converse is immediate.

42.3.5.3 C. Going deeper

Exercise C1.

Show that for $f \in C^{d+1}[a, b]$,

$$f(t) = \sum_{j=0}^d \frac{f^{(j)}(a)}{j!} (t-a)^j + \frac{1}{d!} \int_a^b f^{(d+1)}(s) (t-s)_+^d ds.$$

Interpret it as saying that the truncated power functions are a continuous basis for smooth functions, of which [Eq. 42.3.1](#) keeps K members.

Exercise C2.

Let κ and $\kappa + \epsilon$ be two knots of a cubic spline. Show that as $\epsilon \downarrow 0$ the angle between $(t - \kappa)_+^3$ and $(t - \kappa - \epsilon)_+^3$ tends to zero, while the normalized difference $\{(t - \kappa)_+^3 - (t - \kappa - \epsilon)_+^3\}/(3\epsilon)$ tends to $(t - \kappa)_+^2$. Explain how this both shows that a double knot lowers the smoothness by one order and warns against placing knots close together in the truncated power basis.

Solution. For $t \geq \kappa + \epsilon$, $\{(t - \kappa)^3 - (t - \kappa - \epsilon)^3\}/(3\epsilon) \rightarrow (t - \kappa)^2$ by the definition of the derivative; for $t \leq \kappa$ both terms vanish, and the middle interval, of width ϵ , contributes nothing. The limit is $(t - \kappa)_+^2$, the basis function [Theorem 42.3.1\(b\)](#) adds at a knot of multiplicity two, where only C^1 continuity is required. Two nearly coincident columns whose difference carries the information is what makes a design ill-conditioned ([Definition 1.8.1](#)), and it inflates the coefficients' variances in the sense of [Definition 26.2.1](#): the fit is fine, the coefficients are not.

42.4 Regression splines and truncated power bases

A spline space is finite-dimensional, so fitting a spline is least squares with the columns of [Eq. 42.3.1](#). Nothing new is needed to *do* it; what is needed is judgement about the two things the analyst now chooses, how many knots and where.

Definition 42.4.1 — Regression spline

Given a degree d and fixed interior knots $\kappa_1 < \dots < \kappa_K$ inside the range of the design, the **regression spline** model is the linear model with model matrix

$$\mathbf{X} = [\mathbf{1}, \mathbf{x}, \dots, \mathbf{x}^d, (\mathbf{x} - \kappa_1)_+^d, \dots, (\mathbf{x} - \kappa_K)_+^d],$$

of $d + 1 + K$ columns, and the **regression spline** is the least squares fit $\hat{f}(t) = \mathbf{x}(t)^\top \hat{\boldsymbol{\beta}}$. Other regressors, smooth terms and factors may be added as further columns.

Being an ordinary linear model, it has $n - (d + 1 + K)$ residual degrees of freedom at full rank;

[Theorem 12.1.1](#) gives the fitted curve an interval and [Theorem 12.4.1](#) a band, both conditional on the knots; the leverages average $(d + 1 + K)/n$, which is what “ K knots cost K degrees of freedom” means; adding a knot is a one-degree-of-freedom nested test ([Theorem 11.1.1](#)) asking, by [Exercise \(B3\)](#), whether the d th derivative really jumps there; and choosing K by GCV ([Definition 29.3.2](#)) or AIC ([Proposition 29.2.4](#)) belongs to [Chapter 29](#).

42.4.1 What the knots control

Proposition 42.4.1 — Number, placement and basis

Fit a regression spline of degree d with interior knots $\kappa_1 < \dots < \kappa_K$ inside the range of the design, and write $\mathbf{M}_K$ for the projection onto the column space.

- (a) (*Number.*) If $\mathbf{X}$ has full rank, $\text{tr } \mathbf{M}_K = d + 1 + K$, so the leverages average $(d + 1 + K)/n$ and $\mathbb{E}\|(\mathbf{I} - \mathbf{M}_K)\mathbf{Y}\|^2 = \sigma^2\{n - (d + 1 + K)\} + \|(\mathbf{I} - \mathbf{M}_K)\boldsymbol{\mu}\|^2$. Increasing K decreases both the squared bias and the residual degrees of freedom; the price is the total variance of the fitted curve, $\sigma^2 \text{tr } \mathbf{M}_K = \sigma^2(d + 1 + K)$, which rises by σ^2 per knot. Knots buy bias reduction at one degree of freedom each.
- (b) (*Rank.*) If each piece $[\kappa_k, \kappa_{k+1})$, $k = 0, \dots, K - 1$, and the last piece $[\kappa_K, b]$ contain at least $d + 1$ distinct design points, then $\mathbf{X}$ has full column rank. If some knot exceeds $\max_i x_i$, its column is identically zero and $\mathbf{X}$ does not.
- (c) (*Placement.*) For $d = 0$ the variance of the fit on interval k is σ^2/n_k , with n_k the number of design points there, so equalizing the counts minimizes the largest pointwise variance; quantile knots do that and equally spaced knots need not. For $d \geq 1$ the effect persists in the exact variance $\sigma^2 \mathbf{x}(t)^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}(t)$, which is large wherever an interval is sparsely occupied.
- (d) (*Basis.*) The columns of [Eq. 42.3.1](#) are globally supported and increasingly parallel: beyond the last knot every one behaves like t^d , the angle between $(\mathbf{x} - \kappa_j)_+^d$ and $(\mathbf{x} - \kappa_k)_+^d$ tends to zero as $\kappa_j - \kappa_k \rightarrow 0$ ([Exercise \(C2\)](#)), and $\kappa(\mathbf{X})$ grows with K . A basis of the *same space* whose members are each supported on $d + 1$ consecutive intervals has a **basis condition number** — the worst ratio between the size of a coefficient vector and the size of the function it builds — bounded by a constant depending only on d , whatever the knots (de Boor, 2001). For a design with points in every basis function’s support, $\kappa(\mathbf{X})$ then does not grow with K ; without one nothing is claimed, and $\mathbf{X}$ can be singular.

Proof.

- (a) $\mathbf{M}_K$ is an orthogonal projection, so its trace is its rank ([Proposition 6.3.4](#)), namely $d + 1 + K$ by [Theorem 42.3.1](#) at full rank; the expected residual sum of squares is the decomposition of [Section 9.1](#). Adding a knot enlarges the column space, so the squared bias cannot increase while $\text{tr}(\mathbf{I} - \mathbf{M})$ falls by one.
- (b) Suppose $\mathbf{X}\mathbf{c} = \mathbf{0}$. By [Theorem 42.3.1](#) the function $g = \sum_j c_j \phi_j$ built from the same coefficients is a spline vanishing at every design point. On each piece g is a polynomial of degree at most d with $d + 1$ distinct roots there, hence identically zero there; so $g \equiv 0$ and, the basis being independent, $\mathbf{c} = \mathbf{0}$. For the second statement, $(x_i - \kappa)_+^d = 0$ for every i when $\kappa > \max_i x_i$.
- (c) For $d = 0$ the columns are the orthogonal indicators of the intervals, so $\mathbf{X}^\top \mathbf{X} =$

$\text{diag}(n_0, \dots, n_K)$ and the fit on interval k is $\bar{y}_k$, with variance σ^2/n_k . Over counts summing to n , the largest σ^2/n_k is smallest when they are as equal as possible, which quantile knots achieve up to rounding. For $d \geq 1$ the variance formula is [Theorem 12.1.1](#), and that it is large over a sparse interval is not an identity but an observation.

- (d) The first statement is [Exercise \(C2\)](#). The bound on the basis condition number is quoted from de Boor (2001) and not proved here; that it controls $\kappa(\mathbf{X})$ needs the design to occupy every support, which is the next paragraph.

■

Part (c) is demonstrated in [Example \(A skewed design\)](#) and part (d) in [Example \(Truncated powers against a local basis\)](#), whose nearly uniform design meets the proviso; the local basis is built in [Chapter 43](#).

Part (b) has a sharp form. In the local basis the design matrix has full rank *if and only if* each basis function's support contains a design point — the Schoenberg–Whitney condition (Schoenberg and Whitney, 1953), which is also the proviso in (d). Either way the rule is: no knot where there are no data, and no two knots with a nearly empty interval between them.

42.4.2 Six bases for one trend

Example. (Trend bases for the carbon dioxide series)

Return to the $n = 521$ monthly means with the four seasonal columns fixed, put $K = 6$ interior knots at the quantiles $k/7$ of the time variable, and compare six trend bases.

Trend basis	p	Residual SS	$\hat{\sigma}$	GCV	$\max h_{ii}$
quadratic	7	297.03	0.7602	0.5858	0.0256
degree 9	14	115.57	0.4774	0.2343	0.2054
degree 16	21	92.44	0.4300	0.1926	0.4546
piecewise constant	11	3081.18	2.4580	6.1718	0.0215
piecewise linear	12	116.63	0.4787	0.2345	0.0532
cubic spline	14	108.48	0.4626	0.2199	0.1494

Read the middle rows against each other. At the same $p = 14$ the cubic spline fits better than the degree-9 polynomial (108.48 against 115.57) and spreads its influence more evenly (largest leverage 0.1494 against 0.2054); panel (a) of [Figure 42.4.1](#) shows the two parting where the polynomial has to bend. The step function is a disaster; the broken line is almost as good as the cubic spline with two fewer parameters, at the cost of visible kinks (panel (b)).

In-sample, GCV prefers the degree-16 polynomial to everything else (0.1926) — honest about prediction at the design points and misleading about the fit, since that model has $\max h_{ii} = 0.4546$ and $\kappa(\mathbf{X}) = 5.39 \times 10^5$. Among the piecewise bases the cubic spline is the worst conditioned: $\kappa(\mathbf{X}) = 7.72 \times 10^3$ against 9.75×10^1 .

Figure 42.4.1: (a) The degree-9 polynomial trend and the cubic spline with six quantile knots, both with ten trend parameters, as departures from the quadratic trend. (b) Three fits on the same knots (vertical lines) over the last fifteen years, seasonally adjusted.

    p = np.linalg.matrix_rank(X)
    beta, *_ = np.linalg.lstsq(X, y, rcond=None)
    resid = y - X @ beta
    rss = resid @ resid
    lev = np.einsum("ij,ij->i", X @ np.linalg.pinv(X.T @ X), X)
    print(f"{name:20s} p = {p:2d}    RSS = {rss:8.2f}    sigma = {np.sqrt(rss / (n - p
        )):.4f}")
    f"    GCV = {n * rss / (n - p) ** 2:.4f}    max leverage {lev.max():.4f}"
    f"    cond = {np.linalg.cond(X):.1e}"
```

Locality shows up in the same fits: moving the December 2001 value by 10 ppm moves the March 1958 trend by 0.197 ppm under the degree-12 polynomial but 0.004 under the cubic spline and 0.001 under the step function, where only the shared seasonal columns keep it from being zero.

42.4.3 Where to put them

Example. (A skewed design)

Take $n = 200$ design points drawn once, with a fixed seed, from a skewed distribution on $[0, 1]$, and fit a cubic spline with $K = 5$ interior knots. Equally spaced knots leave 67, 71, 35, 21, 5, 1 points in the six intervals; quantile knots leave 34, 33, 33, 33, 33, 34. Both have full rank — the truncated powers are globally supported, so a nearly empty interval does not kill a column — but it does kill precision. The exact pointwise standard deviation of the fit, in units of σ , reaches 7.452 with the equally spaced knots against 0.987 with the quantile knots; at the median of the design the quantile knots are slightly worse (0.173 against 0.123), having spent four of five knots there.

Quantile knots are a defensible default, not a universal optimum: they make the worst case tolerable. Where the regression function is known to vary fast in a sparse region the knots should follow the function — a choice made from outside the data, or paid for as a selection ([Proposition 29.5.1](#)).

```
import numpy as np

rng = np.random.default_rng(42)
n = 200
x = np.sort(rng.beta(1.5, 6.0, n))
```

a skewed design on [0, 1]

Figure 42.4.2: (a) A skewed design of 200 points with five equally spaced and five quantile knots. (b) Pointwise standard deviation of the fit, in units of σ , log scale.

```
K, d = 5, 3

equal = np.linspace(x.min(), x.max(), K + 2)[1:-1]      # equally spaced knots
quantile = np.quantile(x, np.arange(1, K + 1) / (K + 1))

def spline_design(s, knots):
    """Truncated power basis for degree d with the given interior knots."""
    return np.column_stack([s ** j for j in range(d + 1)]
                           + [np.clip(s - k, 0.0, None) ** d for k in knots])

def counts(knots):
    edges = np.r_[-np.inf, knots, np.inf]
    return [int((x >= a) & (x < b)).sum() for a, b in zip(edges[:-1], edges[1:])]

print("equally spaced knots:", np.round(equal, 3), " points per interval", counts(
    equal))
print("quantile knots:      ", np.round(quantile, 3), " points per interval",
    counts(quantile))
```

```
grid = np.linspace(x.min(), x.max(), 500)
for name, knots in (("equally spaced", equal), ("quantile", quantile)):
    X = spline_design(x, knots)
    G = np.linalg.inv(X.T @ X)
    Xg = spline_design(grid, knots)
    sd = np.sqrt(np.einsum("ij,jk,ik->i", Xg, G, Xg))    # in units of sigma
    print(f"{name:15s} knots: standard deviation of the fit at the median {np.interp(
        np.median(x), grid, sd):.3f},"
          f" largest {sd.max():.3f} at x = {grid[sd.argmax():.3f]}")
```

Idea. Rules of thumb that survive scrutiny, for a fixed-knot regression spline:

- use a low degree, almost always cubic, and control flexibility with K ;
- place knots at quantiles unless something outside the data says otherwise, keeping

several observations between consecutive knots;

- compare a few values of K by GCV or AIC rather than searching finely;
- report the fit as a curve with a band, never as coefficients, which depend on the basis and mean nothing alone.

The middle two leave a discrete, data-dependent choice. [Chapter 43](#) removes it by taking K large and adding a penalty, making flexibility continuous ([Definition 43.3.1](#)).

42.4.4 Why this basis is not the one to compute with

Example. (Truncated powers against a local basis)

For the carbon dioxide design rescaled to $[-1, 1]$, take cubic splines with K quantile knots and compare the condition number of the truncated power basis with that of the local (B-spline) basis for the *same* space, verified by checking that the two sets of columns together have rank $K + 4$.

K	4	8	16	32
truncated powers	1.75×10^3	2.56×10^4	3.65×10^5	4.97×10^6
local basis	5.30	5.18	5.04	5.00

The truncated power condition number multiplies by about fifteen for every doubling of K ; the local basis does not move. By $K = 32$ the normal equations ([Theorem 6.4.2](#)) in the truncated power basis have lost about thirteen digits ([Eq. 10.1.2](#)), the same fit in the local basis one. This design is nearly uniform, so every basis function's support is well occupied — the proviso of part (d).

The remedy is that of [Section 42.2](#): the space is fine and the basis is bad. The local basis is built in [Chapter 43](#) ([Definition 43.2.1](#) and [Proposition 43.2.1](#)). The truncated power basis keeps its place in the theory — [Theorem 42.3.1](#) is easiest to prove with it, and θ_k means a jump in the d th derivative — but it should not be what a program forms.

42.4.5 Honest limits of a fitted curve

Three warnings close the chapter, none of them about arithmetic. *Outside the range there is nothing*: a cubic spline continues as a cubic beyond its last knot, and refitting to the months up to 1990 and predicting 1991–2001 gives root mean squared errors of 2.71 ppm for the broken line, 3.99 for the quadratic, 46.11 for the cubic spline and 923.15 for the degree-9 polynomial — almost the reverse of the ranking inside the data.

A curve is a conditional mean, not a mechanism: dropping linearity removes a functional-form assumption and nothing else, and [Theorem 25.4.1](#) is still what licenses a causal reading. And *a flexible fit is no substitute for a good parameterization*: where the relationship is known to be a power law, the transformations of [Chapter 22](#) give a two-parameter model that a ten-parameter

spline can only approximate and that extrapolates on a principle ([Theorem 22.3.2](#)). A spline is often best used diagnostically: fit it, look at the shape, then ask whether a parametric form with meaning would do.

42.4.6 Exercises

42.4.6.1 A. Check your understanding

Exercise A1.

A cubic regression spline with K quantile knots is fitted to $n = 200$ observations together with three other regressors and an intercept. Give the residual degrees of freedom and the average leverage as functions of K , and the K at which the fit interpolates.

Exercise A2.

Three analysts fit a cubic spline with the same six knots, in the truncated power basis, in the local basis, and as free cubics under the continuity constraints. Which outputs agree exactly, which to rounding, and which disagree?

42.4.6.2 B. Practice

Exercise B1.

Fit cubic splines to the carbon dioxide series with $K = 2, 4, \dots, 20$ quantile knots and plot GCV against K , then the leave-one-out criterion computed by the leverage shortcut of [Theorem 29.3.2](#). Where do the two disagree, and why should you not report the F test comparing the selected K with $K = 2$?

Solution. The two have the same minimizer here or nearly so; GCV replaces each $1 - h_{ii}$ by its average $1 - p/n$, which matters when the leverages are uneven, as at the boundary. The F test is invalid because K minimized a criterion computed from the same data: the residual mean square is biased downwards and the statistic is not F ([Proposition 29.5.1](#)).

Exercise B2.

Compute the pointwise 95% band for the cubic spline fit of [Example \(Trend bases for the carbon dioxide series\)](#) and the simultaneous Working–Hotelling band ([Theorem 12.4.1](#)). By what factor is the simultaneous band wider, and what does each band cover?

Solution. The ratio of half-widths is $\sqrt{pF_{\alpha}(p, n-p)/t_{\alpha/2}(n-p)}$, about two and a half for $p = 14$ and $n = 521$. The pointwise band covers $E(Y \mid x = t)$ at a single pre-chosen t with probability 0.95, the simultaneous band the whole curve. Neither covers anything if the true mean is not in the spline space: both are conditional on the model, and the model includes the knots.

Exercise B3.

A model has a cubic spline in x and a linear term in z . Show that the coefficient of z is the slope of the regression of $\mathbf{y}$ on the part of $\mathbf{z}$ orthogonal to the spline space, and say what it would mean for that part to be nearly zero.

Solution. This is [Theorem 6.6.2](#) with $\mathbf{X}_2$ the spline columns. If $\mathbf{z}$ is nearly a spline function of x — because z is a smooth transformation of it, or because K is so large that the spline space reproduces almost anything — then $(\mathbf{I} - \mathbf{M}_2)\mathbf{z}$ is short, the coefficient's variance huge, and the two terms not separately identified: the additive-model version of collinearity, taken up in [Chapter 44](#) ([Proposition 44.2.3](#)).

42.4.6.3 C. Going deeper**Exercise C1.**

For a regression spline the fitted value at t is $\sum_i \ell_i(t)y_i$ with $\ell_i(t) = \mathbf{x}(t)^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_i$. Show that $\sum_i \ell_i(t) = 1$ and $\sum_i \ell_i(t)(x_i - t)^r = 0$ for $r = 1, \dots, d$ at every t , because $\mathcal{S}_d(\kappa)$ contains $\mathcal{P}_d$ and a projection reproduces its own space. Deduce that the fit reproduces polynomials of degree d exactly, and interpret $\sum_i \ell_i(t)^2$.

Exercise C2.

Suppose K minimizes GCV over $K \in \{1, \dots, 20\}$ and the usual pointwise band is then reported for the selected fit. Simulate 2000 data sets from a known smooth f with normal errors and estimate the coverage of the nominal 95% band at the quartiles of the design, explaining the pattern in terms of [Proposition 29.5.1](#) and of the bias a selected K leaves behind.

42.5 Summary and Notes

42.5.1 Summary

Idea.

1. A polynomial regression is a linear model in a transformed basis ([Definition 42.1.1](#)): estimation, the F tests, the bands, lack of fit and the diagnostics of Parts II and III apply unchanged, and only the reading of an individual coefficient is lost.
2. Raising the degree buys bias and sells variance unevenly: the standard error of the fit grows fastest at the edges, leverage concentrates there, and a single observation moves the whole curve ([Proposition 42.1.1](#)). The monomial basis is also one of the worst conditioned in numerical analysis, its Gram matrix converging to a Hilbert matrix; centring and rescaling to $[-1, 1]$ recover most of that for free.
3. The orthogonal polynomials of a design exist, are unique, and satisfy a three-term recurrence, because multiplication by the argument is self-adjoint and raises degree by one ([Definition 42.2.1](#), [Lemma 42.2.1](#) and [Theorem 42.2.2](#)). In the orthonormal

basis $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$: coefficients do not change with the degree, sequential sums of squares are order-free, and $\kappa(\mathbf{X}) = 1$ ([Corollary 42.2.3](#)).

4. Changing the basis fixes the arithmetic and nothing else: the oscillation, the boundary variance and the extrapolation belong to $\mathcal{P}_d$, not to any list of functions spanning it.
5. Cutting the range at K knots and fitting degree- d pieces with C^{d-1} joins gives a space of dimension $d + 1 + K$ with the truncated power functions as a basis ([Definition 42.3.1](#), [Theorem 42.3.1](#)). The continuity constraints are independent linear restrictions, so each level of smoothness is a testable hypothesis.
6. A regression spline is ordinary least squares in that basis ([Definition 42.4.1](#)). Knots buy flexibility one degree of freedom at a time and spend it locally; their placement controls where the variance goes, and quantile knots are the defensible default ([Proposition 42.4.1](#)).
7. The truncated power basis is for proving things, not for computing with: its condition number grows geometrically with K , while a locally supported basis for the same space, on a design that occupies every support, does not.
8. A fitted curve is still a conditional mean, still says nothing about intervention, and still must not be extrapolated: of the bases compared on the carbon dioxide series, the one that fitted best inside the data was among the worst outside it ([Section 42.4](#)).

42.5.2 Notes and sources

Polynomial regression and ill-conditioning. That the Gram matrix of the monomials is essentially a Hilbert matrix is an old observation; Forsythe (1957) is the paper that drew from it the recommendation to fit in an orthogonal basis, and Seber and Lee (2003, section 7.1.1) cite him for the formula. The conditioning facts are from numerical analysis: Todd (1954) for the Hilbert matrix, and Higham (2002), whose chapters on Vandermonde systems and on test matrices cover the two cases. Runge (1901) gave the interpolation example and Trefethen (2019) is the modern account, including Chebyshev nodes and the Lebesgue constants of [Exercise \(C2\)](#); a least squares polynomial of moderate degree on a large sample is not an interpolant and misbehaves more mildly, but by the same mechanism.

Orthogonal polynomials. The general theory is classical, and SzegHo (1939) remains the reference for the continuous case. The discrete case — orthogonality with respect to a design rather than a measure — was brought into statistical computing by Forsythe (1957), and the recurrence is sometimes named for him there. The integer contrasts tabulated for equally spaced levels are older, and are the ones [Section 8.7](#) uses.

Splines. The name and the theory begin with Schoenberg (1946), and the rank condition in its sharp form with Schoenberg and Whitney (1953). Least squares fitting with fixed knots grew in the 1970s: Poirier (1973) and Wold (1974) are early accounts aimed at data analysis, Smith (1979) a readable introduction. Wold's advice — few knots, several observations between them, at most one extremum per interval — is still sound, and Harrell (2015, chapter 2) gives the modern version. The truncated power basis and its B-spline remedy are treated by de Boor (2001), and in statistical terms by Eilers and Marx (1996) and Ruppert, Wand and Carroll (2003, chapter 3).

Segmented regression. A knot at an unknown location is a nonlinear problem and is not

treated here: see Hudson (1966) for the fitting, Feder (1975) for the asymptotics when the change point is identified, and Seber and Wild (1989, chapter 9) for a survey. Cobb (1978) shows what a conditional analysis of the Nile series of [Example \(Four fits with the same knots\)](#) requires.

Where the thread goes. Two loose ends are tied in [Chapter 43](#): a basis that is stable however many knots there are, and a continuous rather than discrete flexibility parameter. Fahrmeir, Kneib, Lang and Marx (2021, chapter 8), the source for the rest of this part, treats them together, as does Hastie and Tibshirani (1990) from the additive-model side.

Data. The Mauna Loa carbon dioxide series and the Nile flows are public-domain data sets distributed with statsmodels, already used in [Example \(A curved trend and a seasonal cycle\)](#) and [Example \(A trend in the Nile\)](#); the skewed design of [Example \(A skewed design\)](#) is simulated with a fixed seed.

Chapter 43

Smoothing: Kernels, Splines and Penalties

[Chapter 42](#) reached a natural stopping point. Piecewise polynomials can follow almost any shape, but only if someone chooses how many pieces there are and where they join, and that choice is both awkward and consequential. This chapter removes the choice. It replaces the question “how many knots?” with a question about a single continuous dial: how much roughness are we willing to pay for a closer fit? Everything else — the basis, the number of knots, the algorithm — becomes a matter of convenience once that dial exists.

Two traditions answer the question, and they meet in the middle. One fits a simple model in a moving window — a constant, a line, a cubic, weighted by distance from the point being estimated. Its dial is the width of the window, and its theory is asymptotic, a bias–variance calculation that ends in the rate $n^{-4/5}$. The other keeps a single global fit but adds a penalty on roughness; its dial is the weight on the penalty, and its theory is the algebra of [Chapter 27](#) and [Chapter 30](#): a penalized least squares problem, a linear operator, a trace that counts the degrees of freedom spent. The second tradition is the more useful one here, because a penalty carries over unchanged to several covariates ([Chapter 44](#)), to non-normal responses and to parameters other than the mean ([Chapter 45](#)), and because it has a second reading as a normal prior, which turns the smoothing parameter into a variance ratio the data can estimate.

What you need. [Chapter 6](#) (least squares as projection, [Proposition 6.3.4](#), and the leverage [Proposition 6.8.1](#) that returns in [Section 43.5](#)), [Section 21.3](#) (weighted least squares, [Theorem 21.3.1](#)), [Chapter 27](#) (ridge regression [Theorem 27.2.2](#)) and [Section 30.1](#) (penalized least squares, [Definition 30.1.1](#)). From [Chapter 29](#): the leave-one-out shortcut [Theorem 29.3.2](#), generalized cross-validation [Definition 29.3.2](#), AIC [Proposition 29.2.4](#) and the warning [Proposition 29.5.1](#). From [Chapter 32](#): the linear mixed model [Definition 32.2.1](#), Henderson’s equations [Theorem 32.3.2](#), the BLUP [Theorem 32.3.1](#) and REML ([Definition 32.4.1](#), [Theorem 32.4.2](#)). [Section 1.8](#) supplies the condition number [Definition 1.8.1](#), and [Chapter 42](#) the spline space itself ([Definition 42.3.1](#), [Theorem 42.3.1](#), [Proposition 42.4.1](#)). [Section 43.6](#) draws on [Section 39.4](#) for the Bayesian vocabulary ([Definition 39.4.1](#), [Proposition 39.5.1](#)).

Notation for this chapter. There is one covariate x taking values $x_1, \dots, x_n$ in an interval $[a, b]$, one response, and an unknown function f with $\mathbf{f} = \{f(x_1), \dots, f(x_n)\}^\top$. [Section 43.1](#) writes K for a kernel function and h for a bandwidth; from [Section 43.2](#) on, K is instead the *number of interior knots*, written $t_1 < \dots < t_K$, with κ_j reserved for the extended knot sequence of the B-spline recurrence; the kernel does not reappear except by name. $\mathbf{B}$ is a matrix of basis

functions, $\boldsymbol{\gamma}$ its coefficients, $\mathbf{P}$ a penalty matrix, $\mathbf{D}$ a difference matrix and $\mathbf{S}_\lambda$ a smoother matrix. In [Section 43.4](#), $\mathbf{Q}$ and $\mathbf{R}$ are the two band matrices of the Reinsch form, a local use unrelated to the $\mathbf{R}$ of Part VII.

43.1 Kernel and local polynomial regression

Drop the linear predictor. Keep one covariate, keep additive errors, and assume nothing about the shape of the regression function except that it is smooth:

$$y_i = f(x_i) + \varepsilon_i, \quad \mathbf{E}(\varepsilon_i) = 0, \quad \text{Var}(\varepsilon_i) = \sigma^2, \quad i = 1, \dots, n, \quad (43.1.1)$$

with independent errors and design points $x_1, \dots, x_n$ in an interval $[a, b]$. The unknown is now a *function*, not a vector of coefficients, and there is no finite-dimensional parameter to estimate consistently. What replaces it is an assumption of *local* regularity: f does not change much over a short interval, so observations with covariate values near x carry information about $f(x)$.

That sentence is the whole idea of this section. Fix a target point x , take the observations whose covariates lie in a window around it, fit something simple to them by least squares, and read off the fitted value at x ; move x across the interval and the fitted values trace a curve. Everything else is bookkeeping: which observations count as “near”, how much they count, and what “something simple” means.

43.1.1 Local averages

Example. (The running mean)

The crudest smoother averages the responses in a window: fix a half-width h and set $\hat{f}(x) = |N(x)|^{-1} \sum_{i \in N(x)} y_i$ with $N(x) = \{i : |x_i - x| \leq h\}$. Three things go wrong at once. The curve is a step function, since $\hat{f}$ changes only when a point enters or leaves the window; every point in the window counts the same, at the centre or at the edge; and near $x = a$ the window is one-sided, so the average estimates f somewhere to the right of a .

Weighting repairs the first two defects: count a point by a weight that decreases smoothly with distance and vanishes outside the window. The third is deeper, and is repaired by fitting a line rather than a constant. Both repairs fit in one definition.

Definition 43.1.1 — Kernel weights and the local polynomial estimator

A **kernel** is a bounded function K with $\int K(u) du = 1$ and $K(u) = K(-u)$, here always nonnegative and supported on $[-1, 1]$. Its moments are $\mu_j = \int u^j K(u) du$ and $\nu_j = \int u^j K(u)^2 du$, with $R(K) = \nu_0$. For a **bandwidth** $h > 0$ write $K_h(u) = h^{-1}K(u/h)$.

Fix a degree $q \geq 0$. The **local polynomial estimator of degree q** at the point x is $\hat{f}(x) = \hat{b}_0$, where $(\hat{b}_0, \dots, \hat{b}_q)$ minimizes

$$\sum_{i=1}^n K_h(x_i - x) \left\{ y_i - \sum_{j=0}^q b_j (x_i - x)^j \right\}^2. \quad (43.1.2)$$

For $q = 0$ this is the **local constant** or **Nadaraya–Watson** estimator

$$\hat{f}(x) = \frac{\sum_i K_h(x_i - x) y_i}{\sum_i K_h(x_i - x)}, \quad (43.1.3)$$

and for $q = 1$ the **local linear** estimator.

Three kernels are used throughout: the uniform kernel $K(u) = \frac{1}{2}$ on $[-1, 1]$, which gives the running mean back; the **Epanechnikov** kernel $K(u) = \frac{3}{4}(1 - u^2)$ on $[-1, 1]$, with $\mu_2 = 1/5$ and $R(K) = 3/5$; and the standard normal density, whose unbounded support does not literally satisfy the conditions below, though the conclusions are the same. The kernel matters far less than h , as [Exercise \(B2\)](#) quantifies.

[Eq. 43.1.2](#) is a weighted least squares problem ([Theorem 21.3.1](#)) with model matrix and weight matrix

$$\mathbf{U}_x = \begin{pmatrix} 1 & x_1 - x & \cdots & (x_1 - x)^q \\ \vdots & \vdots & & \vdots \\ 1 & x_n - x & \cdots & (x_n - x)^q \end{pmatrix}, \quad \mathbf{W}_x = \text{diag}\{K_h(x_i - x)\}_{i=1}^n.$$

Nothing in it is new; what is new is that it is solved afresh at every x , and that the weights, not a global model, decide which observations matter.

43.1.2 The estimator is linear, and it reproduces polynomials

Proposition 43.1.1 — Equivalent kernel weights

Suppose $\mathbf{U}_x^\top \mathbf{W}_x \mathbf{U}_x$ is nonsingular. Then $\hat{f}(x) = \sum_i \ell_i(x) y_i$ with

$$\ell_i(x) = \mathbf{e}_1^\top (\mathbf{U}_x^\top \mathbf{W}_x \mathbf{U}_x)^{-1} \mathbf{U}_x^\top \mathbf{W}_x \mathbf{e}_i, \quad (43.1.4)$$

where $\mathbf{e}_1$ is the first standard basis vector, and

- (a) $\sum_i \ell_i(x)(x_i - x)^j = \delta_{j0}$ for $j = 0, \dots, q$, where δ_{j0} is one if $j = 0$ and zero otherwise;
- (b) consequently $\hat{f}$ reproduces polynomials: if f is a polynomial of degree at most q then $\sum_i \ell_i(x)f(x_i) = f(x)$ for every x , whatever the design, the kernel and the bandwidth;
- (c) the weights do not depend on $\mathbf{y}$, so $\text{Var}\{\hat{f}(x)\} = \sigma^2 \sum_i \ell_i(x)^2$.

Proof. The weighted normal equations (Theorem 6.4.2) are $\mathbf{U}_x^\top \mathbf{W}_x \mathbf{U}_x \hat{\mathbf{b}} = \mathbf{U}_x^\top \mathbf{W}_x \mathbf{y}$, and $\hat{f}(x) = \mathbf{e}_1^\top \hat{\mathbf{b}}$, which is Eq. 43.1.4. For (a), the j th column of $\mathbf{U}_x$ has entries $(x_i - x)^j$, so $\sum_i \ell_i(x)(x_i - x)^j = \mathbf{e}_1^\top (\mathbf{U}_x^\top \mathbf{W}_x \mathbf{U}_x)^{-1} \mathbf{U}_x^\top \mathbf{W}_x \mathbf{U}_x \mathbf{e}_{j+1} = \mathbf{e}_1^\top \mathbf{e}_{j+1}$. Part (b) follows by writing $f(x_i) = \sum_{j \leq q} c_j (x_i - x)^j$ with $c_0 = f(x)$, and (c) because $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$. ■

Part (a) is the engine of everything that follows. The weights sum to one, so the estimator has no bias against a constant; for $q \geq 1$ they also annihilate $(x_i - x)$, so it has no bias against a linear trend either. That is exactly what the running mean lacked.

The weight profile $u \mapsto \ell_i(x)$, with $u = (x_i - x)/h$, is the **equivalent kernel** of the estimator. For $q = 1$ at an interior point it is asymptotically $K(u)/\{nhg(x)\}$: a local linear fit *is* a kernel average, with the kernel unchanged. For $q = 3$ it is $(\mu_4 - \mu_2 u^2)K(u)/(\mu_4 - \mu_2^2)$, which takes negative values — the price of killing the h^2 bias term.

43.1.3 Bias and variance

Four assumptions make the asymptotics exact rather than heuristic. A random design would work too, at the cost of replacing every statement by one that holds in probability; the proof below is for a *regular* design, where the argument is a clean Riemann-sum estimate.

(A) Design. $x_i = G^{-1}\{(i - \frac{1}{2})/n\}$ for $i = 1, \dots, n$, where G is a distribution function on $[a, b]$ whose density g is continuously differentiable and bounded away from zero.

(B) Kernel. K is as in Definition 43.1.1, of bounded variation, with $\mu_2 > 0$.

(C) Function. f is twice continuously differentiable on $[a, b]$.

(D) Bandwidth. $h = h_n \rightarrow 0$ and $nh \rightarrow \infty$.

Assumption (A) holds exactly for an equally spaced or quantile-spaced design. The next lemma, the only analysis in this chapter, says that a kernel-weighted sum over such a design is an integral plus a bounded error.

Lemma 43.1.2 — Kernel sums are integrals

Let φ be of bounded variation on $\mathbb{R}$ with support in $[-1, 1]$ and total variation $V(\varphi)$. Under (A), for every x and every $h > 0$,

$$\left| \sum_{i=1}^n \varphi\left(\frac{x_i - x}{h}\right) - nh \int_{(a-x)/h}^{(b-x)/h} \varphi(u) g(x + hu) du \right| \leq V(\varphi). \quad (43.1.5)$$

Proof. Put $\Psi(v) = \varphi\{(G^{-1}(v) - x)/h\}$ for $v \in [0, 1]$. Since G^{-1} is increasing, Ψ has the same total variation as $t \mapsto \varphi\{(t - x)/h\}$, namely $V(\varphi)$. The sum on the left is $\sum_i \Psi\{(i - \frac{1}{2})/n\}$, a midpoint sum. Write I_i for the i th subinterval of $[0, 1]$ of length $1/n$ and V_i for the variation of Ψ on I_i . For $v \in I_i$, $|\Psi\{(i - \frac{1}{2})/n\} - \Psi(v)| \leq V_i$, so $|n^{-1}\Psi\{(i - \frac{1}{2})/n\} - \int_{I_i} \Psi| \leq V_i/n$. Summing over i and using $\sum_i V_i = V(\varphi)$ gives $|\sum_i \Psi\{(i - \frac{1}{2})/n\} - n \int_0^1 \Psi| \leq V(\varphi)$. Finally substitute $t = G^{-1}(v)$, so that $dv = g(t) dt$, and then $t = x + hu$. ■

Applied with $\varphi(u) = K(u)u^j$ and with $\varphi = K^2u^j$, the lemma turns every sum that appears below into a moment of the kernel. Write

$$S_{n,j} = \sum_{i=1}^n K_h(x_i - x)(x_i - x)^j,$$

and let $\mathbf{A} = (\mu_{j+k})_{j,k=0}^q$ and $\mathbf{A}^* = (\nu_{j+k})_{j,k=0}^q$ be the kernel's moment matrices, which are positive definite because μ_{j+k} and ν_{j+k} are the Gram matrices of $1, u, \dots, u^q$ in $L^2(K du)$ and $L^2(K^2 du)$.

Theorem 43.1.3 — Bias and variance of a local polynomial estimate

Assume (A)–(D) and let x satisfy $[x - h, x + h] \subset (a, b)$.

(a) (*Local linear*, $q = 1$.)

$$\mathbb{E}\{\hat{f}(x)\} - f(x) = \frac{1}{2}\mu_2 f''(x)h^2 + o(h^2), \quad \text{Var}\{\hat{f}(x)\} = \frac{\sigma^2 R(K)}{nh g(x)} \{1 + o(1)\}.$$

(b) (*Local constant*, $q = 0$.) The variance is the same to first order, and

$$\mathbb{E}\{\hat{f}(x)\} - f(x) = \mu_2 h^2 \left\{ \frac{1}{2} f''(x) + \frac{f'(x)g'(x)}{g(x)} \right\} + o(h^2). \quad (43.1.6)$$

(c) (*At the boundary*.) Let $x = a + ch$ with $c \in [0, 1]$ fixed, and write $\mu_{j,c} = \int_{-c}^1 u^j K(u) du$. Then the local constant estimator has bias $f'(a) h \mu_{1,c}/\mu_{0,c} + O(h^2)$, of exact order h unless $f'(a) = 0$, while the local linear estimator still has bias $O(h^2)$.

(d) (*Optimal bandwidth*.) For the local linear estimator with $f''(x) \neq 0$, the pointwise mean squared error $\frac{1}{4}\mu_2^2 f''(x)^2 h^4 + \sigma^2 R(K)/\{nhg(x)\}$ is minimized at

$$h^*(x) = \left\{ \frac{\sigma^2 R(K)}{g(x) \mu_2^2 f''(x)^2} \right\}^{1/5} n^{-1/5}, \quad (43.1.7)$$

and the minimum value is $\frac{5}{4}\{\mu_2^2 f''(x)^2\}^{1/5}\{\sigma^2 R(K)/g(x)\}^{4/5} n^{-4/5}$.

Proof. Write $u_i = (x_i - x)/h$, let $\mathbf{U}$ have rows $(1, u_i, \dots, u_i^q)$ and $\mathbf{W} = \mathbf{W}_x$. Because $\mathbf{U}_x = \mathbf{U} \text{diag}(1, h, \dots, h^q)$ and the first diagonal entry is one, Eq. 43.1.4 gives $\ell_i(x) = \mathbf{e}_1^\top (\mathbf{U}^\top \mathbf{W} \mathbf{U})^{-1} \mathbf{U}^\top \mathbf{W} \mathbf{e}_i$.

Moment sums. By Lemma 43.1.2 with $\varphi(u) = K(u)u^j$, and because $[x - h, x + h] \subset (a, b)$

makes the range of integration all of $[-1, 1]$,

$$S_{n,j} = h^{j-1} \sum_i K(u_i) u_i^j = nh^j \left\{ \int K(u) u^j g(x + hu) du + O((nh)^{-1}) \right\}.$$

Since $g \in C^1$, $g(x + hu) = g(x) + hug'(x + \theta hu)$ with $\theta \in (0, 1)$, and g' is uniformly continuous, so

$$S_{n,j} = nh^j \{g(x)\mu_j + hg'(x)\mu_{j+1} + o(h) + O((nh)^{-1})\}. \quad (43.1.8)$$

Because $(\mathbf{U}^\top \mathbf{WU})_{jk} = \sum_i K_h(x_i - x) u_i^{j+k} = h^{-(j+k)} S_{n,j+k}$, this says $\mathbf{U}^\top \mathbf{WU} = n\{g(x)\mathbf{A} + O(h) + O((nh)^{-1})\}$. In the same way, with $\varphi = K^2 u^j$, $\mathbf{U}^\top \mathbf{W}^2 \mathbf{U} = (n/h)\{g(x)\mathbf{A}^* + O(h) + O((nh)^{-1})\}$. Assumption (D) makes both error terms vanish, so $\mathbf{U}^\top \mathbf{WU}$ is eventually nonsingular and Proposition 43.1.1 applies.

Variance. By Proposition 43.1.1(c),

$$\text{Var}\{\hat{f}(x)\} = \sigma^2 \mathbf{e}_1^\top (\mathbf{U}^\top \mathbf{WU})^{-1} (\mathbf{U}^\top \mathbf{W}^2 \mathbf{U}) (\mathbf{U}^\top \mathbf{WU})^{-1} \mathbf{e}_1 = \frac{\sigma^2 \mathbf{e}_1^\top \mathbf{A}^{-1} \mathbf{A}^* \mathbf{A}^{-1} \mathbf{e}_1}{nh g(x)} \{1 + o(1)\}.$$

For $q = 0$, $\mathbf{A} = (1)$ and $\mathbf{A}^* = (R(K))$. For $q = 1$ the symmetry of K makes $\mu_1 = 0$, so $\mathbf{A} = \text{diag}(1, \mu_2)$, $\mathbf{A}^{-1} \mathbf{e}_1 = \mathbf{e}_1$ and the quadratic form is $\nu_0 = R(K)$. Both give the stated variance.

Bias, $q = 1$. By Proposition 43.1.1(a) the weights annihilate constants and linear terms, so with a second-order Taylor expansion of f about x , $f(x_i) = f(x) + f'(x)(x_i - x) + \frac{1}{2}f''(\xi_i)(x_i - x)^2$ for some ξ_i between x and x_i ,

$$\mathbb{E}\{\hat{f}(x)\} - f(x) = \frac{1}{2}f''(x) \sum_i \ell_i(x)(x_i - x)^2 + \frac{1}{2} \sum_i \ell_i(x) \{f''(\xi_i) - f''(x)\}(x_i - x)^2.$$

For the first sum, $\sum_i \ell_i(x)(x_i - x)^2 = h^2 \mathbf{e}_1^\top (\mathbf{U}^\top \mathbf{WU})^{-1} \mathbf{U}^\top \mathbf{W} \mathbf{u}^{(2)}$ with $\mathbf{u}_i^{(2)} = u_i^2$, and $(\mathbf{U}^\top \mathbf{W} \mathbf{u}^{(2)})_j = \sum_i K_h(x_i - x) u_i^{j+2} = h^{-(j+2)} S_{n,j+2}$, which by Eq. 43.1.8 equals $n\{g(x)\mu_{j+2} + O(h) + O((nh)^{-1})\}$. Hence

$$\sum_i \ell_i(x)(x_i - x)^2 = h^2 [\mathbf{e}_1^\top \mathbf{A}^{-1}(\mu_2, \mu_3)^\top + O(h) + O((nh)^{-1})] = h^2 \{\mu_2 + o(1)\},$$

using $\mu_3 = 0$. For the second sum, only $|x_i - x| \leq h$ contributes, so $|f''(\xi_i) - f''(x)| \leq \omega(h)$, the modulus of continuity of f'' , which tends to zero. Since $(\mathbf{U}^\top \mathbf{WU})^{-1} = O(n^{-1})$ entrywise and $\sum_i K_h(x_i - x) |u_i|^j = O(n)$ by Lemma 43.1.2, we get $\sum_i |\ell_i(x)| (x_i - x)^2 = O(h^2)$, and the second sum is $O\{\omega(h)h^2\} = o(h^2)$. This proves (a).

Bias, $q = 0$. Now only constants are annihilated, so a term in $f'(x)$ survives:

$$\mathbb{E}\{\hat{f}(x)\} - f(x) = f'(x) \frac{S_{n,1}}{S_{n,0}} + \frac{1}{2}f''(x) \frac{S_{n,2}}{S_{n,0}} + o(h^2),$$

the remainder being controlled as above. By Eq. 43.1.8 and $\mu_1 = 0$, $S_{n,0} = n\{g(x) + o(h)\}$ and $S_{n,1} = nh^2\{g'(x)\mu_2 + o(1)\}$, so $S_{n,1}/S_{n,0} = h^2\mu_2 g'(x)/g(x) + o(h^2)$, while $S_{n,2}/S_{n,0} = h^2\mu_2 + o(h^2)$. This is Eq. 43.1.6.

Boundary. For $x = a + ch$ the range of integration in Lemma 43.1.2 is $[-c, (b - x)/h]$, which for large n is $[-c, 1]$. Every moment μ_j above is therefore replaced by $\mu_{j,c}$ and the moment matrix by $\mathbf{A}_c = (\mu_{j+k,c})$, still positive definite for every $c \in [0, 1]$ because the monomials remain linearly independent in $L^2(K du)$ on $[-c, 1]$. For $q = 0$ the leading term is $f'(a)hS_{n,1}/(hS_{n,0}) = f'(a)h\mu_{1,c}/\mu_{0,c} + O(h^2)$, and $\mu_{1,c} \neq 0$ whenever $c < 1$, since the truncated kernel is no longer symmetric. For $q = 1$ the identity $\sum_i \ell_i(x)(x_i - x) = 0$ of Proposition 43.1.1(a) holds exactly, *at every point, boundary or not*, so the first-order term is absent and the same computation as in (a) leaves $\frac{1}{2}f''(a)h^2\mathbf{e}_1^\top \mathbf{A}_c^{-1}(\mu_{2,c}, \mu_{3,c})^\top + o(h^2)$.

Optimal bandwidth. Write the mean squared error as $Ah^4 + B/(nh)$ with $A = \frac{1}{4}\mu_2^2 f''(x)^2$ and $B = \sigma^2 R(K)/g(x)$. Differentiating, $4Ah^3 = B/(nh^2)$, that is $h^5 = B/(4An)$, which is Eq. 43.1.7; at that h the two terms are in the ratio 1 : 4, so the minimum is $5Ah^4 = 5A^{1/5}\{B/(4n)\}^{4/5}$, the stated value. ■

Idea. Local linear beats local constant twice, and for the same reason both times: the weights of a fit of degree $q \geq 1$ reproduce linear functions *exactly*, whatever the design and wherever the target point. The local linear estimator is therefore blind to how the design points are distributed (no term in g'/g) and to the one-sidedness of a window at the boundary (no term of order h). The local constant estimator is not, and neither extra bias is removed by more data, only by a smaller h .

Part (d) is the rate that every nonparametric method in this chapter obeys. A parametric estimator has variance of order n^{-1} and no bias; here only the $O(nh)$ points in the window contribute, so the variance is of order $(nh)^{-1}$ against a bias of order h^2 . Balancing the two forces $h \asymp n^{-1/5}$ and leaves a mean squared error of order $n^{-4/5}$, strictly slower than n^{-1} . The optimal bandwidth shrinks slowly: ten times the data calls for a window only 1.585 times narrower.

Warning. Eq. 43.1.7 is not a recipe. It involves the unknown $f''(x)$, the unknown σ^2 and the design density, and it is a *pointwise* optimum, so the ideal bandwidth differs at every x . Any formula that gives a bandwidth without an estimate of f'' is smuggling one in.

43.1.4 What the numbers look like

Example. (Bias, variance and the optimal bandwidth)

Take $n = 200$ equally spaced design points on $[0, 1]$ (so $g \equiv 1$), $\sigma = 0.25$ and

$$f(x) = 2x + e^{-25(x-0.35)^2} - \frac{3}{4}e^{-50(x-0.80)^2},$$

a straight line with a bump and a narrower dip. At the top of the bump, $x = 0.35$, $f''(x) = -50.06$, and with the Epanechnikov kernel Eq. 43.1.7 gives $h^* = 0.0715$. Averaging 2000 data sets at each of 29 bandwidths (Figure 43.1.2), the bias at h^* is 0.98 times the asymptotic value $\frac{1}{2}\mu_2 f''(x)h^2$ and the variance 1.02 times $\sigma^2 R(K)/(nh)$, while the empirically best bandwidth is 0.0703. For a first-order expansion at $n = 200$ this is closer agreement than one has any right to expect.

Figure 43.1.1: (a) Local linear fits to one data set at three bandwidths: too small, about right, too large. (b) Bias near the left endpoint over 2000 replicates. Inside $[0, h]$ the local constant window is one-sided, with bias of order h ; the local linear bias stays of order h^2 (Theorem 43.1.3).

Figure 43.1.1 shows fits at three bandwidths. At the left endpoint the two estimators part company. With $h = 0.08$, the local constant estimator has bias 0.0938 there and the local linear estimator -0.0058 , sixteen times smaller. Halving the bandwidth divides the first by 2.10 and the second by 4.38: order h against order h^2 , as Theorem 43.1.3(c) says.

```
import numpy as np

      )
```

43.1.5 Choosing the bandwidth in practice, and what kernels cannot do

Two families of rules are used. A **plug-in** rule estimates the unknowns in [Eq. 43.1.7](#) — usually an integrated version of it, with $f''(x)^2$ replaced by $\int f''(t)^2 g(t) dt$ — from a pilot fit, and iterates; Ruppert, Sheather and Wand (1995) is the standard version. A **cross-validatory** rule estimates prediction error directly, and since the local polynomial estimator is linear in $\mathbf{y}$, everything in [Section 43.5](#) applies to it with $\text{tr}(\mathbf{S}_h)$ for $\text{tr}(\mathbf{S}_\lambda)$.

Remark (Loess). The most widely used kernel smoother in practice is Cleveland's **loess** (Cleveland, 1979), which makes two changes. The bandwidth is a *nearest-neighbour* one: $h(x)$ is the distance from x to its $\lceil \alpha n \rceil$ th nearest design point, so the window holds a fixed

fraction of the data and widens where the design is sparse. And the fit is iterated with bisquare weights on the residuals, the reweighting of [Proposition 20.6.1](#), which makes it resistant to a few wild responses. Neither change affects [Theorem 43.1.3](#) at an interior point where g is continuous, since $h(x) \approx \alpha/\{2g(x)\}$ is then a fixed bandwidth divided by $g(x)$.

There are two reasons this chapter does not stop here. The first is that a kernel estimate is the solution of no global optimization problem: there is no criterion whose minimizer it is and no coefficient vector to report, so there is no obvious way to add a second covariate, a non-normal response or a random effect. The second is dimension. With d covariates the window is a d -dimensional ball holding of order nh^d points, and the optimal rate degrades to $n^{-4/(4+d)}$ — the *curse of dimensionality*. At $d = 5$ it is $n^{-4/9}$, so matching what 100 observations give in one dimension needs of the order of 10^5 of them; [Chapter 44](#) escapes by assuming additivity, not by smoothing harder. The rest of this chapter writes the estimate as the minimizer of a penalized criterion, which keeps a coefficient vector, a linear operator and a criterion, all of which generalize.

43.1.6 Exercises

43.1.6.1 A. Check your understanding

Exercise A1.

Show directly from [Eq. 43.1.3](#) that the Nadaraya–Watson weights are nonnegative and sum to one, and deduce that $\min_i y_i \leq \hat{f}(x) \leq \max_i y_i$. Show by example that the local linear estimator has no such property.

Solution. The weights $K_h(x_i - x)/\sum_j K_h(x_j - x)$ are nonnegative because $K \geq 0$ and sum to one by construction, so $\hat{f}(x)$ is a convex combination of the y_i . For the local linear estimator take $n = 2$, $x_1 = 0$, $x_2 = 1$, both inside the window at $x = 2$ with equal kernel weights: the line through the two points is extrapolated, giving $\hat{f}(2) = 2y_2 - y_1$, outside $[y_1, y_2]$ when $y_2 > y_1$.

43.1.6.2 B. Practice

Exercise B1.

Compute μ_2 and $R(K)$ for the uniform kernel $K(u) = \frac{1}{2}$ on $[-1, 1]$ and for the Epanechnikov kernel, and verify the values $\mu_2 = 1/5$, $R(K) = 3/5$ quoted after [Definition 43.1.1](#).

Exercise B2.

By [Theorem 43.1.3\(d\)](#), the smallest achievable mean squared error is proportional to $\{\mu_2^2 R(K)^4\}^{1/5}$. Compute this quantity for the uniform, Epanechnikov and normal kernels (for the normal, $\mu_2 = 1$ and $R(K) = 1/(2\sqrt{\pi})$), and express each as a ratio to the Epanechnikov value. Conclude that the choice of kernel changes the attainable error by

a few per cent, whereas Eq. 43.1.7 shows that getting h wrong by a factor of two can change it by much more.

Solution. Write $C(K) = \{\mu_2^2 R(K)^4\}^{1/5}$. Epanechnikov: $\{(1/5)^2(3/5)^4\}^{1/5} = (0.04 \times 0.1296)^{1/5} = 0.3491$. Uniform: $\{(1/3)^2(1/2)^4\}^{1/5} = (0.11111 \times 0.0625)^{1/5} = 0.3701$, a ratio of 1.0602. Normal: $R(K) = 0.2821$, so $(0.2821^4)^{1/5} = 0.3633$, a ratio of 1.0408. Six per cent and four per cent. By contrast, replacing h^* by $2h^*$ in $Ah^4 + B/(nh)$ multiplies the first term by 16 and divides the second by 2, and with the terms in the ratio 1 : 4 at the optimum this raises the criterion by a factor $(16 + 2)/5 = 3.6$.

Exercise B3.

Suppose f is exactly linear, $f(x) = \alpha + \beta x$. Show that the local linear estimator is unbiased at every x and for every bandwidth, and that the Nadaraya–Watson estimator is unbiased at x only if $\sum_i K_h(x_i - x)(x_i - x) = 0$. Relate the second condition to Eq. 43.1.6.

43.1.6.3 C. Going deeper

Exercise C1.

Suppose f is four times and g three times continuously differentiable, and let K be symmetric with $\mu_2 = 0$ and $\mu_4 \neq 0$ — a *fourth-order* kernel, which must take negative values, and which violates assumption (B).

- (a) Carry Eq. 43.1.8 two terms further, to $S_{n,j} = nh^j \sum_{r=0}^3 h^r g^{(r)}(x) \mu_{j+r} / r! + o(nh^{j+3})$, and redo the local constant ($q = 0$) bias calculation in the proof of Theorem 43.1.3 to get

$$E\{\hat{f}(x)\} - f(x) = \mu_4 h^4 \left\{ \frac{f'g'''}{6g} + \frac{f''g''}{4g} + \frac{f'''g'}{6g} + \frac{f^{(4)}}{24} \right\}(x) + o(h^4).$$

Deduce that the optimal bandwidth is of order $n^{-1/9}$ and the mean squared error of order $n^{-8/9}$.

- (b) Show that for $q = 1$ the limiting moment matrix is $\mathbf{A} = \text{diag}(\mu_0, \mu_2) = \text{diag}(1, 0)$, which is singular, so the expansion in the proof does not apply. Writing $a = S_{n,0}$, $b = h^{-1}S_{n,1}$, $c = h^{-2}S_{n,2}$ and $u_i = (x_i - x)/h$, show from Eq. 43.1.4 that $\ell_i(x) = K_h(x_i - x)(c - bu_i)/(ac - b^2)$, that $b/c = O(h)$, and hence that the local linear weights collapse to the local constant ones.
- (c) Why is a fourth-order kernel rarely worth using? Consider the sign of $\hat{f}$ when every $y_i \geq 0$, the size of the constants, and (b).

Solution.

- (a) Symmetry gives $\mu_1 = \mu_3 = \mu_5 = 0$, and $\mu_2 = 0$ by assumption, so the expansion leaves $S_{n,0} = ng(x)\{1 + O(h^4)\}$ and, to relative order $o(1)$, $S_{n,1} = nh^4\mu_4 g'''(x)/6$, $S_{n,2} = nh^4\mu_4 g''(x)/2$, $S_{n,3} = nh^4\mu_4 g'(x)$ and $S_{n,4} = nh^4\mu_4 g(x)$. Substituting these in $\sum_{j=1}^4 f^{(j)}(x)S_{n,j}/(j!S_{n,0})$ gives the display: every term of order h , h^2 and h^3 has vanished. Balancing the squared bias h^8 against the variance $(nh)^{-1}$ gives

$h \asymp n^{-1/9}$ and mean squared error of order $n^{-8/9}$.

- (b) $\mathbf{A} = (\mu_{j+k})_{j,k=0}^1$ has entries $\mu_0 = 1$, $\mu_1 = 0$, $\mu_2 = 0$; it is singular, and the step of the proof that inverts it fails. For the finite-sample weights, $\mathbf{U}^\top \mathbf{W} \mathbf{U} = \begin{pmatrix} a & b \\ b & c \end{pmatrix}$ in the notation of the proof, whose inverse has first row $(c, -b)/(ac - b^2)$, and $(\mathbf{U}^\top \mathbf{W})_{ji} = K_h(x_i - x)u_i^j$; multiplying gives the stated $\ell_i(x)$. By (a), $b = nh^3\mu_4 g'''/6$ and $c = nh^2\mu_4 g''/2$ to leading order, so $b/c = O(h)$ and $\ell_i(x) = K_h(x_i - x)/a + O(h)$, the Nadaraya–Watson weights. In floating point the matrix is worse than singular: it is ill conditioned with an entry of indefinite sign.
- (c) The constant now involves $f^{(4)}$, far harder to estimate than f'' ; the gain over $n^{-4/5}$ shows only at sample sizes where the two rates differ appreciably; negative weights can make $\hat{f}$ negative where the data are not, which is unacceptable for a variance or a probability; and by
- (d) the fit loses the boundary and design-bias advantages that were the reason for $q = 1$.

Exercise C2.

Replace assumption (A) by: $x_1, \dots, x_n$ are independent with density g , continuous and positive at x . Show that $E\{S_{n,j}\} = nh^j\{g(x)\mu_j + O(h)\}$ and $\text{Var}(S_{n,j}) = O(nh^{2j-1})$, so that $(nh^j)^{-1}S_{n,j} \rightarrow g(x)\mu_j$ in probability. Explain why this gives the conditional bias and variance of [Theorem 43.1.3](#) with o_p in place of o , and why the argument needs more care than the fixed-design one when the bias term of order h^2 is required (compare the size of the stochastic error $(nh^3)^{-1/2}$ with h at $h \asymp n^{-1/5}$).

Solution. $E\{S_{n,j}\} = n E\{K_h(x_1 - x)(x_1 - x)^j\} = nh^j \int K(u)u^j g(x+hu) du = nh^j\{g(x)\mu_j + O(h)\}$ by continuity of g , and $\text{Var}(S_{n,j}) \leq n E\{K_h(x_1 - x)^2(x_1 - x)^{2j}\} = O(nh^{2j-1})$. The standard deviation of $(nh^j)^{-1}S_{n,j}$ is therefore $O\{(nh)^{-1/2}\}$, which tends to zero under (D), and Slutsky's theorem transfers every limit in the proof. The difficulty is that the stochastic error in the bias is of order $h^2(nh)^{-1/2}$, which at $h \asymp n^{-1/5}$ is $n^{-4/5}$, the same order as the squared bias. A statement about the *conditional* bias given the design therefore needs the sharper expansions of Fan and Gijbels (1996, ch. 3).

43.2 B-splines

[Chapter 42](#) fixed the space we shall work in. Given a degree $d \geq 0$, an interval $[a, b]$ and K interior knots $a < t_1 < \dots < t_K < b$, the **spline space** is the set of functions that are polynomials of degree at most d on each interval between consecutive knots and have $d - 1$ continuous derivatives at each knot ([Definition 42.3.1](#)). Its dimension is $d + 1 + K$, and the truncated power functions $1, x, \dots, x^d, (x - t_1)_+^d, \dots, (x - t_K)_+^d$ are a basis ([Theorem 42.3.1](#)). ([Chapter 42](#) writes κ_i for these knots; here κ is needed for the longer sequence built next.)

That basis is a bad one to compute with, for the reason [Proposition 42.4.1](#) gives: its members are global, nearly collinear, and of wildly different sizes once the knots are close together. This section builds the basis everything else in the chapter uses. It spans the same space, so nothing about the *fit* changes; only the numbers do, and they change dramatically.

Warning. From here to the end of the chapter K is the number of interior knots, not a kernel; the kernel $K(\cdot)$ of [Section 43.1](#) does not reappear.

43.2.1 The knot sequence and the recurrence

B-splines are defined by a recurrence on the degree, and the recurrence needs knots outside $[a, b]$ as well as inside it. Collect the interior knots and $d + 1$ copies of each endpoint into a nondecreasing **extended knot sequence** $\kappa_1 \leq \kappa_2 \leq \cdots \leq \kappa_{m+d+1}$ with $m = K + d + 1$, namely

$$\begin{aligned} \kappa_1 = \cdots = \kappa_{d+1} &= a, & \kappa_{d+1+i} &= t_i \quad (i = 1, \dots, K), \\ \kappa_{d+K+2} = \cdots = \kappa_{m+d+1} &= b. \end{aligned} \tag{43.2.1}$$

This is the **clamped** sequence; an alternative is discussed below. In either case there are $m + d + 1 = K + 2d + 2$ entries and, as we shall see, $m = K + d + 1$ B-splines, exactly the dimension of the spline space. From here on κ_j always means an entry of the extended sequence.

Definition 43.2.1 — B-splines

Given a nondecreasing sequence $\kappa_1 \leq \cdots \leq \kappa_{m+d+1}$, define

$$B_j^0(x) = \begin{cases} 1, & \kappa_j \leq x < \kappa_{j+1}, \\ 0, & \text{otherwise,} \end{cases} \quad j = 1, \dots, m + d,$$

and recursively, for $r = 1, \dots, d$ and $j = 1, \dots, m + d + 1 - r$,

$$B_j^r(x) = \omega_j^r(x) B_j^{r-1}(x) + \{1 - \omega_{j+1}^r(x)\} B_{j+1}^{r-1}(x), \tag{43.2.2}$$

where $\omega_j^r(x) = (x - \kappa_j) / (\kappa_{j+r} - \kappa_j)$.

A term whose denominator vanishes is read as zero. The functions $B_1^d, \dots, B_m^d$ are the **B-splines of degree d** on the sequence, and the matrix $\mathbf{B}$ with $\mathbf{B}_{ij} = B_j^d(x_i)$ is the **B-spline basis matrix** of a design.

The recurrence is due to de Boor (1972) and Cox (1972). It has an immediate reading: B_j^r is a weighted average of two B-splines of one degree lower, with weights that ramp linearly from 0 to 1 across the support. The piece of the definition that does the work is the convention about zero denominators, which is what lets the endpoints be repeated; a repeated knot makes the corresponding lower-degree B-spline identically zero, and the offending term disappears with it.

43.2.2 What B-splines are like

Proposition 43.2.1 — Properties of the B-spline basis

Let $B_1^d, \dots, B_m^d$ be as in [Definition 43.2.1](#). Then:

- (a) (*Local support.*) $B_j^d(x) = 0$ for $x \notin [\kappa_j, \kappa_{j+d+1})$, and, for the sequence [Eq. 43.2.1](#) with distinct interior knots, $B_j^d(x) > 0$ for $\kappa_j < x < \kappa_{j+d+1}$. In particular at most $d + 1$ of the B_j^d are nonzero at any point.
- (b) (*Nonnegativity.*) $B_j^d \geq 0$ everywhere.
- (c) (*Partition of unity.*) For the sequence [Eq. 43.2.1](#), $\sum_{j=1}^m B_j^d(x) = 1$ for every $x \in [a, b)$.
- (d) (*Piecewise polynomial.*) On each interval between consecutive distinct knots, B_j^d is a polynomial of degree at most d .
- (e) (*Derivative.*) For $d \geq 1$,

$$\frac{d}{dx} B_j^d(x) = d \left\{ \frac{B_j^{d-1}(x)}{\kappa_{j+d} - \kappa_j} - \frac{B_{j+1}^{d-1}(x)}{\kappa_{j+d+1} - \kappa_{j+1}} \right\}, \quad (43.2.3)$$

with the same convention on zero denominators. Consequently B_j^d has $d - 1$ continuous derivatives at every simple knot.

- (f) (*Basis.*) For the sequence [Eq. 43.2.1](#) with distinct interior knots, $B_1^d, \dots, B_m^d$ are linearly independent on $[a, b]$ and span the spline space of [Theorem 42.3.1](#), of which they are therefore a basis. (With a repeated interior knot they span a larger space, one with a weaker continuity requirement there; see [Exercise \(C1\)](#).)

Proof.

- (a) and (b) go together, by induction on r . For $r = 0$ both are clear. Suppose they hold for $r - 1$. By [Eq. 43.2.2](#), B_j^r is a combination of B_j^{r-1} , supported in $[\kappa_j, \kappa_{j+r})$, and B_{j+1}^{r-1} , supported in $[\kappa_{j+1}, \kappa_{j+r+1})$, so B_j^r vanishes outside $[\kappa_j, \kappa_{j+r+1})$. On that interval $\omega_j^r(x) = (x - \kappa_j)/(\kappa_{j+r} - \kappa_j) \geq 0$ and $1 - \omega_{j+1}^r(x) = (\kappa_{j+r+1} - x)/(\kappa_{j+r+1} - \kappa_{j+1}) \geq 0$, so $B_j^r \geq 0$. For strict positivity, let $\kappa_j < x < \kappa_{j+r+1}$. If $x < \kappa_{j+r}$ then $\kappa_j < \kappa_{j+r}$, so $\omega_j^r(x) > 0$ and $B_j^{r-1}(x) > 0$ by the induction hypothesis, and the second term is nonnegative. If $x \geq \kappa_{j+r}$ then $\kappa_{j+1} < \kappa_{j+r+1}$ — otherwise $\kappa_{j+r} = \kappa_{j+r+1}$, which contradicts $\kappa_{j+r} \leq x < \kappa_{j+r+1}$ — so $1 - \omega_{j+1}^r(x) > 0$ and $B_{j+1}^{r-1}(x) > 0$. Finally, a point lies in at most $d + 1$ of the intervals $[\kappa_j, \kappa_{j+d+1})$.
- (b) Induct on r , proving $\sum_{j=1}^{m+d+1-r} B_j^r(x) = 1$ for $x \in [a, b)$. For $r = 0$ the intervals $[\kappa_j, \kappa_{j+1})$ that are nonempty partition $[a, b)$. For the step, substitute [Eq. 43.2.2](#) and collect terms with the same lower index:

$$\begin{aligned} \sum_j B_j^r &= \omega_1^r B_1^{r-1} + \sum_{j \geq 2} \{\omega_j^r + 1 - \omega_j^r\} B_j^{r-1} \\ &\quad + \{1 - \omega_{L+1}^r\} B_{L+1}^{r-1}, \end{aligned}$$

where $L = m + d + 1 - r$ is the largest index of a degree- r B-spline. The first and last terms vanish on $[a, b)$: for [Eq. 43.2.1](#), B_1^{r-1} is supported in $[\kappa_1, \kappa_r) = [a, a)$, which is empty when $r \leq d$, and B_{L+1}^{r-1} in $[\kappa_{L+1}, \kappa_{L+r}) = [b, b)$. What is left is $\sum_{j=2}^L B_j^{r-1}$, which is the partition of unity one degree lower.

- (c) By induction: B_j^0 is constant on each such interval, and [Eq. 43.2.2](#) multiplies polynomials of degree $r - 1$ by linear functions.
- (d) Induct on d . Write $D_j^r = (\kappa_{j+r} - \kappa_j)^{-1}$, so that $\omega_j^r(x) = (x - \kappa_j) D_j^r$ and $\{\omega_j^r\}' = D_j^r$. For $d = 1$, B_j^1 is continuous and piecewise linear, and differentiating [Eq. 43.2.2](#) on the interior of each knot interval gives $D_j^1 B_j^0 - D_{j+1}^1 B_{j+1}^0$, which is [Eq. 43.2.3](#). For

the step, differentiate Eq. 43.2.2:

$$(B_j^d)' = D_j^d B_j^{d-1} - D_{j+1}^d B_{j+1}^{d-1} + \omega_j^d (B_j^{d-1})' + \{1 - \omega_{j+1}^d\} (B_{j+1}^{d-1})',$$

so it suffices to show that the last two terms equal $(d-1)\{D_j^d B_j^{d-1} - D_{j+1}^d B_{j+1}^{d-1}\}$. Substituting the induction hypothesis on the left and Eq. 43.2.2 on the right, both sides become combinations of B_j^{d-2} , B_{j+1}^{d-2} and B_{j+2}^{d-2} , and it is enough to match the three coefficients. For B_j^{d-2} : $\omega_j^d D_j^{d-1} = (x - \kappa_j) D_j^d D_j^{d-1}$ on the left and $D_j^d \omega_j^{d-1} = D_j^d (x - \kappa_j) D_j^{d-1}$ on the right. For B_{j+2}^{d-2} : $-\{1 - \omega_{j+1}^d\} D_{j+2}^{d-1} = -(\kappa_{j+d+1} - x) D_{j+1}^d D_{j+2}^{d-1}$ on the left, and $-D_{j+1}^d \{1 - \omega_{j+2}^{d-1}\} = -D_{j+1}^d (\kappa_{j+d+1} - x) D_{j+2}^{d-1}$ on the right. For B_{j+1}^{d-2} the two coefficients are $D_{j+1}^{d-1} \{1 - \omega_j^d - \omega_{j+1}^d\}$ and $D_j^d - \omega_{j+1}^{d-1} (D_j^d + D_{j+1}^d)$, and their difference reduces, after cancelling $(x - \kappa_{j+1}) D_{j+1}^{d-1} D_{j+1}^d$ and collecting the terms in D_j^d , to $D_j^d \{D_{j+1}^{d-1} (\kappa_{j+d} - \kappa_{j+1}) - 1\}$, which is zero because $D_{j+1}^{d-1} = (\kappa_{j+d} - \kappa_{j+1})^{-1}$. Smoothness now follows by a second induction: B_j^1 is continuous, and if every B-spline of degree $d-1$ is C^{d-2} at simple knots, then Eq. 43.2.2 makes B_j^d at least C^{d-2} , while Eq. 43.2.3 makes its derivative a combination of C^{d-2} functions, so $B_j^d \in C^{d-1}$.

- (e) By (d) and (e) each B_j^d belongs to the spline space, which by Theorem 42.3.1 has dimension $d+1+K=m$. Since there are m of them, it is enough to prove independence, and we do so by induction on d . For $d=0$, $m=K+1$ and the B_j^0 are indicators of disjoint intervals. Let $d \geq 1$ and suppose $s = \sum_{j=1}^m c_j B_j^d \equiv 0$ on $[a, b]$. By Eq. 43.2.3, with $c_0 = c_{m+1} = 0$,

$$s' = d \sum_{j=2}^m \frac{c_j - c_{j-1}}{\kappa_{j+d} - \kappa_j} B_j^{d-1}, \quad (43.2.4)$$

the terms $j=1$ and $j=m+1$ having vanished because $\kappa_{1+d} = \kappa_1 = a$ and $\kappa_{m+1+d} = \kappa_{m+1} = b$ for the sequence Eq. 43.2.1. The knots $\kappa_2, \dots, \kappa_{m+d}$ are the clamped sequence of degree $d-1$ for the same K interior knots, and $B_2^{d-1}, \dots, B_m^{d-1}$ are its $K+d=m-1$ B-splines. By the induction hypothesis they are independent, so every $c_j - c_{j-1} = 0$ for $j=2, \dots, m$ (the denominators are positive, since no $d+1$ consecutive knots of Eq. 43.2.1 coincide). Hence all c_j are equal to some c , and $0 = s = c \sum_j B_j^d = c$ on $[a, b]$ by (c). So $c=0$. ■

Idea. Local support is the whole point. Since only $d+1$ B-splines are nonzero at any x , the matrix $\mathbf{B}$ has $d+1$ nonzero entries per row and $\mathbf{B}^\top \mathbf{B}$ is banded of bandwidth d , and moving one coefficient γ_j changes the curve only on $[\kappa_j, \kappa_{j+d+1})$. Neither statement holds for the truncated power basis, where changing the coefficient of $(x - t_1)_+^d$ moves everything to the right of t_1 .

43.2.3 The coefficients live at the Greville abscissae

A spline written in the B-spline basis, $f = \sum_j \gamma_j B_j^d$, has coefficients that are not values of f , but are close to being so, and sit at identifiable places.

Proposition 43.2.2 — Greville abscissae

Let $\xi_j = (\kappa_{j+1} + \dots + \kappa_{j+d})/d$ for $j = 1, \dots, m$, the **Greville abscissae** of the sequence. For [Eq. 43.2.1](#),

$$\sum_{j=1}^m \xi_j B_j^d(x) = x \quad \text{for all } x \in [a, b]. \quad (43.2.5)$$

Consequently $\sum_j (\alpha + \beta \xi_j) B_j^d(x) = \alpha + \beta x$: coefficients that are an affine function of the Greville abscissae produce an affine function of x .

Proof. Let $s(x) = \sum_j \xi_j B_j^d(x)$. Since $\xi_j - \xi_{j-1} = (\kappa_{j+d} - \kappa_j)/d$, [Eq. 43.2.4](#) gives $s'(x) = \sum_{j=2}^m B_j^{d-1}(x) = 1$ on $[a, b]$, by the partition of unity of degree $d-1$ established in the proof of [Proposition 43.2.1\(c\)](#). So $s(x) = x + c$ for a constant c , and s is continuous for $d \geq 2$ (for $d = 1$ the identity is immediate). At $x = a$ only B_1^d is nonzero by [Proposition 43.2.1\(a\)](#), so $B_1^d(a) = 1$ by the partition of unity, and $s(a) = \xi_1 = (\kappa_2 + \dots + \kappa_{d+1})/d = a$. Hence $c = 0$. The second statement follows by adding α times the partition of unity. ■

Remark (A uniform knot sequence). [Eq. 43.2.1](#) is not the only choice. Penalized splines ([Section 43.3](#)) use instead a sequence that continues the equal spacing $\delta = (b-a)/(K+1)$ of the interior knots d steps beyond each end: $a-d\delta, \dots, a-\delta, a, t_1, \dots, t_K, b, b+\delta, \dots, b+d\delta$. There are again $K+2d+2$ knots and $m = K+d+1$ B-splines, and restricted to $[a, b]$ they span the same spline space, so every fitted curve is identical. The advantage is that the Greville abscissae are then equally spaced, $\xi_j = a + \{j - (d+1)/2\}\delta$, consecutive ones δ apart, which is what makes the difference penalty of [Section 43.3](#) behave exactly as advertised. That this sequence too has the partition of unity on $[a, b]$, gives a basis of the spline space there, and satisfies [Eq. 43.2.5](#) is quoted from de Boor (2001, chs. IX–X) — the proofs of (a), (c) and (f) above used the repeated endpoints — and confirmed numerically in [Example \(Two bases for the same space\)](#).

43.2.4 Conditioning

Example. (Two bases for the same space)

Take $n = 300$ design points drawn uniformly on $[0, 1]$, cubic splines ($d = 3$) and $K = 6$ equally spaced interior knots, so the spline space has dimension 10. Least squares in the truncated power basis and least squares in the B-spline basis give fitted values that

Figure 43.2.1: (a) The ten cubic B-splines on $[0, 1]$ with six equally spaced interior knots (vertical lines); the dashed line is their sum (Proposition 43.2.1(c)). (b) A least squares fit in this basis: thin curves $\gamma_j B_j^3$, thick curve their sum, dots the coefficients γ_j at the Greville abscissae of Proposition 43.2.2.

agree to 1.5×10^{-13} , and the uniform sequence of the remark above agrees with the clamped one to 1.8×10^{-15} : three bases, one fit. The condition numbers Definition 1.8.1 of the two design matrices do not agree at all — here 5.3 and 2.1×10^4 . The table shows how they move with the number of knots.

K	$\kappa(\mathbf{B})$, B-spline	κ , truncated power
5	5.3	1.25×10^4
10	5.8	1.08×10^5
20	5.5	1.01×10^6
40	7.4	1.45×10^7

Figure 43.2.1 draws the basis and a fit in it. The B-spline condition number is essentially constant; the truncated power one grows by a decade for every doubling of the knot count, and squaring it to form a cross-product matrix costs twice as many digits again (Section 6.10). At $K = 40$ the truncated power fit has lost most of double precision, the B-spline fit a digit.

The whole recurrence is a dozen lines of numpy.

```

43.2.5 Choosing the knots, and why we shall stop choosing

With a B-spline basis, an unpenalized **regression spline** is ordinary least squares: $\hat{\mathbf{y}} = (\mathbf{B}^\top \mathbf{B})^{-1} \mathbf{B}^\top \mathbf{y}$, with $d+1+K$ parameters and the whole of Parts I–III available for its inference. Nothing is nonparametric about it. The difficulty is the one [Proposition 42.4.1](#) describes: the fit depends on K and on where the knots are, the dependence is not smooth, and the selection machinery of [Chapter 29](#) is then applied to a discrete search whose answer is unstable. Quantile-spaced knots are better than equally spaced ones when the design is uneven, but no placement rule removes the problem: the fit is a step function of K . [Section 43.3](#) takes the opposite route — fix K at more knots than the data can support and control the fit with a penalty — so that a continuous dial takes the place of a discrete one.

43.2.6 Exercises

43.2.6.1 A. Check your understanding

Exercise A1.

For $d = 3$ and $K = 6$ interior knots, write out the clamped knot sequence [Eq. 43.2.1](#) and check that it has $K + 2d + 2$ entries and yields $m = K + d + 1$ B-splines. Which B-splines are nonzero at $x = a$? At the midpoint of $[\kappa_3, \kappa_4]$?

43.2.6.2 B. Practice

Exercise B1.

Using the cell above, verify numerically for $d = 3$, $K = 6$ that $\sum_j B_j^3(x) = 1$, that B_j^3 vanishes outside $[\kappa_j, \kappa_{j+4}]$, that at most four B-splines are nonzero at any point, and that [Eq. 43.2.5](#) holds. Then check [Eq. 43.2.3](#) against a central difference.

Exercise B2.

Show that $\mathbf{B}^\top \mathbf{B}$ has $(\mathbf{B}^\top \mathbf{B})_{jk} = 0$ whenever $|j - k| > d$, and deduce that a Cholesky factorization ([Theorem 10.2.1](#)) of $\mathbf{B}^\top \mathbf{B}$ costs $O(nd^2)$ rather than $O(nm^2)$ operations. Why does the same statement fail for the truncated power basis?

Solution. $(\mathbf{B}^\top \mathbf{B})_{jk} = \sum_i B_j^d(x_i) B_k^d(x_i)$, and the supports $[\kappa_j, \kappa_{j+d+1})$ and $[\kappa_k, \kappa_{k+d+1})$ are disjoint when $|j - k| > d$, so every term is zero. The Cholesky factor of a band matrix inherits its bandwidth. Induct on j in [Eq. 10.2.1](#): if $r_{ki} = 0$ whenever $i - k > d$ for every $k < j$, then for $i - j > d$ each product $r_{kj} r_{ki}$ in the sum vanishes — a nonzero r_{kj} needs $j - k \leq d$, whence $i - k > d$ — and $a_{ji} = 0$, so $r_{ji} = 0$. The factorization of [Theorem 10.2.1](#) therefore visits $O(md^2)$ entries instead of $O(m^3)$, and forming the band of $\mathbf{B}^\top \mathbf{B}$ costs $O(nd^2)$. The truncated power functions have nested, not local, supports — the last is nonzero on $(t_K, b]$ and the first everywhere — so no entry of their cross-product matrix is structurally zero.

43.2.6.3 C. Going deeper

Exercise C1.

Suppose an interior knot is repeated ν times, $1 \leq \nu \leq d + 1$. Show from [Eq. 43.2.3](#), by induction on ν , that the B-splines are $C^{d-\nu}$ there, and that $\nu = d + 1$ allows a jump. How would you use this to fit a curve that is smooth everywhere except at one known breakpoint, where it is only continuous?

Exercise C2.

Prove that $\sum_j \psi_j(y) B_j^d(x) = (y - x)^d$ for all $x \in [a, b]$ and all y , where $\psi_j(y) = (y - \kappa_{j+1}) \cdots (y - \kappa_{j+d})$, for $d = 0$ and $d = 1$. (This is Marsden's identity; the general case is de Boor, 2001, ch. IX. Differentiating it $d - 1$ times in y and setting $y = x$ recovers

Eq. 43.2.5.)

Solution. For $d = 0$ the claim is $\sum_j B_j^0(x) = 1$, the empty product being one. For $d = 1$, $\psi_j(y) = y - \kappa_{j+1}$, and on $[\kappa_i, \kappa_{i+1})$ only B_{i-1}^1 and B_i^1 are nonzero, with values $(\kappa_{i+1} - x)/(\kappa_{i+1} - \kappa_i)$ and $(x - \kappa_i)/(\kappa_{i+1} - \kappa_i)$; their combination is

$$\frac{(y - \kappa_i)(\kappa_{i+1} - x) + (y - \kappa_{i+1})(x - \kappa_i)}{\kappa_{i+1} - \kappa_i} = y - x,$$

after expanding, since the terms in $\kappa_i \kappa_{i+1}$ cancel.

43.3 Penalized splines

The last section ended with a dilemma. A regression spline with few knots is too rigid to follow the data; one with many knots overfits; and the number of knots is a discrete parameter that cannot be tuned gently. The resolution is to stop treating the knots as the control: take *too many* of them — enough that the basis could interpolate — and shrink the coefficients towards a smooth configuration with a quadratic penalty. This is [Definition 30.1.1](#) with a particular penalty, and by [Theorem 27.2.2](#) it is ridge regression in the B-spline basis.

43.3.1 The difference penalty

If the basis is rich, neighbouring B-splines overlap heavily and neighbouring coefficients describe nearly the same part of the curve. A wiggly fit is one whose coefficient sequence $\gamma_1, \dots, \gamma_m$ jumps about, a smooth fit one whose coefficients change slowly with j , so penalizing the differences of the coefficients penalizes roughness — with no integrals to evaluate, since the penalty is a quadratic form whose matrix is known in advance.

Write $\Delta\gamma_j = \gamma_j - \gamma_{j-1}$ and $\Delta^k = \Delta(\Delta^{k-1})$, so that $\Delta^2\gamma_j = \gamma_j - 2\gamma_{j-1} + \gamma_{j-2}$. Let $\mathbf{D}_k$ be the $(m - k) \times m$ matrix with $(\mathbf{D}_k\boldsymbol{\gamma})_j = \Delta^k\gamma_{j+k}$; for $k = 1$ and $k = 2$ its rows are $(\dots, -1, 1, \dots)$ and $(\dots, 1, -2, 1, \dots)$.

Definition 43.3.1 — Penalized spline

Let $\mathbf{B}$ be the B-spline basis matrix of [Definition 43.2.1](#) for K interior knots, equally spaced, with K chosen generously (say 20 to 40, and in any case no more than n). For $\lambda \geq 0$ and an integer $k \geq 1$, the **penalized spline** or **P-spline** estimate is the function $\hat{f} = \sum_j \hat{\gamma}_j B_j^d$ whose coefficients minimize

$$\|\mathbf{y} - \mathbf{B}\boldsymbol{\gamma}\|^2 + \lambda \|\mathbf{D}_k\boldsymbol{\gamma}\|^2 = \|\mathbf{y} - \mathbf{B}\boldsymbol{\gamma}\|^2 + \lambda \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}, \quad \mathbf{P} = \mathbf{D}_k^\top \mathbf{D}_k. \quad (43.3.1)$$

λ is the **smoothing parameter** and k the **order** of the penalty.

This is the construction of Eilers and Marx (1996), who gave it the name P-spline. In the scaling of [Definition 30.1.1](#) the criterion carries a factor $\frac{1}{2}$ and $P(\boldsymbol{\gamma}) = \frac{1}{2}\boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}$; nothing depends on the convention except the numerical value of λ .

Three things have changed since [Section 43.2](#). The number of knots is a computational decision, not a modelling one: take enough. The estimate is no longer a projection, so it has bias even when f lies in the spline space. And the dial is continuous.

43.3.2 The fit, and what the penalty does to it

Lemma 43.3.1 — The two matrices diagonalize together

Suppose $\mathbf{B}$ has full column rank m , and let $\mathbf{P}$ be nonnegative definite. There is a nonsingular $\mathbf{T}$ with $\mathbf{T}^\top \mathbf{B}^\top \mathbf{B} \mathbf{T} = \mathbf{I}$ and $\mathbf{T}^\top \mathbf{P} \mathbf{T} = \text{diag}(e_1, \dots, e_m)$, where $0 \leq e_1 \leq \dots \leq e_m$ and exactly $\text{rank}(\mathbf{P})$ of the e_j are positive. The columns $\mathbf{u}_1, \dots, \mathbf{u}_m$ of $\mathbf{B} \mathbf{T}$ are orthonormal.

Proof. $\mathbf{B}^\top \mathbf{B}$ is positive definite, so [Corollary 1.7.8\(b\)](#) supplies a nonsingular $\mathbf{T}$ with $\mathbf{T}^\top \mathbf{B}^\top \mathbf{B} \mathbf{T} = \mathbf{I}$ and $\mathbf{T}^\top \mathbf{P} \mathbf{T}$ diagonal. Its entries are nonnegative because $\mathbf{P}$ is nonnegative definite, and the number of nonzero ones is $\text{rank}(\mathbf{T}^\top \mathbf{P} \mathbf{T}) = \text{rank}(\mathbf{P})$; permuting the columns of $\mathbf{T}$ puts them in increasing order and preserves both identities. Orthonormality of the columns of $\mathbf{B} \mathbf{T}$ is the statement $(\mathbf{B} \mathbf{T})^\top (\mathbf{B} \mathbf{T}) = \mathbf{I}$. ■

The vectors $\mathbf{u}_j$ are the **Demmler–Reinsch basis** of the smoother. Ordered by e_j , they run from smooth to rough: those with $e_j = 0$ are the shapes the penalty does not see at all.

Proposition 43.3.2 — A P-spline is a ridge regression

Let $\mathbf{B}$ have full column rank and $\lambda > 0$, and write $\mathbf{T}, e_j, \mathbf{u}_j$ as in [Lemma 43.3.1](#).

- (a) $\hat{\boldsymbol{\gamma}} = (\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})^{-1} \mathbf{B}^\top \mathbf{y}$ is the unique minimizer of [Eq. 43.3.1](#), and the fitted vector is $\hat{\mathbf{f}} = \mathbf{S}_\lambda \mathbf{y}$ with

$$\mathbf{S}_\lambda = \mathbf{B}(\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})^{-1} \mathbf{B}^\top = \sum_{j=1}^m \frac{1}{1 + \lambda e_j} \mathbf{u}_j \mathbf{u}_j^\top. \quad (43.3.2)$$

- (b) $\mathbf{S}_\lambda$ is symmetric with eigenvalues $(1 + \lambda e_j)^{-1} \in (0, 1]$ and the same eigenvectors for every λ . Its **effective degrees of freedom** — the count of [Theorem 27.2.2\(b\)](#), now for a roughness penalty —

$$\text{df}(\lambda) = \text{tr}(\mathbf{S}_\lambda) = \sum_{j=1}^m \frac{1}{1 + \lambda e_j} \quad (43.3.3)$$

decrease strictly and continuously from m at $\lambda = 0$ to $m - \text{rank}(\mathbf{P})$ as $\lambda \rightarrow \infty$. For a k th-order difference penalty, $\text{rank}(\mathbf{P}) = m - k$, so the limit is k .

- (c) As $\lambda \rightarrow \infty$, $\mathbf{S}_\lambda$ tends to the orthogonal projection onto $\mathcal{C}\{\mathbf{B} \mathcal{N}(\mathbf{P})\}$, a space of dimension k .

Proof.

- (a) The criterion is $\boldsymbol{\gamma}^\top (\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P}) \boldsymbol{\gamma} - 2 \boldsymbol{\gamma}^\top \mathbf{B}^\top \mathbf{y} + \mathbf{y}^\top \mathbf{y}$, and $\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P}$ is positive

definite because $\mathbf{B}^\top \mathbf{B}$ is and $\mathbf{P}$ is nonnegative definite; Proposition 1.11.2 gives the unique minimizer. In the coordinates $\boldsymbol{\gamma} = \mathbf{T}\boldsymbol{\alpha}$ the criterion becomes $\|\mathbf{y} - \mathbf{B}\mathbf{T}\boldsymbol{\alpha}\|^2 + \lambda \sum_j e_j \alpha_j^2$, and because the columns of $\mathbf{B}\mathbf{T}$ are orthonormal this separates: $\|\mathbf{y}\|^2 - \sum_j \{2\alpha_j \mathbf{u}_j^\top \mathbf{y} - \alpha_j^2(1 + \lambda e_j)\}$ plus the part of $\mathbf{y}$ orthogonal to all the $\mathbf{u}_j$. Minimizing term by term gives $\hat{\alpha}_j = \mathbf{u}_j^\top \mathbf{y} / (1 + \lambda e_j)$ and $\hat{\mathbf{f}} = \sum_j \hat{\alpha}_j \mathbf{u}_j$, which is Eq. 43.3.2.

- (b) The representation Eq. 43.3.2 is a spectral decomposition, since the $\mathbf{u}_j$ are orthonormal; the trace is the sum of the eigenvalues. Each term $(1 + \lambda e_j)^{-1}$ is constant in λ if $e_j = 0$ and strictly decreasing to zero otherwise, and there are $\text{rank}(\mathbf{P})$ of the latter. For the difference penalty, $\mathbf{D}_k$ has $m - k$ rows and full row rank (its leading $(m - k) \times (m - k)$ submatrix is triangular with ± 1 on the diagonal), so $\text{rank}(\mathbf{P}) = \text{rank}(\mathbf{D}_k) = m - k$.
- (c) By Eq. 43.3.2, $\mathbf{S}_\lambda \rightarrow \sum_{j:e_j=0} \mathbf{u}_j \mathbf{u}_j^\top$, the orthogonal projection onto the span of those $\mathbf{u}_j$. Those columns of $\mathbf{B}\mathbf{T}$ are $\mathbf{B}$ times the columns of $\mathbf{T}$ with $\mathbf{T}^\top \mathbf{P}\mathbf{T}$ -entry zero, and $\mathbf{T}^\top \mathbf{P}\mathbf{T}\mathbf{e}_j = 0$ with $\mathbf{T}$ nonsingular means $\mathbf{T}\mathbf{e}_j \in \mathcal{N}(\mathbf{P})$; counting dimensions gives all of $\mathcal{N}(\mathbf{P})$.

■

Idea. Compare Theorem 27.2.2(b). Ridge shrinks the coordinate along the j th singular direction by $d_j^2/(d_j^2 + \lambda)$, and the small singular values are shrunk most. A P-spline shrinks the coordinate along $\mathbf{u}_j$ by $1/(1 + \lambda e_j)$, and the *rough* directions are shrunk most. The difference is only in what the geometry calls “small”: ridge measures size by the design, a smoother measures it by roughness. Both count what is left with a trace.

43.3.3 What survives as the penalty grows

Part (c) says the limit is a projection onto a k -dimensional space. Which one?

Proposition 43.3.3 — The limiting fit

Let $\mathbf{D}_k$ be the k th difference matrix.

- (a) $\mathcal{N}(\mathbf{D}_k) = \{\boldsymbol{\gamma} : \gamma_j = p(j) \text{ for a polynomial } p \text{ of degree } < k\}$, of dimension k .
- (b) For $k = 1$, the limiting fit of Proposition 43.3.2(c) is the constant $\bar{y}$, whatever the knots.
- (c) For $k = 2$ and equally spaced Greville abscissae (Proposition 43.2.2) — the uniform knot sequence of Section 43.2 — the limiting fit is the ordinary least squares line.

Proof.

- (a) If $\gamma_j = p(j)$ with $\deg p < k$ then Δ lowers the degree by one, so $\Delta^k \boldsymbol{\gamma} = 0$. Conversely the set of such $\boldsymbol{\gamma}$ has dimension k (the polynomials $1, j, \dots, j^{k-1}$ restricted to $j = 1, \dots, m$ are independent as long as $m \geq k$), and $\dim \mathcal{N}(\mathbf{D}_k) = m - \text{rank}(\mathbf{D}_k) = k$ by the proof of Proposition 43.3.2(b). Two subspaces of the same dimension, one inside the other, coincide.
- (b) For $k = 1$, $\mathcal{N}(\mathbf{D}_1)$ is spanned by $\mathbf{1}$, and $\mathbf{B}\mathbf{1}$ is the vector of values of $\sum_j B_j^d$, which is $\mathbf{1}$ by Proposition 43.2.1(c). The projection onto $\text{span}\{\mathbf{1}\}$ sends $\mathbf{y}$ to $\bar{y}\mathbf{1}$.

- (c) For $k = 2$, $\mathcal{N}(\mathbf{D}_2)$ is spanned by $\mathbf{1}$ and $\mathbf{j} = (1, \dots, m)^\top$. If the Greville abscissae satisfy $\xi_j = \xi_1 + (j - 1)\delta$, then $\mathbf{j} = \{\mathbf{1}(\delta - \xi_1) + \boldsymbol{\xi}\}/\delta$ with $\boldsymbol{\xi} = (\xi_1, \dots, \xi_m)^\top$, so $\text{span}\{\mathbf{1}, \mathbf{j}\} = \text{span}\{\mathbf{1}, \boldsymbol{\xi}\}$. By [Proposition 43.2.1\(c\)](#) and [Eq. 43.2.5](#), $\mathbf{B}\mathbf{1}$ is the vector of ones and $\mathbf{B}\boldsymbol{\xi}$ is the vector $(x_1, \dots, x_n)^\top$. So $\mathcal{C}\{\mathbf{B}\mathcal{N}(\mathbf{P})\}$ is the column space of $[\mathbf{1}, \mathbf{x}]$, and the projection onto it is the least squares line. ■

Remark (Why the knot sequence matters here and nowhere else). Part (c) is exactly true for the uniform sequence and only approximately true for the clamped sequence [Eq. 43.2.1](#), whose Greville abscissae bunch up near the endpoints. On the Nile data of [Example \(Nile flow, 1871 to 1970\)](#), against a response range of 914, the uniform fit at $\lambda = 10^{12}$ departs from the least squares line by 3.2×10^{-2} — the numerical remainder of a penalty that is large but finite — while the clamped fit departs by 11.4, some 1.2 per cent of that range: visually almost nothing, but not the line. Since the two sequences span the same functions, the choice affects only what “the penalty is zero” means. For $k \geq 3$ the limiting space is a k -dimensional space of splines containing the straight lines, and consists exactly of the polynomials of degree $k - 1$ when the knots are equally spaced (Eilers and Marx, 1996; de Boor, 2001, ch. IX), a fact we use but do not prove.

43.3.4 Knots stop mattering

Example. (Nile flow, 1871 to 1970)

The annual flow of the Nile at Aswan was recorded for 100 years from 1871 to 1970. Rescale the year to $[0, 1]$ and fit cubic P-splines with a second-order penalty. Reaching 3, 8 and 20 effective degrees of freedom needs $\lambda = 9.1 \times 10^2$, 4.7×10^0 and 1.5×10^{-2} : five orders of magnitude for a threefold change in df, which is why λ is searched on a logarithmic scale and reported as df.

Now hold df at 8 and change the number of knots. With $K = 10, 20, 40$ and 80 — the last giving 84 coefficients for 100 observations — the four curves differ nowhere by more than 16.60, or 1.82 per cent of the response range, and the $K = 40$ and $K = 80$ curves by at most 1.373. Without the penalty the same knot counts give curves differing by up to 258.2, fifteen times as much.

[Figure 43.3.1](#) draws both comparisons. The fitted curve descends steeply around 1900, and it is worth saying what a smoother does and does not know: the historical record is of an abrupt change, and a smoother with a second-order penalty cannot represent a jump. It renders one as a steep smooth descent and reports no lack of fit ([Theorem 14.6.2](#) would, if the design had replicates). Smoothness is an assumption, and like every assumption in this book it buys precision by excluding something.

```

43.3.5 Choices that remain

How many knots. Enough that adding more changes nothing, which [Example \(Nile flow, 1871 to 1970\)](#) suggests is a few dozen; Ruppert's rule of thumb is $K = \min(n/4, 35)$, and by [Exercise \(B2\)](#) generosity is cheap.

The degree. Cubic ($d = 3$) throughout; higher degrees buy nothing once a penalty is present.

The order of the penalty. $k = 2$ is the default, because its null space is the straight lines: when the data say there is no curvature, the fit degrades to the linear model of Part II rather than to a horizontal line ($k = 1$) or a parabola ($k = 3$). The order also fixes the behaviour *beyond* the data, where the penalty is all there is: a k th-order penalty extrapolates as a polynomial of degree $k - 1$, one more reason to distrust an extrapolated smooth ([Proposition 42.1.1](#)).

The smoothing parameter. [Section 43.5](#).

Remark (Derivative penalties). A different penalty measures roughness by an integral, $\int_a^b \{f''(t)\}^2 dt = \boldsymbol{\gamma}^\top \boldsymbol{\Omega} \boldsymbol{\gamma}$ with $\Omega_{jk} = \int B_j'' B_k''$, computable exactly from [Eq. 43.2.3](#) and Gauss–Legendre quadrature and banded for the same reason $\mathbf{B}^\top \mathbf{B}$ is. This is the O'Sullivan (1986) penalty, and it makes the P-spline a finite-dimensional version of the smoothing spline of the next section; Wand and Ormerod (2008) show that for equally spaced knots [Definition 43.3.1](#)'s penalty is a difference approximation to it, which is why the two fits look identical. The difference penalty is simpler to state and easier to generalize — nothing in [Eq. 43.3.1](#) mentions an integral — and is the one used in [Chapter 44](#).

43.3.6 Exercises

43.3.6.1 A. Check your understanding

Exercise A1.

Using [Eq. 43.3.3](#), sketch $\text{df}(\lambda)$ against $\log \lambda$ for $m = 24$ and a second-order penalty. What are the two horizontal asymptotes, and why is $\log \lambda$ the right scale for the horizontal axis?

43.3.6.2 B. Practice

Exercise B1.

A model with 8 parameters uses 8 degrees of freedom; a P-spline at $\text{df}(\lambda) = 8$ uses 24 parameters. Explain, using [Eq. 43.3.2](#), in what sense the two are comparable, and show that $\text{tr}(\mathbf{S}_\lambda \mathbf{S}_\lambda^\top) \leq \text{tr}(\mathbf{S}_\lambda)$ with equality only when $\mathbf{S}_\lambda$ is a projection. (Both traces are used as degrees of freedom in the literature; see [Section 43.5](#).)

Solution. By [Eq. 43.3.2](#), $\mathbf{S}_\lambda$ has eigenvalues $s_j = (1 + \lambda e_j)^{-1} \in (0, 1]$, so $\text{tr}(\mathbf{S}_\lambda) = \sum_j s_j$ and $\text{tr}(\mathbf{S}_\lambda \mathbf{S}_\lambda^\top) = \sum_j s_j^2 \leq \sum_j s_j$, with equality iff every $s_j \in \{0, 1\}$, that is iff $\mathbf{S}_\lambda$ is a projection ([Theorem 6.3.3](#)). A least squares fit on p columns has p eigenvalues equal to one; a smoother spreads the same total over more directions, using each only partly. This is the covariance-penalty degrees of freedom [Definition 29.1.2](#) applied to a linear rule.

Exercise B2.

Show that the P-spline criterion [Eq. 43.3.1](#) is [Theorem 29.3.2](#)'s criterion $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \mathbf{b}^\top \boldsymbol{\Omega} \mathbf{b}$ with $\mathbf{X} = \mathbf{B}$ and $\boldsymbol{\Omega} = \lambda \mathbf{P}$, and conclude that the leave-one-out shortcut $(y_i - \hat{f}(x_i))/(1 - s_{ii})$ is exact for a P-spline. What changes if the knots are chosen by looking at the data first?

43.3.6.3 C. Going deeper

Exercise C1.

Compute the Demmler–Reinsch basis of [Lemma 43.3.1](#) for a cubic P-spline with $K = 20$, $k = 2$, on 100 equally spaced design points, and plot $\mathbf{u}_1, \mathbf{u}_2, \mathbf{u}_5, \mathbf{u}_{10}$ against x . Confirm that $e_1 = e_2 = 0$ and that the corresponding $\mathbf{u}_j$ span the constant and linear functions, and that $\mathbf{u}_j$ crosses zero more often as e_j grows. Relate the picture to [Eq. 43.3.2](#): which shapes survive a large λ ?

Exercise C2.

[Proposition 43.3.2](#) assumes $\mathbf{B}$ has full column rank, which fails if some knot interval contains no design point. Show that the minimizer of [Eq. 43.3.1](#) is still unique provided $\mathcal{N}(\mathbf{B}) \cap \mathcal{N}(\mathbf{P}) = \{\mathbf{0}\}$, and give an example with K large and a gap in the design where

this fails for $k = 1$ but holds for $k = 2 \dots$ or show that it cannot fail for $k = 2$ either. (Hint: [Theorem 30.1.1\(c\)](#), and the fact that $\mathcal{N}(\mathbf{P}) = \mathcal{N}(\mathbf{D}_k)$.)

Solution. $\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P}$ is nonnegative definite, and $\boldsymbol{\gamma}^\top (\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P}) \boldsymbol{\gamma} = 0$ forces $\mathbf{B} \boldsymbol{\gamma} = \mathbf{0}$ and $\mathbf{D}_k \boldsymbol{\gamma} = \mathbf{0}$; so the matrix is positive definite, and the minimizer unique, exactly when the two null spaces meet only at zero. This is [Theorem 30.1.1\(c\)](#) with a strictly convex penalty on the relevant subspace. For $k = 2$, $\boldsymbol{\gamma} \in \mathcal{N}(\mathbf{D}_2)$ means $\gamma_j = \alpha + \beta j$, and by [Proposition 43.3.3\(c\)](#) the corresponding function is $\alpha' + \beta' x$ with $\beta' \propto \beta$; such a function vanishes at all $n \geq 2$ distinct design points only if $\alpha' = \beta' = 0$. So the intersection is trivial for $k = 2$ whatever the gaps, and the fit is always unique. For $k = 1$ the same argument with constants gives the same conclusion. The moral is that a penalty repairs rank deficiency exactly on its own null space — which is why a generous K is safe.

Exercise C3.

Assume $E(\mathbf{Y}) = \mathbf{f}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$. Using [Eq. 43.3.2](#), show that

$$E\|\hat{\mathbf{f}} - \mathbf{f}\|^2 = \sum_j \left(\frac{\lambda e_j}{1 + \lambda e_j} \right)^2 (\mathbf{u}_j^\top \mathbf{f})^2 + \sigma^2 \sum_j \frac{1}{(1 + \lambda e_j)^2} + \|(\mathbf{I} - \mathbf{U}\mathbf{U}^\top)\mathbf{f}\|^2,$$

where $\mathbf{U} = [\mathbf{u}_1, \dots, \mathbf{u}_m]$. Identify the three terms, and say which of them no choice of λ can reduce.

Solution. Write $\mathbf{f} = \mathbf{U}\mathbf{U}^\top \mathbf{f} + (\mathbf{I} - \mathbf{U}\mathbf{U}^\top)\mathbf{f}$. Since $\mathbf{S}_\lambda = \mathbf{U} \text{diag}(s_j) \mathbf{U}^\top$ with $s_j = (1 + \lambda e_j)^{-1}$, $\hat{\mathbf{f}} - \mathbf{f} = \mathbf{U}\{\text{diag}(s_j)\mathbf{U}^\top(\mathbf{f} + \boldsymbol{\varepsilon}) - \mathbf{U}^\top \mathbf{f}\} - (\mathbf{I} - \mathbf{U}\mathbf{U}^\top)\mathbf{f}$, and the three pieces are orthogonal in expectation. The first sum is the squared shrinkage bias, $(s_j - 1)\mathbf{u}_j^\top \mathbf{f} = -\lambda e_j \mathbf{u}_j^\top \mathbf{f} / (1 + \lambda e_j)$; the second the variance $\sigma^2 \sum_j s_j^2$; the third the *approximation* error, the part of $\mathbf{f}$ outside the spline space, which does not involve λ . Only a richer basis reduces it, which is the argument for a generous K .

43.4 Smoothing splines

A P-spline starts from a basis and adds a penalty to it. The smoothing spline does the opposite: it asks a question about functions, with no basis in sight — among *all* twice-differentiable functions, which balances fit against roughness best? — and the answer turns out to be a spline, by the shortest and most satisfying derivation in the subject.

43.4.1 The variational problem

Measure the roughness of a function by $\int_a^b \{f''(t)\}^2 dt$: zero exactly for straight lines, large for a function that turns sharply, and, unlike the number of knots, defined for every function smooth enough to have it. Let

$$\mathcal{W} = \left\{ f : [a, b] \rightarrow \mathbb{R} \mid f' \text{ is absolutely continuous and } \int_a^b \{f''(t)\}^2 dt < \infty \right\}$$

be the set of such functions, and consider

$$S_\lambda(f) = \sum_{i=1}^n \{y_i - f(x_i)\}^2 + \lambda \int_a^b \{f''(t)\}^2 dt, \quad \lambda > 0. \quad (43.4.1)$$

Take the design points distinct and ordered, $a \leq x_1 < \cdots < x_n \leq b$. (If some coincide, replace each group by its mean with a weight equal to its size; [Exercise \(B1\)](#) checks that this changes nothing.)

The two extremes are clear. As $\lambda \rightarrow 0$ the criterion is minimized by any function through the data, so the problem is ill-posed without the penalty; as $\lambda \rightarrow \infty$ the penalty forces $f'' \equiv 0$ and the minimizer is the least squares line. In between the minimizer is some compromise between an interpolating curve and a line, and it is not obvious in advance that it is finite-dimensional.

Definition 43.4.1 — Natural cubic spline

A **natural cubic spline** with knots $x_1 < \cdots < x_n$ is a function $g : [a, b] \rightarrow \mathbb{R}$ that is a cubic polynomial on each $[x_i, x_{i+1}]$, has two continuous derivatives on $[a, b]$, and is linear on $[a, x_1]$ and on $[x_n, b]$. Equivalently: on $[x_1, x_n]$, g is a cubic spline with interior knots $x_2, \dots, x_{n-1}$ satisfying the **natural boundary conditions** $g''(x_1) = g''(x_n) = 0$, extended to $[a, b]$ by its tangent lines at x_1 and x_n . (The two conditions are exactly what makes the extension C^2 .)

43.4.2 Interpolation with the least roughness

Everything follows from one integration by parts.

Lemma 43.4.1 — The natural interpolant, and why it is the smoothest

Let $n \geq 2$ and $x_1 < \cdots < x_n$.

- (a) If g is a natural cubic spline with these knots and $h \in \mathcal{W}$ satisfies $h(x_i) = 0$ for every i , then $\int_a^b g'' h'' = 0$.
- (b) For every $\mathbf{z} \in \mathbb{R}^n$ there is exactly one natural cubic spline g with $g(x_i) = z_i$; the space of natural cubic splines with these knots has dimension n .
- (c) That g is the unique minimizer of $\int_a^b f'^2$ among all $f \in \mathcal{W}$ with $f(x_i) = z_i$.

Proof.

- (a) Integrating by parts, $\int_a^b g'' h'' = [g'' h']_a^b - \int_a^b g''' h'$. The boundary term vanishes because g is linear near a and b , so $g''(a) = g''(b) = 0$. On $[a, x_1]$ and $[x_n, b]$ we have $g''' = 0$, and on (x_i, x_{i+1}) the third derivative of a cubic is a constant c_i . Hence

$$\int_a^b g''' h' = \sum_{i=1}^{n-1} c_i \int_{x_i}^{x_{i+1}} h' = \sum_{i=1}^{n-1} c_i \{h(x_{i+1}) - h(x_i)\} = 0.$$

- (b) A cubic spline on $[x_1, x_n]$ with the $n - 2$ interior knots $x_2, \dots, x_{n-1}$ lives in a space of dimension $4 + (n - 2) = n + 2$ ([Theorem 42.3.1](#) with $d = 3$), and extending

it linearly outside is determined once $g''(x_1) = g''(x_n) = 0$. Those are two linear constraints, so the natural cubic splines form a space of dimension at least n . The evaluation map $g \mapsto \{g(x_1), \dots, g(x_n)\}$ is linear into $\mathbb{R}^n$; if g is in its kernel, apply (a) with $h = g$ to get $\int_a^b g''^2 = 0$, so $g'' \equiv 0$ and g is linear, and a line vanishing at $n \geq 2$ distinct points is zero. The map is therefore injective, so the dimension is at most n and hence exactly n , and the map is a bijection.

- (c) Let $f \in \mathcal{W}$ interpolate $\mathbf{z}$ and put $h = f - g$, so $h(x_i) = 0$. By (a) the cross term vanishes, leaving

$$\int_a^b f''^2 = \int_a^b g''^2 + 2 \int_a^b g'' h'' + \int_a^b h''^2 = \int_a^b g''^2 + \int_a^b h''^2,$$

which is at least $\int_a^b g''^2$, with equality iff $h'' \equiv 0$, that is iff h is linear; and a line vanishing at $n \geq 2$ points is zero. ■

Theorem 43.4.2 — The smoothing spline

Let $\lambda > 0$ and $n \geq 2$ distinct design points. Then S_λ of Eq. 43.4.1 has a unique minimizer over $\mathcal{W}$, and it is the natural cubic spline with knots at $x_1, \dots, x_n$ whose vector of values is

$$\hat{\mathbf{f}} = (\mathbf{I} + \lambda \mathbf{P})^{-1} \mathbf{y}, \quad (43.4.2)$$

where $\mathbf{P}$ is the nonnegative definite matrix representing the roughness, $\int_a^b g''^2 = \mathbf{z}^\top \mathbf{P} \mathbf{z}$, of the natural cubic spline with values $\mathbf{z}$.

Proof. Let $f \in \mathcal{W}$ be arbitrary and let g be the natural cubic spline with $g(x_i) = f(x_i)$, which exists and is unique by Lemma 43.4.1(b). The two functions have the same residual sum of squares, and by Lemma 43.4.1(c) the penalty of g is no larger, strictly smaller unless $f = g$. Hence $S_\lambda(g) \leq S_\lambda(f)$ with equality only if $f = g$, and it suffices to minimize over the n -dimensional space of natural cubic splines.

Parameterize that space by $\mathbf{z} \in \mathbb{R}^n$ through the bijection of Lemma 43.4.1(b). Since g depends linearly on $\mathbf{z}$, so does g'' , and the penalty $\int_a^b g''^2$ is a quadratic form $\mathbf{z}^\top \mathbf{P} \mathbf{z}$ with $\mathbf{P}$ symmetric and nonnegative definite. Eq. 43.4.1 becomes $\|\mathbf{y} - \mathbf{z}\|^2 + \lambda \mathbf{z}^\top \mathbf{P} \mathbf{z}$, a strictly convex quadratic in $\mathbf{z}$ because $\mathbf{I} + \lambda \mathbf{P}$ is positive definite; by Proposition 1.11.2 its unique minimizer is Eq. 43.4.2. ■

Idea. The theorem is a *representer* result: an optimization over an infinite-dimensional space of functions has a finite-dimensional solution, with one basis function per observation. The reason is the orthogonality in Lemma 43.4.1(a): any direction in which f differs from a natural spline without changing the fit costs roughness and buys nothing. Kimeldorf and Wahba (1971) proved the general version; see the notes.

43.4.3 The Reinsch algorithm

The proof used $\mathbf{P}$ without exhibiting it. Doing so turns Eq. 43.4.2, an $n \times n$ dense solve, into a banded one.

Proposition 43.4.3 — Band matrices for the roughness

Let $h_i = x_{i+1} - x_i$ for $i = 1, \dots, n-1$, and let $n \geq 3$. Define $\mathbf{Q}$, of size $n \times (n-2)$, and $\mathbf{R}$, symmetric tridiagonal of order $n-2$, by

$$q_{j-1,j} = \frac{1}{h_{j-1}}, \quad q_{j,j} = -\frac{1}{h_{j-1}} - \frac{1}{h_j}, \quad q_{j+1,j} = \frac{1}{h_j},$$

$$r_{jj} = \frac{h_{j-1} + h_j}{3}, \quad r_{j,j+1} = r_{j+1,j} = \frac{h_j}{6},$$

for $j = 2, \dots, n-1$ (columns and rows indexed by the interior knots), all other entries zero. Then:

- (a) $\mathbf{R}$ is positive definite.
- (b) If g is the natural cubic spline with values $\mathbf{z}$ and $\boldsymbol{\gamma} = \{g''(x_2), \dots, g''(x_{n-1})\}^\top$, then $\mathbf{R}\boldsymbol{\gamma} = \mathbf{Q}^\top \mathbf{z}$ and $\int_a^b g''^2 = \boldsymbol{\gamma}^\top \mathbf{R}\boldsymbol{\gamma}$, so that $\mathbf{P} = \mathbf{Q}\mathbf{R}^{-1}\mathbf{Q}^\top$.
- (c) The fit of Theorem 43.4.2 satisfies

$$(\mathbf{R} + \lambda \mathbf{Q}^\top \mathbf{Q}) \hat{\boldsymbol{\gamma}} = \mathbf{Q}^\top \mathbf{y}, \quad \hat{\mathbf{f}} = \mathbf{y} - \lambda \mathbf{Q}\hat{\boldsymbol{\gamma}}, \quad (43.4.3)$$

and $\mathbf{R} + \lambda \mathbf{Q}^\top \mathbf{Q}$ has bandwidth two, so the fit costs $O(n)$ operations.

Proof.

- (a) $\mathbf{R}$ is symmetric with positive diagonal, and $r_{j,j-1} + r_{j,j+1} = (h_{j-1} + h_j)/6 < r_{jj}$, so it is strictly diagonally dominant and therefore positive definite.
- (b) On $[x_j, x_{j+1}]$, g'' is linear with endpoint values γ_j and γ_{j+1} (setting $\gamma_1 = \gamma_n = 0$). Writing $u = t - x_j$ and integrating twice,

$$g(x_j + u) = z_j + g'(x_j)u + \frac{1}{2}\gamma_j u^2 + \frac{\gamma_{j+1} - \gamma_j}{6h_j} u^3.$$

Setting $u = h_j$ and solving for $g'(x_j)$ gives $g'(x_j) = (z_{j+1} - z_j)/h_j - h_j(2\gamma_j + \gamma_{j+1})/6$, and differentiating at $u = h_j$,

$$g'(x_{j+1}^-) = \frac{z_{j+1} - z_j}{h_j} + \frac{h_j(\gamma_j + 2\gamma_{j+1})}{6}.$$

Equating this with $g'(x_{j+1}^+)$, read off the interval $[x_{j+1}, x_{j+2}]$, and writing $i = j+1$,

$$\frac{z_{i+1} - z_i}{h_i} - \frac{z_i - z_{i-1}}{h_{i-1}} = \frac{h_{i-1}\gamma_{i-1} + 2(h_{i-1} + h_i)\gamma_i + h_i\gamma_{i+1}}{6},$$

which is $(\mathbf{Q}^\top \mathbf{z})_i = (\mathbf{R}\boldsymbol{\gamma})_i$. For the penalty, $\int_{x_j}^{x_{j+1}} g''^2 = h_j(\gamma_j^2 + \gamma_j\gamma_{j+1} + \gamma_{j+1}^2)/3$ by direct integration of a linear function squared, and summing over j reproduces $\boldsymbol{\gamma}^\top \mathbf{R}\boldsymbol{\gamma}$ term by term. Since $\boldsymbol{\gamma} = \mathbf{R}^{-1}\mathbf{Q}^\top \mathbf{z}$, the penalty is $\mathbf{z}^\top \mathbf{Q}\mathbf{R}^{-1}\mathbf{Q}^\top \mathbf{z}$.

Figure 43.4.1: (a) Smoothing splines at three values of λ , labelled by effective degrees of freedom. (b) Three rows of $\mathbf{S}_\lambda$ at $\text{df} = 9$, the weights producing $\hat{f}(x)$ at $x = 0.02, 0.29$ and 0.62 : local, summing to one, slightly negative beside the peak.

- (c) Put $\boldsymbol{\gamma} = \mathbf{R}^{-1}\mathbf{Q}^\top \hat{\mathbf{f}}$. From Eq. 43.4.2, $\hat{\mathbf{f}} + \lambda\mathbf{Q}\boldsymbol{\gamma} = \mathbf{y}$, and multiplying by $\mathbf{Q}^\top$ and using $\mathbf{R}\boldsymbol{\gamma} = \mathbf{Q}^\top \hat{\mathbf{f}}$ gives $\mathbf{R}\boldsymbol{\gamma} = \mathbf{Q}^\top \mathbf{y} - \lambda\mathbf{Q}^\top \mathbf{Q}\boldsymbol{\gamma}$, which is Eq. 43.4.3. $\mathbf{R}$ is tridiagonal and $\mathbf{Q}$ has three nonzero entries per column in consecutive rows, so $\mathbf{R} + \lambda\mathbf{Q}^\top \mathbf{Q}$ has bandwidth two. A Cholesky factor inherits the bandwidth: in Eq. 10.2.1, if $r_{ki} = 0$ whenever $i - k > 2$ for every $k < j$, then for $i - j > 2$ every product $r_{kj}r_{ki}$ in the sum vanishes (a nonzero r_{kj} needs $j - k \leq 2$, whence $i - k > 2$) and so does a_{ji} , so $r_{ji} = 0$. The factorization of Theorem 10.2.1 therefore visits $O(n)$ entries instead of $O(n^3)$, and so do the two multiplications by $\mathbf{Q}$.

■

Reinsch (1967) gave this algorithm before the variational theorem was widely known; it is why smoothing splines remain the cheapest smoother for a single covariate. Nothing in it forms $\mathbf{S}_\lambda = (\mathbf{I} + \lambda\mathbf{P})^{-1}$, which is dense; the diagonal of $\mathbf{S}_\lambda$, needed for cross-validation in Section 43.5, can also be got in $O(n)$ from a banded inverse (Hutchinson and de Hoog, 1985).

Example. (A smoothing spline, checked three ways)

Take $n = 120$ design points drawn uniformly on $[0, 1]$ and the mean function of Example (Bias, variance and the optimal bandwidth) with $\sigma = 0.25$. At $\lambda = 1 \times 10^{-4}$ the fit uses 12.32 effective degrees of freedom. Three independent computations agree with it. The roughness $\boldsymbol{\gamma}^\top \mathbf{R}\boldsymbol{\gamma}$ of the natural spline interpolating the true curve, 1069.5, matches $\int_a^b g''^2$ from a separately constructed natural cubic interpolant to a relative error of 1.6×10^{-12} ; the banded solve Eq. 43.4.3 agrees with the dense form Eq. 43.4.2 to 1.3×10^{-10} ; and minimizing $\|\mathbf{y} - \mathbf{B}\boldsymbol{\gamma}\|^2 + \lambda\boldsymbol{\gamma}^\top \boldsymbol{\Omega}\boldsymbol{\gamma}$ over the *whole* space of cubic splines with a knot at every design point — dimension 122, with $\boldsymbol{\Omega}_{jk} = \int B_j'' B_k''$ computed exactly — gives fitted values differing from the smoothing spline by 4.4×10^{-10} . That is Theorem 43.4.2 in numerical form: the minimizer over the larger space is the natural spline.

43.4.4 Variations, and the relation to penalized splines

Other orders. Replacing f'' by $f^{(m)}$ in Eq. 43.4.1 gives a **natural spline of degree $2m-1$** : the proof of Lemma 43.4.1 goes through with m integrations by parts and the boundary conditions $f^{(j)}(x_1) = f^{(j)}(x_n) = 0$ for $j = m, \dots, 2m-2$. The case $m = 1$ gives a piecewise linear fit, $m = 2$ the cubic one above, $m = 3$ a quintic. In practice $m = 2$ is used almost always; the extra

smoothness of $m = 3$ rarely shows.

Reproducing kernels. The penalty $\int f''^2$ is the squared norm of the part of f orthogonal to the straight lines, in a Hilbert space of functions in which evaluation $f \mapsto f(x)$ is a bounded linear functional and so representable as an inner product with a function R_x , the *reproducing kernel*. In that language [Theorem 43.4.2](#) is a special case of the representer theorem of Kimeldorf and Wahba (1971): the minimizer of $\sum_i \{y_i - f(x_i)\}^2 + \lambda \|Pf\|^2$ lies in the span of $R_{x_1}, \dots, R_{x_n}$ plus the null space of P . That is the route of Wahba (1990), and it covers thin-plate splines, splines on a sphere and the kernel methods of machine learning. This book does not develop it; the proof above is self-contained for a single covariate.

Smoothing splines and P-splines. A smoothing spline is a penalized spline with a knot at every distinct design point and the exact derivative penalty, as [Example \(A smoothing spline, checked three ways\)](#) confirms numerically, and a P-spline with $K = 20$ knots is a *low-rank* approximation to it: both fits are determined, through [Eq. 43.3.2](#), by how the penalty ranks a handful of smooth directions, so the two agree once m comfortably exceeds the effective degrees of freedom. The smoothing spline has no knot choice and costs $O(n)$; the P-spline carries an explicit coefficient vector and generalizes to several covariates and to non-normal responses, which is why [Chapter 44](#) uses it.

Remark (The equivalent kernel of a smoothing spline). Panel (b) of [Figure 43.4.1](#) shows the rows of $\mathbf{S}_\lambda$, the smoothing spline's equivalent kernel in the sense of [Section 43.1](#). Silverman (1984) proved that at an interior point, for large n and small λ , the weight given to a design point at distance u is approximately $\{nb(x)g(x)\}^{-1} \frac{1}{2} \exp(-|v|/\sqrt{2}) \sin(|v|/\sqrt{2} + \pi/4)$ with $v = u/b(x)$ and local bandwidth $b(x) = \{\lambda/(ng(x))\}^{1/4}$. Two features of that formula show in the picture: the weights decay exponentially, and the sine makes them change sign, so a smoothing spline is a kernel smoother with a small negative side lobe — here the most negative weight is -0.0034 against a peak of 0.0778 . The bandwidth adapts to the design density by itself, as $g(x)^{-1/4}$. We state this without proof; the argument is a Green's-function calculation.

43.4.5 Exercises

43.4.5.1 A. Check your understanding

Exercise A1.

Show directly from [Eq. 43.4.3](#) that $\hat{\mathbf{f}} \rightarrow \mathbf{y}$ as $\lambda \rightarrow 0$ and that $\hat{\mathbf{f}}$ tends to the least squares line as $\lambda \rightarrow \infty$. (For the second, use [Proposition 43.4.3\(b\)](#): what does $\mathbf{Q}^\top \mathbf{z} = \mathbf{0}$ say about $\mathbf{z}$?)

Solution. As $\lambda \rightarrow 0$, [Eq. 43.4.3](#) gives $\hat{\mathbf{y}} \rightarrow \mathbf{R}^{-1} \mathbf{Q}^\top \mathbf{y}$, bounded, so $\hat{\mathbf{f}} = \mathbf{y} - \lambda \mathbf{Q} \hat{\mathbf{y}} \rightarrow \mathbf{y}$. As $\lambda \rightarrow \infty$, the penalty $\mathbf{z}^\top \mathbf{P} \mathbf{z}$ must tend to zero, and $\mathbf{P} = \mathbf{Q} \mathbf{R}^{-1} \mathbf{Q}^\top$ with $\mathbf{R}$ positive definite, so $\mathbf{Q}^\top \mathbf{z} \rightarrow \mathbf{0}$. Now $(\mathbf{Q}^\top \mathbf{z})_i$ is a second divided difference of $\mathbf{z}$ at x_{i-1}, x_i, x_{i+1} , and it vanishes for all i exactly when the points (x_i, z_i) are collinear. So the limit lies in the two-dimensional space $\mathcal{C}([1, \mathbf{x}])$, and since the residual sum of squares is still being minimized there, it is the least squares line.

43.4.5.2 B. Practice

Exercise B1.

Suppose the design has ties: the distinct values are $t_1 < \dots < t_N$ and n_k observations share t_k , with mean $\bar{y}_k$. Show that $\sum_i \{y_i - f(x_i)\}^2 = \sum_k n_k \{\bar{y}_k - f(t_k)\}^2 + C$ with C free of f , so that [Theorem 43.4.2](#) holds with knots at the distinct values and $\mathbf{I}$ replaced by $\text{diag}(n_1, \dots, n_N)$ in [Eq. 43.4.2](#).

Exercise B2.

Using the cell above, build $\mathbf{Q}$ and $\mathbf{R}$ for $n = 8$ equally spaced points on $[0, 1]$ and verify by hand that $\mathbf{R}$ is tridiagonal with $r_{jj} = 2h/3$ and $r_{j,j+1} = h/6$, and that $\mathbf{Q}^\top \mathbf{1} = \mathbf{0}$ and $\mathbf{Q}^\top \mathbf{x} = \mathbf{0}$. What does the second pair of identities say about $\mathbf{S}_\lambda \mathbf{1}$ and $\mathbf{S}_\lambda \mathbf{x}$?

43.4.5.3 C. Going deeper**Exercise C1.**

State and prove the analogue of [Lemma 43.4.1\(a\)](#) for the penalty $\int_a^b \{f^{(m)}\}^2$, with g a natural spline of degree $2m - 1$. Which boundary conditions are needed to kill the boundary terms after m integrations by parts, and what replaces “a line vanishing at $n \geq 2$ points is zero”?

Exercise C2.

Show that if $\lambda > 0$ then $\hat{f}$ never interpolates the data unless the data already lie on a straight line. (Use [Eq. 43.4.2](#) and the fact that $\mathbf{P}\mathbf{z} = \mathbf{0}$ iff $\mathbf{z} \in \mathcal{C}([\mathbf{1}, \mathbf{x}])$, which [Exercise \(A1\)](#) establishes.) Contrast this with a regression spline with $K = n - 4$ knots, and say what the difference means for the leave-one-out shortcut of [Theorem 29.3.2](#).

Solution. $\hat{\mathbf{f}} = \mathbf{y}$ requires $(\mathbf{I} + \lambda \mathbf{P})\mathbf{y} = \mathbf{y}$, that is $\mathbf{P}\mathbf{y} = \mathbf{0}$, that is $\mathbf{y}$ in $\mathcal{C}([\mathbf{1}, \mathbf{x}])$. So for $\lambda > 0$ the fit leaves a nonzero residual unless the data are exactly linear, and every s_{ii} is strictly less than one, which is what makes the shortcut of [Theorem 29.3.2](#) well defined. An unpenalized regression spline with n basis functions interpolates, every $s_{ii} = 1$, the shortcut divides by zero, and cross-validation is useless — one more reason the dial should be a penalty and not a knot count.

43.5 Choosing the smoothing parameter

Four smoothers have appeared: the local constant and local linear estimators of [Section 43.1](#), the penalized spline of [Section 43.3](#) and the smoothing spline of [Section 43.4](#). Each is linear in $\mathbf{y}$, each has one dial, and none has said how to set it. The rules of this section approximate a risk that cannot be observed: they agree when the sample is large and the errors independent, and fail in recognisably different ways when it is not.

43.5.1 Every smoother here is a linear operator

Proposition 43.5.1 — Linear smoothers

Call $\hat{\mathbf{f}} = \mathbf{S}\mathbf{y}$ a **linear smoother** with **smoother matrix** $\mathbf{S}$ when $\mathbf{S}$ does not depend on $\mathbf{y}$. The estimators of [Definition 43.1.1](#), [Definition 43.3.1](#) and [Theorem 43.4.2](#) are linear smoothers, with $\mathbf{S}$ given by [Eq. 43.1.4](#), [Eq. 43.3.2](#) and [Eq. 43.4.2](#). Suppose $E(\mathbf{Y}) = \mathbf{f}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$. Then:

- (a) (*Moments.*) $E(\hat{\mathbf{f}}) = \mathbf{S}\mathbf{f}$, $\text{Cov}(\hat{\mathbf{f}}) = \sigma^2 \mathbf{S}\mathbf{S}^\top$, and

$$E\|\hat{\mathbf{f}} - \mathbf{f}\|^2 = \|(\mathbf{I} - \mathbf{S})\mathbf{f}\|^2 + \sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top). \quad (43.5.1)$$

- (b) (*Residuals.*) $E\|\mathbf{y} - \hat{\mathbf{f}}\|^2 = \|(\mathbf{I} - \mathbf{S})\mathbf{f}\|^2 + \sigma^2\{n - 2\text{tr}(\mathbf{S}) + \text{tr}(\mathbf{S}\mathbf{S}^\top)\}$, so

$$\hat{\sigma}^2 = \frac{\|\mathbf{y} - \hat{\mathbf{f}}\|^2}{n - 2\text{tr}(\mathbf{S}) + \text{tr}(\mathbf{S}\mathbf{S}^\top)} \quad (43.5.2)$$

is unbiased for σ^2 when the bias term is negligible.

- (c) (*Degrees of freedom.*) If $\mathbf{S}$ is symmetric with eigenvalues in $[0, 1]$ — as it is for a penalized or smoothing spline, by [Proposition 43.3.2\(b\)](#) — then $\text{tr}(\mathbf{S}\mathbf{S}^\top) \leq \text{tr}(\mathbf{S}) \leq 2\text{tr}(\mathbf{S}) - \text{tr}(\mathbf{S}\mathbf{S}^\top)$, with equality throughout iff $\mathbf{S}$ is an orthogonal projection, in which case all three equal its rank.
- (d) (*Shrinkage.*) For a penalized spline, [Eq. 43.3.2](#) writes $\mathbf{S}_\lambda$ in the Demmler–Reinsch basis as a diagonal shrinkage $\mathbf{u}_j^\top \mathbf{y} \mapsto \mathbf{u}_j^\top \mathbf{y} / (1 + \lambda e_j)$: smooth directions (e_j small) pass through, rough ones are damped. The smoothing spline has the same form with e_j the eigenvalues of the roughness matrix relative to the identity.
- (e) (*Pointwise bands.*) $\hat{f}(x_i) \pm z_{1-\alpha/2} \hat{\sigma} \sqrt{(\mathbf{S}\mathbf{S}^\top)_{ii}}$ is an interval for $E\{\hat{f}(x_i)\} = (\mathbf{S}\mathbf{f})_i$, not for $f(x_i)$. Its coverage of $f(x_i)$ is $1 - \alpha$ only to the extent that the bias $\{(\mathbf{S} - \mathbf{I})\mathbf{f}\}_i$ is small next to $\sigma \sqrt{(\mathbf{S}\mathbf{S}^\top)_{ii}}$.

Proof. Linearity is [Proposition 43.1.1](#) for the kernel estimators, [Proposition 43.3.2\(a\)](#) for the penalized spline and [Eq. 43.4.2](#) for the smoothing spline; in each case the matrix is built from the design, the knots and the tuning constant alone.

- (a) $E(\mathbf{S}\mathbf{Y}) = \mathbf{S}\mathbf{f}$ and $\text{Cov}(\mathbf{S}\mathbf{Y}) = \mathbf{S}\text{Cov}(\mathbf{Y})\mathbf{S}^\top$. For the risk, $\hat{\mathbf{f}} - \mathbf{f} = (\mathbf{S} - \mathbf{I})\mathbf{f} + \mathbf{S}\boldsymbol{\varepsilon}$, the two terms are uncorrelated, and $E\|\mathbf{S}\boldsymbol{\varepsilon}\|^2 = \sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top)$.
- (b) $\mathbf{y} - \hat{\mathbf{f}} = (\mathbf{I} - \mathbf{S})\mathbf{f} + (\mathbf{I} - \mathbf{S})\boldsymbol{\varepsilon}$, and

$$\begin{aligned} E\|(\mathbf{I} - \mathbf{S})\boldsymbol{\varepsilon}\|^2 &= \sigma^2 \text{tr}\{(\mathbf{I} - \mathbf{S})(\mathbf{I} - \mathbf{S})^\top\} \\ &= \sigma^2\{n - 2\text{tr}(\mathbf{S}) + \text{tr}(\mathbf{S}\mathbf{S}^\top)\}. \end{aligned}$$

- (c) With eigenvalues $s_j \in [0, 1]$ we have $\text{tr}(\mathbf{S}) = \sum_j s_j$ and $\text{tr}(\mathbf{S}\mathbf{S}^\top) = \sum_j s_j^2$, while $s_j^2 \leq s_j \leq 2s_j - s_j^2$, the last inequality because $(1 - s_j)^2 \geq 0$. Equality in either needs every $s_j \in \{0, 1\}$, which for a symmetric matrix means $\mathbf{S}$ is idempotent ([Theorem 6.3.3](#)); its trace is then its rank ([Proposition 6.3.4](#)).
- (d) is [Eq. 43.3.2](#); for the smoothing spline apply [Lemma 43.3.1](#) with $\mathbf{B} = \mathbf{I}$ and the roughness matrix of [Proposition 43.4.3\(b\)](#) in place of $\mathbf{P}$.
- (e) By (a), $\hat{f}(x_i)$ has mean $(\mathbf{S}\mathbf{f})_i$ and standard deviation $\sigma\{(\mathbf{S}\mathbf{S}^\top)_{ii}\}^{1/2}$, so under normal errors the interval covers that mean with probability $1 - \alpha$ if $\hat{\sigma}$ is replaced

by σ . Writing $f(x_i) = (\mathbf{S}\mathbf{f})_i - \{(\mathbf{S} - \mathbf{I})\mathbf{f}\}_i$ shows that its coverage of $f(x_i)$ is the normal probability of an interval displaced by the bias.

■

Warning. Part (e) is the most important caveat in this chapter, and the one most often ignored. A smoother is *deliberately* biased; that is what the penalty buys. The interval above treats the bias as zero, so where f curves most — a peak, a trough, the boundary — it is centred in the wrong place and undercovers, while on flat stretches it overcovers. [Section 43.6](#) gives a band that repairs the average of this, and says what “average” means.

43.5.2 Three rules

The quantity one would like to minimize is the risk [Eq. 43.5.1](#), which involves the unknown $\mathbf{f}$. Each rule estimates something close to it.

Theorem 43.5.2 — Cross-validation, generalized cross-validation and AIC for smoothers

Let $\mathbf{S}_\lambda$ be the smoother matrix, $\hat{\mathbf{f}} = \mathbf{S}_\lambda \mathbf{y}$, $\text{df} = \text{tr}(\mathbf{S}_\lambda)$ and s_{ii} the diagonal entries of $\mathbf{S}_\lambda$ — the leverage of [Proposition 6.8.1](#) and [Section 20.2](#), read now for a smoother instead of a projection.

- (a) (*The leave-one-out shortcut is exact.*) For a penalized spline and for a smoothing spline,

$$\text{CV}(\lambda) = \frac{1}{n} \sum_{i=1}^n \{y_i - \hat{f}^{(-i)}(x_i)\}^2 = \frac{1}{n} \sum_{i=1}^n \left(\frac{y_i - \hat{f}(x_i)}{1 - s_{ii}} \right)^2, \quad (43.5.3)$$

where $\hat{f}^{(-i)}$ is the fit computed without case i at the same λ . The same identity holds for a local polynomial estimator, with $s_{ii} = \ell_i(x_i)$.

- (b) (*Generalized cross-validation.*) Replacing each s_{ii} by the average df/n gives [Definition 29.3.2](#),

$$\text{GCV}(\lambda) = \frac{n^{-1} \|\mathbf{y} - \hat{\mathbf{f}}\|^2}{(1 - \text{df}/n)^2}, \quad (43.5.4)$$

which needs only the trace, and satisfies $\text{GCV} = n^{-1} \|\mathbf{y} - \hat{\mathbf{f}}\|^2 (1 + 2 \text{df}/n) + O(\text{df}^2/n^2)$.

- (c) (*Information criteria.*) Under normal errors with σ^2 profiled out, [Proposition 29.2.4](#) gives $\text{AIC}(\lambda) = n \log(\|\mathbf{y} - \hat{\mathbf{f}}\|^2/n) + 2 \text{df}$. Its small-sample correction (Hurvich, Simonoff and Tsai, 1998) is

$$\text{AIC}_c(\lambda) = \log\left(\frac{\|\mathbf{y} - \hat{\mathbf{f}}\|^2}{n}\right) + 1 + \frac{2(\text{df} + 1)}{n - \text{df} - 2}, \quad (43.5.5)$$

which penalizes large df much more heavily and has a pole at $\text{df} = n - 2$.

- (d) (*What they estimate.*) If $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, then $E\{\text{CV}(\lambda)\}$ is, up to $O(n^{-1})$ terms, the average prediction error at a fresh response, which exceeds n^{-1} times the risk Eq. 43.5.1 by σ^2 . A minimizer of any of the three is therefore aiming at Eq. 43.5.1, not at λ itself, and nothing here estimates a “true” smoothing parameter, since no such thing is assumed to exist.

Proof.

- (a) A penalized spline minimizes $\|\mathbf{y} - \mathbf{B}\boldsymbol{\gamma}\|^2 + \boldsymbol{\gamma}^\top \boldsymbol{\Omega} \boldsymbol{\gamma}$ with $\boldsymbol{\Omega} = \lambda \mathbf{P}$, and a smoothing spline minimizes $\|\mathbf{y} - \mathbf{z}\|^2 + \mathbf{z}^\top (\lambda \mathbf{P}) \mathbf{z}$, which is the same form with $\mathbf{B} = \mathbf{I}$. Both have $\boldsymbol{\Omega}$ nonnegative definite and the deleted cross-product matrices nonsingular, so Theorem 29.3.2 applies verbatim and gives Eq. 43.5.3. For a local polynomial estimator, fix i and let $\tilde{\mathbf{y}}$ be $\mathbf{y}$ with y_i replaced by $\hat{f}^{(-i)}(x_i)$. The weighted least squares problem Eq. 43.1.2 at $x = x_i$ with data $\tilde{\mathbf{y}}$ has the same minimizer as the problem with case i deleted. Indeed the row of $\mathbf{U}_x$ belonging to case i is $(1, 0, \dots, 0)$, so the objective with $\tilde{\mathbf{y}}$ is the deleted objective plus $K_h(0)(\tilde{y}_i - b_0)^2$; the deleted minimizer makes the first term as small as possible and the second term zero, so it minimizes the sum. Hence $\hat{f}^{(-i)}(x_i) = \sum_j \ell_j(x_i) \tilde{y}_j = \hat{f}(x_i) + \ell_i(x_i) \{\hat{f}^{(-i)}(x_i) - y_i\}$; solving for $y_i - \hat{f}^{(-i)}(x_i)$ gives $\{y_i - \hat{f}(x_i)\} / \{1 - \ell_i(x_i)\}$.
- (b) The substitution is the definition of GCV; the expansion is $(1-t)^{-2} = 1 + 2t + O(t^2)$ with $t = \text{df}/n$.
- (c) With a normal likelihood and σ^2 replaced by its maximum likelihood estimate $\|\mathbf{y} - \hat{\mathbf{f}}\|^2/n$, the maximized log likelihood is $-\frac{n}{2} \log(\|\mathbf{y} - \hat{\mathbf{f}}\|^2/n) + \text{const}$, and Proposition 29.2.4 counts $\text{df} + 1$ parameters, the $+1$ being σ^2 ; dropping constants gives AIC. Eq. 43.5.5 is the stated correction, which reduces to AIC/n plus constants when $\text{df}/n \rightarrow 0$.
- (d) is Proposition 29.3.1 and Definition 29.1.1, which do not use the form of the estimator.

■

Idea. All three rules do the same arithmetic: residual sum of squares, inflated by a factor that grows with the degrees of freedom — $(1 - s_{ii})^{-2}$ case by case, $(1 - \text{df}/n)^{-2}$ on average, $\exp\{2 \text{df}/n\}$ approximately for AIC. That is why they usually agree, and why they part company at large df . Mallows' C_p (Definition 29.2.1) inflates additively, $\|\mathbf{y} - \hat{\mathbf{f}}\|^2 + 2\hat{\sigma}^2 \text{tr}(\mathbf{S}_\lambda)$, but needs a $\hat{\sigma}^2$ from outside — usually Eq. 43.5.2 at a deliberately undersmoothed fit — and inherits whatever that choice got wrong.

43.5.3 What they do in practice

Example. (The three criteria on one data set, and over 200 of them)

Take $n = 120$ equally spaced design points, the mean function of Example (Bias, variance and the optimal bandwidth), $\sigma = 0.25$, and a cubic P-spline with $K = 25$ knots and a second-order penalty. On one data set the shortcut Eq. 43.5.3 agrees with 120 actual refits to 4.6×10^{-15} , and the three criteria choose 9.83, 10.29 and 9.40 degrees of freedom.

Over 200 replicates the three are hard to tell apart. Each has median selected df 7.82,

and the average $n^{-1}\|\hat{\mathbf{f}} - \mathbf{f}\|^2$ is 0.00448 for CV, 0.00449 for GCV and 0.00429 for AIC_c . The differences show in the upper tail: CV and GCV choose more than 15 degrees of freedom in 2.5 per cent of the samples, AIC_c in 0.5 per cent. The criteria are flat to the right of the minimum (Figure 43.5.1(a)), so an occasional sample sends the minimum far out, and steep to the left, so gross oversmoothing is rare.

Warning (Three small-sample failures). **A flat criterion.** Near the minimum, GCV can change by a fraction of a per cent over a factor of two in λ ; the choice is then arbitrary, and reporting the fit at a single λ hides that. Plot the criterion.

Interpolation. Since $(1 - \text{df}/n)^{-2}$ becomes large only as $\text{df} \rightarrow n$, a small sample can give GCV a *local* minimum at the interpolating end. AIC_c cannot, because of the pole in Eq. 43.5.5; this is its main practical advantage.

Correlated errors. All three estimate prediction error at a *new, independent* response. If the errors are serially correlated, a wiggly fit predicts its neighbours well without describing f at all, and every criterion rewards it (Example (What correlated errors do)).

Example. (What correlated errors do)

Repeat the simulation with errors from a stationary AR(1) process of the same marginal standard deviation and autocorrelation $\rho = 0.7$ (Definition 21.6.1). The median selected degrees of freedom rise from 7.82 to 25.40 for CV, 24.53 for GCV and 23.50 for AIC_c , and the average squared error rises from the values just quoted to 0.04209, 0.04145 and 0.03982 — roughly a ninefold loss. The fitted curve in Figure 43.5.1(b) uses 27 degrees of freedom and traces every excursion of the error process.

There is no repair inside this section: a smooth mean and smooth-looking noise are not separately identified without an assumption about one of them. The honest responses are to model the correlation (Part VII), to choose λ by a criterion that accounts for it — leaving out whole blocks rather than single points, or REML in the mixed-model form of Section 43.6 — or to say that the wiggles are not interpretable. Opsomer, Wang and Yang (2001) survey what is known.

43.5.4 After the choice

Remark (Inference after selecting the smoothing parameter). Every interval, test and standard error in this chapter is computed *as if* λ were fixed in advance. It was not: it was chosen by minimizing a criterion computed from the same $\mathbf{y}$. This is [Proposition 29.5.1](#) in a continuous guise. The residual sum of squares at the selected λ is the smallest of many, so $\hat{\sigma}^2$ from [Eq. 43.5.2](#) is biased downwards and a pointwise band does not attain its nominal coverage.

The effect is modest when the criterion has a well-determined minimum, which is why the practice survives, and large when it does not. The defences are those of [Chapter 29](#): hold out data, bootstrap the whole procedure including the selection of λ ([Chapter 23](#)), or report the fit at several λ and let the reader see the dependence. What is not a defence is quoting a p -value from a fit whose flexibility was chosen to make that p -value small.

43.5.5 Exercises

43.5.5.1 A. Check your understanding

Exercise A1.

For the projection onto a p -dimensional space, compute $\text{tr}(\mathbf{S})$, $\text{tr}(\mathbf{S}\mathbf{S}^\top)$ and $2\text{tr}(\mathbf{S}) - \text{tr}(\mathbf{S}\mathbf{S}^\top)$. For a P-spline at $\text{df} = 8$ with $m = 24$, which of the three is largest? Using [Proposition 43.5.1\(c\)](#), say which one the residual degrees of freedom $n - 2\text{tr}(\mathbf{S}) + \text{tr}(\mathbf{S}\mathbf{S}^\top)$ subtracts.

43.5.5.2 B. Practice

Exercise B1.

Using the cell above, verify [Eq. 43.5.3](#) against n refits at three values of λ , including one so large that $\text{df} \approx 2$ and one so small that $\text{df} \approx m$. Then do the same for a *local linear*

estimator, using $\ell_i(x_i)$ from [Section 43.1](#).

Exercise B2.

Show that $\log \text{GCV} = \log(n^{-1}\|\mathbf{y} - \hat{\mathbf{f}}\|^2) - 2\log(1 - \text{df}/n)$ and that $-2\log(1 - t) = 2t + t^2 + O(t^3)$. Compare with [Eq. 43.5.5](#) expanded for small df/n , and explain why GCV and AIC almost always choose the same λ when n is large and differ when df is an appreciable fraction of n .

Solution. The first identity is immediate from [Eq. 43.5.4](#). Expanding, $\log \text{GCV} = \log(\text{RSS}/n) + 2\text{df}/n + (\text{df}/n)^2 + \dots$, while $\text{AIC}_c = \log(\text{RSS}/n) + 1 + 2(\text{df} + 1)/(n - \text{df} - 2) = \log(\text{RSS}/n) + 1 + 2\text{df}/n + 2\text{df}^2/n^2 + \dots$. To first order in df/n the two differ by a constant, so their minimizers agree; the second-order terms differ by a factor of two, and AIC_c has a pole at $\text{df} = n - 2$ where GCV has one only at $\text{df} = n$. Hence they separate exactly when df/n is not small.

43.5.5.3 C. Going deeper

Exercise C1.

GCV was introduced by Craven and Wahba (1979) as a version of cross-validation invariant to rotation. Show that if $\mathbf{\Gamma}$ is orthogonal and one replaces $\mathbf{y}$ by $\mathbf{\Gamma y}$ and $\mathbf{S}_\lambda$ by $\mathbf{\Gamma S}_\lambda \mathbf{\Gamma}^\top$, then GCV is unchanged while CV is not. Why is this a virtue for ridge regression (where such rotations are natural) and less obviously one for a smoother (where they are not)?

Solution. Under the substitution, the residual vector becomes $\mathbf{\Gamma}(\mathbf{I} - \mathbf{S}_\lambda)\mathbf{y}$, whose squared length is unchanged, and $\text{tr}(\mathbf{\Gamma S}_\lambda \mathbf{\Gamma}^\top) = \text{tr}(\mathbf{S}_\lambda)$; so [Eq. 43.5.4](#) is invariant, while CV depends on the individual s_{ii} , which are not. In ridge regression the canonical coordinates of [Theorem 27.2.2](#) are as natural as the original ones, so invariance is attractive; for a smoother the coordinates are cases in a fixed order along the x -axis and the s_{ii} carry real information — small in dense regions, large in sparse ones — which replacing them by their average throws away. Hence CV and GCV differ most in designs with isolated points.

Exercise C2.

For the simulation of [Example \(The three criteria on one data set, and over 200 of them\)](#), record for each replicate the *set* of λ within one per cent of the GCV minimum, and report the median ratio of the largest to the smallest df in that set. Then plot, for one replicate, the fits at both ends of the interval. Does the choice within the flat region matter for what one would say about f ?

43.6 Mixed-model and Bayesian representations

The criteria of [Section 43.5](#) treat λ as a tuning constant to be optimized. There is another way to think about it. A quadratic penalty is, up to a constant, the logarithm of a normal density, so penalizing $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma}$ is the same as believing in advance that $\boldsymbol{\gamma}$ is a draw from a normal distribution with precision proportional to $\mathbf{P}$. Then λ is a ratio of two variances, and a variance is not a tuning constant but a parameter the data can estimate. The machinery of [Chapter 32](#) becomes available, with a second dividend: an interval whose width knows about the bias.

43.6.1 Splitting the penalty

The obstacle is that $\mathbf{P}$ is singular. A normal prior with precision matrix $\mathbf{P}/\tau^2$ constrains nothing on the k -dimensional null space $\mathcal{N}(\mathbf{P})$ — the straight lines, for a second-order penalty — so it is not proper. The fix is to split $\boldsymbol{\gamma}$ into the part the penalty does not see, a *fixed* effect, and the rest, a *random* effect with a proper distribution.

Theorem 43.6.1 — A penalized spline is a linear mixed model

Let $\mathbf{P}$ be nonnegative definite of order m and rank $r = m - k$, write $\mathbf{P} = \mathbf{L}\mathbf{L}^\top$ with $\mathbf{L}$ of size $m \times r$ and full column rank, let $\mathbf{X}_\gamma$ be $m \times k$ with columns spanning $\mathcal{N}(\mathbf{P})$, and set $\mathbf{Z}_\gamma = \mathbf{L}(\mathbf{L}^\top \mathbf{L})^{-1}$.

- (a) (*The transformation.*) $[\mathbf{X}_\gamma, \mathbf{Z}_\gamma]$ is nonsingular, so every $\boldsymbol{\gamma}$ is uniquely $\boldsymbol{\gamma} = \mathbf{X}_\gamma \boldsymbol{\beta} + \mathbf{Z}_\gamma \mathbf{u}$; moreover $\mathbf{u} = \mathbf{L}^\top \boldsymbol{\gamma}$ and $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = \mathbf{u}^\top \mathbf{u}$.
- (b) (*The mixed model.*) With $\mathbf{X} = \mathbf{B}\mathbf{X}_\gamma$ and $\mathbf{Z} = \mathbf{B}\mathbf{Z}_\gamma$, the P-spline criterion [Eq. 43.3.1](#) is

$$\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}\|^2 + \lambda \mathbf{u}^\top \mathbf{u}, \quad (43.6.1)$$

which is the penalized criterion [Eq. 32.3.6](#) of the linear mixed model $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u} + \boldsymbol{\varepsilon}$, $\mathbf{u} \sim N_r(\mathbf{0}, \sigma_u^2 \mathbf{I})$, $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$ independent, with

$$\lambda = \sigma^2 / \sigma_u^2. \quad (43.6.2)$$

Its solution is Henderson's ([Theorem 32.3.2](#)): $\hat{\boldsymbol{\beta}}$ is the generalized least squares estimate and $\hat{\mathbf{u}}$ the BLUP ([Theorem 32.3.1](#)).

- (c) (*The Bayesian reading.*) Suppose σ^2 is known and $\boldsymbol{\gamma}$ has the prior with density proportional to $\exp\{-\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} / (2\tau^2)\}$, $\tau^2 = \sigma^2 / \lambda$ — equivalently $\boldsymbol{\beta}$ flat and $\mathbf{u} \sim N_r(\mathbf{0}, \tau^2 \mathbf{I})$. Then

$$\boldsymbol{\gamma} \mid \mathbf{Y} = \mathbf{y} \sim N_m\{\hat{\boldsymbol{\gamma}}, \sigma^2(\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})^{-1}\}, \quad (43.6.3)$$

with $\hat{\boldsymbol{\gamma}}$ the penalized estimate of [Proposition 43.3.2\(a\)](#).

- (d) (*REML.*) The marginal distribution is $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2 \mathbf{V}_\lambda)$ with $\mathbf{V}_\lambda = \mathbf{I} + \lambda^{-1} \mathbf{Z}\mathbf{Z}^\top$. Profiling σ^2 out of the restricted likelihood ([Definition 32.4.1](#), [Theorem 32.4.2](#)) leaves

$$-2\ell_R(\lambda) = (n - k) \log \hat{\sigma}_\lambda^2 + \log|\mathbf{V}_\lambda| + \log|\mathbf{X}^\top \mathbf{V}_\lambda^{-1} \mathbf{X}| + c, \quad (43.6.4)$$

where $\hat{\sigma}_\lambda^2 = \mathbf{y}^\top \mathbf{A}_\lambda \mathbf{y} / (n - k)$ with $\mathbf{A}_\lambda = \mathbf{V}_\lambda^{-1} - \mathbf{V}_\lambda^{-1} \mathbf{X} (\mathbf{X}^\top \mathbf{V}_\lambda^{-1} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V}_\lambda^{-1}$, and c does not depend on λ . Minimizing Eq. 43.6.4 over $\lambda > 0$ estimates the smoothing parameter.

Proof.

- (a) From $\mathbf{P} = \mathbf{L}\mathbf{L}^\top$ we get $\mathbf{P}\boldsymbol{\gamma} = \mathbf{0}$ iff $\|\mathbf{L}^\top \boldsymbol{\gamma}\|^2 = \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma} = 0$ iff $\mathbf{L}^\top \boldsymbol{\gamma} = \mathbf{0}$, so $\mathcal{N}(\mathbf{P}) = \mathcal{N}(\mathbf{L}^\top) = \mathcal{C}(\mathbf{L})^\perp$ and $\mathcal{C}(\mathbf{Z}_\gamma) = \mathcal{C}(\mathbf{L}) = \mathcal{N}(\mathbf{P})^\perp$. Hence $\mathcal{C}(\mathbf{X}_\gamma)$ and $\mathcal{C}(\mathbf{Z}_\gamma)$ are orthogonal subspaces of dimensions k and r that together span $\mathbb{R}^m$, so $[\mathbf{X}_\gamma, \mathbf{Z}_\gamma]$ has rank m and the decomposition is unique. Multiplying $\boldsymbol{\gamma} = \mathbf{X}_\gamma \boldsymbol{\beta} + \mathbf{Z}_\gamma \mathbf{u}$ by $\mathbf{L}^\top$ gives $\mathbf{L}^\top \boldsymbol{\gamma} = \mathbf{0} + \mathbf{L}^\top \mathbf{L} (\mathbf{L}^\top \mathbf{L})^{-1} \mathbf{u} = \mathbf{u}$, and then $\boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma} = \|\mathbf{L}^\top \boldsymbol{\gamma}\|^2 = \mathbf{u}^\top \mathbf{u}$.
- (b) Substituting $\mathbf{B}\boldsymbol{\gamma} = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\mathbf{u}$ and (a) into Eq. 43.3.1 gives Eq. 43.6.1. In the mixed model with $\mathbf{G} = \sigma_u^2 \mathbf{I}$ and $\mathbf{R} = \sigma^2 \mathbf{I}$, Henderson's criterion is $\sigma^{-2} \|\mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \mathbf{Z}\mathbf{u}\|^2 + \sigma_u^{-2} \mathbf{u}^\top \mathbf{u}$, which is σ^{-2} times Eq. 43.6.1 when $\lambda = \sigma^2 / \sigma_u^2$; the two have the same minimizers.
- (c) The prior is flat in $\boldsymbol{\beta}$ and normal in $\mathbf{u}$, so the joint density of $(\mathbf{y}, \boldsymbol{\gamma})$ is proportional to $\exp[-\{\|\mathbf{y} - \mathbf{B}\boldsymbol{\gamma}\|^2 + \lambda \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}\} / (2\sigma^2)]$. By the algebra in the proof of Proposition 43.3.2(a), the exponent is $-\{(\boldsymbol{\gamma} - \hat{\boldsymbol{\gamma}})^\top (\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})(\boldsymbol{\gamma} - \hat{\boldsymbol{\gamma}}) + C\} / (2\sigma^2)$ with C free of $\boldsymbol{\gamma}$. As a function of $\boldsymbol{\gamma}$ this is the normal density Eq. 43.6.3 (Definition 39.4.1).
- (d) $\text{Cov}(\mathbf{Y}) = \sigma_u^2 \mathbf{Z}\mathbf{Z}^\top + \sigma^2 \mathbf{I} = \sigma^2 \mathbf{V}_\lambda$ by Eq. 32.2.2, and Theorem 32.4.2 gives the restricted log likelihood $-\frac{1}{2} \{(n - k) \log \sigma^2 + \log|\mathbf{V}_\lambda| + \log|\mathbf{X}^\top \mathbf{V}_\lambda^{-1} \mathbf{X}| + \mathbf{y}^\top \mathbf{A}_\lambda \mathbf{y} / \sigma^2\}$ up to a constant. Differentiating in σ^2 gives $\hat{\sigma}_\lambda^2 = \mathbf{y}^\top \mathbf{A}_\lambda \mathbf{y} / (n - k)$, and substituting it back gives Eq. 43.6.4.

■

Idea. The same algebra has now been read three ways. A quadratic penalty is a shrinkage rule (Theorem 27.2.2), a normal prior (Proposition 39.5.1) and a variance component. Only the third makes the tuning constant estimable, because only the third supplies a probability model for the coefficients and with it a likelihood in λ . Nothing is obtained for nothing: that model says the true f is a draw from a particular distribution of curves, a stronger assumption than “ f is smooth”.

Remark (What the transformation looks like). For a second-order difference penalty, $\mathcal{N}(\mathbf{D}_2)$ is spanned by $\mathbf{1}$ and $(1, \dots, m)^\top$, so the two fixed-effect columns of $\mathbf{X} = \mathbf{B}\mathbf{X}_\gamma$ span the constant and the linear function (Proposition 43.3.3(c)): the mixed model has a straight line as its fixed part and the deviations from it as its random part — the decomposition a data analyst would choose by hand, forced by the penalty rather than assumed. Other choices of $\mathbf{L}$ and $\mathbf{X}_\gamma$ give the same fitted values, since they differ by a nonsingular reparameterization (Theorem 6.7.1).

43.6.2 Bands that know about the bias

Proposition 43.5.1(e) left a problem: the obvious interval is centred at $E\{\hat{f}(x_i)\}$, which is not $f(x_i)$. The posterior Eq. 43.6.3 offers a different interval, and it is wider.

Proposition 43.6.2 — Wahba–Nychka bands

Let $\mathbf{S}_\lambda = \mathbf{B}(\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})^{-1} \mathbf{B}^\top$ with diagonal entries s_{ii} .

- (a) Under [Theorem 43.6.1\(c\)](#), $f(x_i) = \mathbf{B}_i \boldsymbol{\gamma}$ has posterior distribution $N(\hat{f}(x_i), \sigma^2 s_{ii})$, giving the **Bayesian band**

$$\hat{f}(x_i) \pm z_{1-\alpha/2} \hat{\sigma} \sqrt{s_{ii}}. \quad (43.6.5)$$

- (b) $s_{ii} \geq (\mathbf{S}_\lambda \mathbf{S}_\lambda^\top)_{ii}$, so [Eq. 43.6.5](#) is never narrower than the interval of [Proposition 43.5.1\(e\)](#), and is strictly wider unless $\mathbf{S}_\lambda$ is a projection.
- (c) (*Stated, not proved.*) Treating f as fixed, the extra width in (b) accounts approximately for the squared bias, in the sense that $n^{-1} \sum_i \sigma^2 s_{ii}$ approximates $n^{-1} \sum_i [\text{Var}\{\hat{f}(x_i)\} + \text{bias}\{\hat{f}(x_i)\}^2]$ when λ is near its risk-optimal value. Consequently the *average* over the design points of the coverage of [Eq. 43.6.5](#) is close to $1 - \alpha$, while the coverage at any single x_i is not: it is below nominal where f curves sharply and above it where f is nearly straight. This is **across-the-function** coverage (Wahba, 1983; Nychka, 1988).

Proof.

- (a) By [Eq. 43.6.3](#), $\mathbf{B}_i \boldsymbol{\gamma}$ is normal with mean $\mathbf{B}_i \hat{\boldsymbol{\gamma}} = \hat{f}(x_i)$ and variance $\sigma^2 \mathbf{B}_i (\mathbf{B}^\top \mathbf{B} + \lambda \mathbf{P})^{-1} \mathbf{B}_i^\top = \sigma^2 s_{ii}$.
- (b) $\mathbf{S}_\lambda$ is symmetric with eigenvalues $s_j \in (0, 1]$ by [Proposition 43.3.2\(b\)](#), so $\mathbf{S}_\lambda - \mathbf{S}_\lambda^2$ is symmetric with eigenvalues $s_j(1 - s_j) \geq 0$ and hence nonnegative definite; its i th diagonal entry $s_{ii} - (\mathbf{S}_\lambda \mathbf{S}_\lambda^\top)_{ii}$ is therefore nonnegative, and zero for all i only if the matrix is zero, that is only if every $s_j \in \{0, 1\}$.

Part (c) is not proved here; see the notes. ■

Warning. “Across-the-function” is a weaker guarantee than it sounds. Count how often the band contains the true curve across the design points and the fraction is about $1 - \alpha$. It does not say that the band contains the curve *everywhere* with probability $1 - \alpha$ — that is a simultaneous band, which is wider (Sun and Loader, 1994) — nor that the interval at any one chosen point has nominal coverage. If a particular x is the question, [Eq. 43.6.5](#) is not the answer.

Example. (Measuring the coverage)

Take $n = 120$ equally spaced points, the mean function of [Example \(Bias, variance and the optimal bandwidth\)](#) and $\sigma = 0.25$, with a cubic P-spline on $K = 20$ knots, so $m = 24$ coefficients split into $k = 2$ fixed and $r = 22$ random ones. On one data set the transformation of [Theorem 43.6.1](#) reproduces the penalized fit to machine precision, REML chooses $\lambda = 5.01 \times 10^0$, which is 8.12 effective degrees of freedom, against 7.10 for GCV; the REML estimate of σ is 0.254.

Over 400 replicates, with λ re-estimated by REML each time, the nominal 95 per cent band [Eq. 43.6.5](#) covers $f(x_i)$ at a fraction 0.954 of the design points on average, the

Figure 43.6.1: (a) One data set, the REML fit, and the nominal 95 per cent Bayesian band Eq. 43.6.5. (b) Coverage of that band at each design point over 400 replicates, λ re-estimated each time; dashed line nominal, dotted line the average over the design points.

pointwise coverages running from 0.900 at the narrow dip near $x = 0.8$, where the fit is most biased, to 0.985 on the flat stretches (Figure 43.6.1). The Bayesian standard errors are on average 1.12 times the naive ones of Proposition 43.5.1(e), whose bands cover only 0.927 of the design points: a twelve per cent widening buys back nearly three percentage points of average coverage, and what is left over is the bias that no single width can equalize.

43.6.3 REML against the criteria, and full Bayes

REML and GCV estimate different things. GCV aims at prediction error; REML maximizes a likelihood under the assumption that f is a draw from the prior — which nobody believes, since nobody believes the deviations from a straight line are exchangeable normal increments. In practice the two rarely differ by much: in [Example \(Measuring the coverage\)](#) REML chose 8.12 effective degrees of freedom against GCV's 7.10. But REML is the more stable, its criterion better determined near the optimum, and it almost never produces the interpolating fits that GCV occasionally does (Reiss and Ogden, 2009). It has no answer when the error model is wrong: with the AR(1) errors of [Example \(What correlated errors do\)](#) it overfits just as GCV does, unless the correlation is put into $\text{Cov}(\epsilon)$, which the mixed-model form at least makes possible ([Definition 33.4.1](#)).

Remark (Full Bayes). [Theorem 43.6.1\(c\)](#) fixes λ . A fully Bayesian treatment puts a prior on τ^2 and σ^2 too — conventionally inverse-gamma, which is conditionally conjugate — and samples $(\gamma, \tau^2, \sigma^2)$ by the Gibbs sampler of [Definition 39.4.2](#): each sweep draws γ from [Eq. 43.6.3](#), then τ^2 from an inverse-gamma with shape $a + r/2$ and scale $b + \mathbf{u}^\top \mathbf{u}/2$, then σ^2 likewise. The posterior for f then averages over the smoothing parameter instead of conditioning on an estimate of it, the cleanest answer to the selection problem of [Section 43.5](#). It is also where the prior shows its weakness: the posterior for τ^2 is sensitive to the hyperparameters, as [Proposition 39.5.1](#) warns. [Chapter 44](#) uses this machinery for several smooth terms at once.

43.6.4 What this book does not do with smoothing

Three threads end here rather than continue, and it is only fair to name them.

Adaptive smoothing. A single λ is a compromise when f is rough in one place and flat in another; letting it vary with x — a second smooth for $\log \lambda$, free-knot splines (Denison, Mallick and Smith, 1998), wavelet thresholding (Donoho and Johnstone, 1994) — is a subject this book does not enter.

Simultaneous bands. Eq. 43.6.5 is pointwise, or at best across-the-function; a band containing the whole curve with a stated probability needs the tube formula of Sun and Loader (1994) or a bootstrap over the whole fit.

Shape constraints. Monotone, convex or unimodal fits add linear inequality constraints to Eq. 43.3.1, a quadratic program; Ramsay (1988) treats the monotone case.

What does continue is the penalty. Everything after Section 43.2 rests on one idea — a rich basis, a quadratic penalty, a trace that counts what was spent, and a variance ratio that can be estimated — and that idea is indifferent to how many covariates there are, to whether the response is normal, and to which parameter of the response distribution is modelled. Chapter 44 adds covariates and Chapter 45 parameters, both by writing down more terms of the form Eq. 43.3.1.

43.6.5 Exercises

43.6.5.1 A. Check your understanding

Exercise A1.

Using Eq. 43.6.2, say what $\sigma_u^2 \rightarrow 0$ and $\sigma_u^2 \rightarrow \infty$ correspond to in Proposition 43.3.2, and what a REML estimate $\hat{\sigma}_u^2 = 0$ would mean about the fitted curve. Is that estimate on the boundary of the parameter space, and does Theorem 32.5.2 apply?

Solution. $\sigma_u^2 \rightarrow 0$ gives $\lambda \rightarrow \infty$, leaving only the fixed part, the straight line; $\sigma_u^2 \rightarrow \infty$ gives $\lambda \rightarrow 0$, the unpenalized spline fit. A REML estimate of zero means the data give no evidence of departure from a straight line, and the reported fit *is* the least squares line. It is on the boundary, so a likelihood ratio test of $\sigma_u^2 = 0$ has not the usual χ^2 null distribution but the mixture of Theorem 32.5.2 — the same caution as for testing whether a smooth term is needed at all.

43.6.5.2 B. Practice

Exercise B1.

Run the simulation of Example (The three criteria on one data set, and over 200 of them) again with λ chosen by REML, and compare the median selected degrees of freedom, the average squared error and the upper tail of the df distribution with the values for CV, GCV and AIC_c . Which criterion is safest, and at what cost?

Exercise B2.

Example (Measuring the coverage) uses $\hat{\sigma}$ from Eq. 43.5.2 in Eq. 43.6.5. Repeat the coverage simulation with σ known, and with $z_{1-\alpha/2}$ replaced by a t quantile on $n - 2 \operatorname{tr}(\mathbf{S}) + \operatorname{tr}(\mathbf{S}\mathbf{S}^\top)$ degrees of freedom. How much of the departure from nominal coverage

is due to estimating σ , and how much to the bias?

43.6.5.3 C. Going deeper

Exercise C1.

Show that in the mixed model of [Theorem 43.6.1\(b\)](#), the BLUP satisfies $\hat{\mathbf{u}} = (\mathbf{Z}^\top \mathbf{Z} + \lambda \mathbf{I})^{-1} \mathbf{Z}^\top (\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}})$, and hence that $\hat{\mathbf{u}}$ is a ridge estimate ([Theorem 27.2.2](#)) on the residuals from the fixed part. Explain, using [Theorem 32.3.1](#), why the shrinkage factor is $\sigma_u^2 / (\sigma_u^2 + \sigma^2 / d_j^2)$ in the j th singular direction of $\mathbf{Z}$, and what happens to it as n grows with r fixed.

Solution. The second block of Henderson's equations is $\mathbf{Z}^\top \mathbf{X} \hat{\boldsymbol{\beta}} + (\mathbf{Z}^\top \mathbf{Z} + \lambda \mathbf{I}) \hat{\mathbf{u}} = \mathbf{Z}^\top \mathbf{y}$, which rearranges to the displayed formula; it is [Eq. 27.2.1](#) with response $\mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}}$ and ridge parameter $\lambda = \sigma^2 / \sigma_u^2$. With $\mathbf{Z} = \sum_j d_j \mathbf{u}_j \mathbf{v}_j^\top$, [Theorem 27.2.2\(a\)](#) gives the factor $d_j^2 / (d_j^2 + \lambda) = \sigma_u^2 / \{\sigma_u^2 + \sigma^2 / d_j^2\}$, which is [Eq. 32.3.3](#): the random effect is shrunk according to how much information the data carry about it. As n grows with the basis fixed, every d_j^2 grows like n and the factors tend to one, which is why a low-rank smoother with a fixed basis is asymptotically a parametric fit unless m grows with n .

Exercise C2.

The prior of [Theorem 43.6.1\(c\)](#) is improper on $\mathcal{N}(\mathbf{P})$. Show that the posterior [Eq. 43.6.3](#) is nevertheless proper, provided $\mathbf{B}\mathbf{X}_\gamma$ has full column rank. By [Exercise \(C2\)](#) that holds for $k \leq 2$ whenever the design has at least k distinct points, however the knots fall; show that it fails when it has fewer — for $k = 2$, a design concentrated at a single x — and say what the posterior then does in the unidentified direction. Compare with the discussion of improper priors in [Section 39.5](#).

43.7 Summary and Notes

43.7.1 Summary

Idea.

1. A local polynomial fit is weighted least squares solved afresh at every point; its weights are linear in $\mathbf{y}$ and reproduce polynomials of the fitted degree exactly, whatever the design and the bandwidth ([Proposition 43.1.1](#)).
2. Under a regular design, a bounded-variation kernel and a twice-differentiable f , the local linear estimate has bias $\frac{1}{2} \mu_2 f''(x) h^2 + o(h^2)$ and variance $\sigma^2 R(K) / \{n h g(x)\}$; the local constant estimate adds $\mu_2 h^2 f' g' / g$ in the interior and a term of order h at the boundary. The optimal bandwidth is of order $n^{-1/5}$ and the pointwise mean squared error of order $n^{-4/5}$ ([Lemma 43.1.2](#), [Theorem 43.1.3](#)).
3. B-splines, defined by the de Boor recurrence, are nonnegative, supported on $d + 2$ consecutive knots, sum to one, are C^{d-1} at simple knots, have a derivative that is again a combination of B-splines, and form a basis of the spline space of

Theorem 42.3.1 (**Definition 43.2.1**, **Proposition 43.2.1**); coefficients at the Greville abscissae reproduce the identity (**Proposition 43.2.2**). The basis matrix is banded and well conditioned where the truncated power basis is neither.

4. A penalized spline takes a rich B-spline basis and a difference penalty (**Definition 43.3.1**). The fit is a generalized ridge regression: it shrinks the Demmler–Reinsch coordinates by $(1 + \lambda e_j)^{-1}$, spends $\text{tr}(\mathbf{S}_\lambda) = \sum_j (1 + \lambda e_j)^{-1}$ degrees of freedom, and as $\lambda \rightarrow \infty$ tends to the least squares fit in the null space of the penalty — a constant for $k = 1$, a line for $k = 2$ (**Lemma 43.3.1**, **Proposition 43.3.2**, **Proposition 43.3.3**). Once the penalty is there, the number of knots stops mattering.
5. Among all functions with square-integrable second derivative, the minimizer of $\sum_i \{y_i - f(x_i)\}^2 + \lambda \int f''^2$ is the natural cubic spline with knots at the design points (**Lemma 43.4.1**, **Theorem 43.4.2**). Its fit solves a pentadiagonal system in $O(n)$ operations (**Proposition 43.4.3**).
6. Every smoother here is a linear operator $\mathbf{S}_\lambda$. Its trace measures what was spent, $\sigma^2 \mathbf{S}_\lambda \mathbf{S}_\lambda^\top$ is the covariance of the fit, and the obvious pointwise interval is an interval for $E\{\hat{f}(x_i)\}$, not for $f(x_i)$ (**Proposition 43.5.1**).
7. The smoothing parameter can be chosen by leave-one-out cross-validation, which needs no refitting, by generalized cross-validation, which needs only the trace, or by a corrected AIC: they agree in large samples with independent errors, differ in the upper tail, and all overfit badly when the errors are correlated (**Theorem 43.5.2**).
8. A quadratic penalty is a normal prior. Splitting the coefficients into the penalty’s null space and its complement turns a penalized spline into a linear mixed model with $\lambda = \sigma^2/\sigma_u^2$, so that REML estimates the smoothing parameter and the posterior supplies a band (**Theorem 43.6.1**). That band is wider than the naive one by roughly the amount needed to absorb the bias on average — stated, not proved, in **Proposition 43.6.2(c)** — which buys across-the-function coverage and not pointwise coverage.

43.7.2 Notes and sources

Kernels and local polynomials. The local constant estimator is due independently to Nadaraya (1964) and Watson (1964), and the optimality of the kernel named after him to Epanechnikov (1969), though as **Exercise (B2)** shows the gain is a few per cent. The modern theory of local *polynomial* fitting is Fan and Gijbels (1996), whose chapter 3 has the random-design version of **Theorem 43.1.3** with the conditional expansions handled properly; Wand and Jones (1995) give the background. The design-bias and boundary-bias comparisons in **Theorem 43.1.3(b)** and (c) are why local linear replaced Nadaraya–Watson, an argument made forcefully by Hastie and Loader (1993). The fixed-design proof given here, through **Lemma 43.1.2**, makes every error term explicit; the price is assumption (A), and **Exercise (C2)** says what changes without it. That the rate $n^{-4/5}$ cannot be improved for twice-differentiable f is Stone (1980, 1982), whose curse of dimensionality is what makes **Chapter 44** necessary. Loess is Cleveland (1979), extended by Cleveland and Devlin (1988), and plug-in bandwidths are Ruppert, Sheather and Wand (1995).

B-splines. Splines as a subject begin with Schoenberg (1946). The stable recurrence **Eq. 43.2.2** is due to de Boor (1972) and Cox (1972); de Boor (2001) is the standard reference and contains Marsden’s identity, the Curry–Schoenberg theorem that the B-splines span the spline space for a general knot sequence, and the general form of **Proposition 43.2.2**. The proofs here need only

the recurrence, the partition of unity and the derivative formula, and are stated for the clamped sequence; the induction in [Proposition 43.2.1\(f\)](#) is the shortest route I know to the basis property for it.

Penalized splines. Penalizing differences of a fitted sequence is Whittaker’s (1923) graduation, rediscovered many times; its marriage with the B-spline basis is Eilers and Marx (1996), which introduced both the name and the practice of taking many knots and letting the penalty do the work. O’Sullivan (1986) had earlier used the integral penalty on a B-spline basis, and Wand and Ormerod (2008) relate the two. Ruppert (2002) is the source of the rule of thumb for the knot count and Ruppert, Wand and Carroll (2003) the book-length treatment. The simultaneous diagonalization of [Lemma 43.3.1](#) goes back to Demmler and Reinsch (1975).

Smoothing splines. Reinsch (1967) gave the algorithm; the variational characterization [Theorem 43.4.2](#) and the integration-by-parts argument behind it are due to Schoenberg and to Reinsch, and the treatment here follows Green and Silverman (1994, ch. 2), whose band matrices are those of [Proposition 43.4.3](#). Wahba (1990) is the definitive account from the reproducing-kernel side, with the representer theorem of Kimeldorf and Wahba (1971) at its centre; Eubank (1999) is gentler. Silverman (1984) computed the equivalent kernel quoted in [Section 43.4](#), and Silverman (1985) surveys the approach; the $O(n)$ computation of the diagonal of $\mathbf{S}_\lambda$ is Hutchinson and de Hoog (1985).

Choosing the smoothing parameter. Generalized cross-validation is Craven and Wahba (1979), and the leave-one-out shortcut for quadratic penalties is [Theorem 29.3.2](#). The corrected AIC [Eq. 43.5.5](#) is Hurvich, Simonoff and Tsai (1998), who make the case that its pole is a feature. Opsomer, Wang and Yang (2001) review what correlated errors do, which is what [Example \(What correlated errors do\)](#) illustrates: no automatic rule separates a smooth mean from smooth noise without an assumption. Reiss and Ogden (2009) compare REML and GCV. Nothing here addresses inference *after* the selection except by saying so; [Proposition 29.5.1](#) is the warning, and the remedies are those of [Chapter 23](#) and [Chapter 29](#).

Mixed models and Bayes. The equivalence between a smoothing penalty and a random effect is old — implicit in Whittaker’s graduation and explicit in Wahba (1978) — and was made into a working method by Ruppert, Wand and Carroll (2003), whose chapter 4 contains the transformation of [Theorem 43.6.1\(a\)](#) in essentially the form given here. Wahba (1983) introduced the Bayesian band and Nychka (1988) analysed its coverage, coining the across-the-function reading that [Proposition 43.6.2\(c\)](#) states; that part is quoted, not proved, and the simulation in [Example \(Measuring the coverage\)](#) is the evidence offered for it. Sun and Loader (1994) give genuinely simultaneous bands. The adaptive methods named at the end of [Section 43.6](#) are Denison, Mallick and Smith (1998), Donoho and Johnstone (1994) and Ramsay (1988).

Coverage. This chapter follows the ground of Fahrmeir, Kneib, Lang and Marx (2021, §8.1 and §8.3); their §8.2, on bivariate and spatial smoothing, belongs to [Chapter 44](#), as does Hastie and Tibshirani (1990), the book that made smoothers part of the regression curriculum.

Chapter 44

Additive, Geoadditive and Structured Additive Models

[Chapter 43](#) learned to estimate one unknown curve. Real data sets have a dozen covariates, and one unknown surface in a dozen dimensions is hopeless: no neighbourhood of a point holds enough observations to average. The way out is a structural assumption weaker than linearity but far stronger than nothing — the covariates act **additively**, each through its own unknown function — which turns a hopeless problem into a stack of one-dimensional ones held together by a single penalized criterion.

This chapter builds that framework and keeps widening it. A coefficient may vary smoothly with a second covariate. A term may be a spatial effect, penalized towards its neighbours on a map or towards a smooth surface over coordinates. A term may be a random intercept, a penalized term whose penalty is the identity. All of these are *one* model — a structured additive predictor — with *one* estimation theory: a quadratic penalty per term, effective degrees of freedom from a trace, smoothing parameters from a restricted likelihood, and a Bayesian reading in which every penalty is a prior. The last section puts a link and a response distribution in front of that predictor and closes the circle with [Part VIII](#).

What you need. [Chapter 6](#) (projections, the trace as a rank, [Proposition 6.3.4](#), and [Theorem 6.6.2](#)), [Chapter 26](#) (collinearity and the variance inflation factor, [Definition 26.2.1](#)), [Chapter 27](#) and [Chapter 30](#) (ridge, penalized least squares and effective degrees of freedom, [Theorem 27.2.2](#) and [Definition 30.1.1](#)), [Chapter 29](#) (cross-validation and information criteria, [Theorem 29.3.2](#), [Definition 29.3.2](#), [Proposition 29.5.1](#)), [Chapter 32](#) (mixed models, BLUP and REML, [Definition 32.2.1](#), [Theorem 32.3.1](#), [Theorem 32.4.2](#)), [Chapter 34](#) (the generalized linear model and IRLS, [Definition 34.2.1](#), [Theorem 34.4.1](#)), [Chapter 38](#) (quasi-likelihood and dispersion, [Definition 38.2.1](#), [Proposition 38.3.2](#)), [Chapter 39](#) (the Bayesian machinery, [Definition 39.4.1](#), [Proposition 39.5.1](#)) and, above all, [Chapter 43](#), whose P-spline blocks and smoothing-parameter criteria are used here as given.

Remark (Notation in this chapter). A **term** is a pair: a design block $\mathbf{Z}_j$ of size $n \times d_j$ and a nonnegative definite penalty $\mathbf{P}_j$, with coefficients $\boldsymbol{\gamma}_j$ and smoothing parameter λ_j — the $\mathbf{P}$, $\boldsymbol{\gamma}$ and λ of [Chapter 43](#), now carrying a term index. So $\mathbf{Z}$ keeps its meaning from [Part VII](#), the design of the coefficients that are shrunk, and [Section 44.5](#) shows the two uses are the same. Unpenalized columns stay in $\mathbf{X}$ with coefficients $\boldsymbol{\beta}$; $\mathbf{A} = \mathbf{Z}^\top \mathbf{W} \mathbf{Z} + \mathbf{P}$ is the penalized cross-product, $\mathbf{W}$ the working weights of [Chapter 34](#), $\mathbf{S}$ the smoother matrix and $\mathbf{C}_j$ the operator producing the j th component.

44.0.1 Roadmap

- The additive model
- Backfitting and concurvity
- Varying-coefficient models
- Spatial effects
- Structured additive regression
- Generalized additive models
- Summary and notes

44.1 The additive model

Suppose a response depends on five continuous covariates and nothing is known about the shape of that dependence. The honest model is $E(Y \mid \mathbf{z}) = f(z_1, \dots, z_5)$, f unknown and smooth. Chapter 43 estimated such an f from one covariate by averaging the responses near the point of interest; in five dimensions that fails, for a reason that has nothing to do with the estimator.

44.1.1 Why additivity

Take n points spread over the unit cube in q dimensions. To collect a fixed fraction c of them, a cube-shaped neighbourhood must have side $c^{1/q}$: with $c = 0.05$ that is 0.05 in one dimension, about 0.55 in five and about 0.74 in ten. An average over three quarters of the range of every covariate is not local, and no estimator repairs that: the data are not dense enough. This is the *curse of dimensionality*, and the rates make it quantitative. For a twice-differentiable curve Theorem 43.1.3 gives a mean squared error of order $n^{-4/5}$; in q dimensions the same expansion gives $n^{-4/(4+q)}$, and no estimator does better for twice-differentiable regression functions (Stone, 1980, whose conditions and proof are not reproduced here). At $q = 5$ a twelve-fold increase in sample size buys only what a four-fold increase buys in one dimension.

The response is to restrict the shape of f — not to a linear function, usually too severe a restriction, but to a sum of functions of one variable each.

Definition 44.1.1 — Additive model

Let $(y_i, \mathbf{x}_{(i)}, z_{i1}, \dots, z_{iq})$, $i = 1, \dots, n$, be observed, where $\mathbf{x}_{(i)}^\top$ is the i th row of an $n \times p$ matrix $\mathbf{X}$ whose first column is $\mathbf{1}$. The **additive model** is

$$y_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \sum_{j=1}^q f_j(z_{ij}) + \varepsilon_i, \quad E(\varepsilon_i) = 0, \quad \text{Var}(\varepsilon_i) = \sigma^2, \quad (44.1.1)$$

with the ε_i uncorrelated, the f_j unknown smooth functions, and the **identifiability constraints**

$$\sum_{i=1}^n f_j(z_{ij}) = 0, \quad j = 1, \dots, q. \quad (44.1.2)$$

The vector $\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} + \sum_j \mathbf{f}_j$, where $\mathbf{f}_j = \{f_j(z_{1j}), \dots, f_j(z_{nj})\}^\top$, is the **additive predictor**. If $\mathbf{X} = \mathbf{1}$ the model is *purely additive*; otherwise it is a **partial linear** or semiparametric model.

Two comments at once. The model contains no interactions: the effect of z_1 is the same curve whatever z_2 does, and [Section 44.3](#) buys some of that flexibility back. And [Eq. 44.1.2](#) is not a restriction on the model but a choice of representation, because the additive predictor fixes the pieces only up to constants.

Proposition 44.1.1 — Identifiability of the components

Write $\mathcal{V}_j$ for the linear space of vectors $\{g(z_{1j}), \dots, g(z_{nj})\}^\top$ as g ranges over the functions the j th term is allowed to take, and assume $\mathbf{1} \in \mathcal{V}_j$ for each j .

- (a) If $(\boldsymbol{\beta}, f_1, \dots, f_q)$ and $(\tilde{\boldsymbol{\beta}}, \tilde{f}_1, \dots, \tilde{f}_q)$ give the same additive predictor and both satisfy [Eq. 44.1.2](#), then every difference $\mathbf{f}_j - \tilde{\mathbf{f}}_j$ is orthogonal to $\mathbf{1}$, and so is $\mathbf{X}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = -\sum_j (\mathbf{f}_j - \tilde{\mathbf{f}}_j)$. If in addition the centred spaces $\mathcal{C}(\mathbf{X}) \cap \mathbf{1}^\perp$, $\mathcal{V}_1 \cap \mathbf{1}^\perp, \dots, \mathcal{V}_q \cap \mathbf{1}^\perp$ admit no nontrivial relation — no *exact concavity*, the condition studied in [Section 44.2](#) — then $\mathbf{X}\boldsymbol{\beta} = \mathbf{X}\tilde{\boldsymbol{\beta}}$ and $\mathbf{f}_j = \tilde{\mathbf{f}}_j$ for every j .
- (b) Without [Eq. 44.1.2](#) the components are determined only up to constants that sum to zero: replacing f_j by $f_j + c_j$ with $\sum_j c_j = 0$ leaves $\boldsymbol{\eta}$ unchanged.
- (c) If $\mathbf{f}_j = \mathbf{Z}_j \boldsymbol{\gamma}_j$ for a design block $\mathbf{Z}_j$, the constraint $\mathbf{1}^\top \mathbf{Z}_j \boldsymbol{\gamma}_j = 0$ is imposed exactly by writing $\boldsymbol{\gamma}_j = \mathbf{U}_j \boldsymbol{\alpha}_j$, where the columns of $\mathbf{U}_j$ are an orthonormal basis of $\{\boldsymbol{\gamma} : \mathbf{1}^\top \mathbf{Z}_j \boldsymbol{\gamma} = 0\}$: minimizing any criterion over $\boldsymbol{\alpha}_j$ with design $\mathbf{Z}_j \mathbf{U}_j$ and penalty $\mathbf{U}_j^\top \mathbf{P}_j \mathbf{U}_j$ is the same as minimizing it over $\boldsymbol{\gamma}_j$ subject to the constraint.

Proof.

- (b) is immediate from $\sum_j (f_j + c_j) = \sum_j f_j + \sum_j c_j$. For (a), equality of the predictors gives $\mathbf{X}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = -\sum_j (\mathbf{f}_j - \tilde{\mathbf{f}}_j)$. Each difference $\mathbf{f}_j - \tilde{\mathbf{f}}_j$ lies in $\mathcal{V}_j \cap \mathbf{1}^\perp$, because both terms satisfy [Eq. 44.1.2](#), so the left-hand side lies in $\mathcal{C}(\mathbf{X}) \cap \mathbf{1}^\perp$ and the displayed equation is a relation among the centred spaces. That alone does not separate the pieces. Under the additional hypothesis the relation must be trivial, so $\mathbf{X}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = \mathbf{0}$ and every difference vanishes.

For (c), $\{\boldsymbol{\gamma} : \mathbf{1}^\top \mathbf{Z}_j \boldsymbol{\gamma} = 0\}$ is the null space of the row vector $\mathbf{c}^\top = \mathbf{1}^\top \mathbf{Z}_j$, of dimension $d_j - 1$ when $\mathbf{c} \neq \mathbf{0}$, and $\mathbf{U}_j$ is a bijection from $\mathbb{R}^{d_j-1}$ onto it. At $\boldsymbol{\gamma}_j = \mathbf{U}_j \boldsymbol{\alpha}_j$ the design term is $(\mathbf{Z}_j \mathbf{U}_j) \boldsymbol{\alpha}_j$ and the penalty $\boldsymbol{\alpha}_j^\top (\mathbf{U}_j^\top \mathbf{P}_j \mathbf{U}_j) \boldsymbol{\alpha}_j$, so the two minimizations agree at corresponding points and the correspondence is onto the feasible set. ■

A QR factorization of $\mathbf{Z}_j^\top \mathbf{1}$ produces $\mathbf{U}_j$ in one line: the first column of $\mathbf{Q}$ spans $\mathbf{c}$, the rest its orthogonal complement. Absorbing the constraint this way rather than centring the columns of $\mathbf{Z}_j$ matters, because a basis with the partition-of-unity property of [Proposition 43.2.1](#) has $\mathbf{Z}_j \mathbf{1} = \mathbf{1}$: subtracting column means leaves $\mathbf{Z}_j$ with a null vector and the penalized cross-product singular ([Exercise \(B1\)](#)).

44.1.2 Terms, designs and penalties

Every term in this chapter is represented in a basis. Choose d_j basis functions for the j th component and write

$$f_j(z) = \sum_{l=1}^{d_j} \gamma_{jl} B_{jl}(z), \quad \mathbf{f}_j = \mathbf{Z}_j \boldsymbol{\gamma}_j, \quad (\mathbf{Z}_j)_{il} = B_{jl}(z_{ij}), \quad (44.1.3)$$

after which the constraint of [Proposition 44.1.1\(c\)](#) has been absorbed, so that $\mathbf{Z}_j$ has d_j columns summing to zero. With the B-spline basis of [Definition 43.2.1](#) and the difference penalty of [Definition 43.3.1](#) this is a P-spline block, the default term throughout the chapter; but nothing below uses that particular basis. All that is used is that the roughness of the j th component is a quadratic form $\boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j$ with $\mathbf{P}_j$ symmetric nonnegative definite.

The estimate is then the minimizer of a penalized least squares criterion in the sense of [Definition 30.1.1](#), with one penalty per term:

$$Q(\boldsymbol{\beta}, \boldsymbol{\gamma}_1, \dots, \boldsymbol{\gamma}_q) = \left\| \mathbf{y} - \mathbf{X}\boldsymbol{\beta} - \sum_{j=1}^q \mathbf{Z}_j \boldsymbol{\gamma}_j \right\|^2 + \sum_{j=1}^q \lambda_j \boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j. \quad (44.1.4)$$

Collect the pieces: let $\mathbf{Z} = [\mathbf{X}, \mathbf{Z}_1, \dots, \mathbf{Z}_q]$ with $d = p + \sum_j d_j$ columns, let $\boldsymbol{\gamma} = (\boldsymbol{\beta}^\top, \boldsymbol{\gamma}_1^\top, \dots, \boldsymbol{\gamma}_q^\top)^\top$, and let

$$\mathbf{P} = \begin{pmatrix} \mathbf{0} & & & \\ & \lambda_1 \mathbf{P}_1 & & \\ & & \ddots & \\ & & & \lambda_q \mathbf{P}_q \end{pmatrix} \quad (44.1.5)$$

be the block-diagonal penalty, with a zero block for the unpenalized columns. Then [Eq. 44.1.4](#) is $\|\mathbf{y} - \mathbf{Z}\boldsymbol{\gamma}\|^2 + \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}$, a ridge-type criterion with a structured penalty, and differentiating gives the **penalized normal equations**

$$\mathbf{A}\boldsymbol{\gamma} = \mathbf{Z}^\top \mathbf{y}, \quad \mathbf{A} = \mathbf{Z}^\top \mathbf{Z} + \mathbf{P}. \quad (44.1.6)$$

Example. (Two P-spline blocks)

Take $q = 2$, a cubic B-spline basis of 15 functions on equally spaced knots for each covariate, and the second-difference penalty of [Definition 43.3.1](#). Unconstrained, each block has 15 columns summing to $\mathbf{1}$ row by row and a penalty of rank 13; after [Proposition 44.1.1\(c\)](#) it has 14 columns summing to zero and a penalty of the same rank, so $\mathbf{Z} = [\mathbf{1}, \mathbf{Z}_1, \mathbf{Z}_2]$ has 29 columns. Of the two unpenalized directions per block, constant and linear trend, the constraint removes one: the term still fits a straight line in z_j free of charge, but not an arbitrary level.

44.1.3 The fit is a linear smoother

Because [Eq. 44.1.4](#) is quadratic, the fit is linear in $\mathbf{y}$ — a linear smoother in the sense of [Proposition 43.5.1](#) — and every quantity of interest is a trace, exactly as for ridge regression.

Proposition 44.1.2 — Smoother matrix and degrees of freedom

Suppose $\mathbf{A} = \mathbf{Z}^\top \mathbf{Z} + \mathbf{P}$ is nonsingular, and let $\mathbf{C} = \mathbf{A}^{-1} \mathbf{Z}^\top$, so that $\hat{\mathbf{y}} = \mathbf{C} \mathbf{y}$. Write $\mathbf{C}_j = \mathbf{Z}_j \mathbf{C}_{[j]}$, where $\mathbf{C}_{[j]}$ holds the rows of $\mathbf{C}$ belonging to the j th block.

- (a) The fitted vector is $\hat{\mathbf{y}} = \mathbf{S} \mathbf{y}$ with $\mathbf{S} = \mathbf{Z} \mathbf{A}^{-1} \mathbf{Z}^\top$, a symmetric matrix whose eigenvalues lie in $[0, 1]$; the fitted j th component is $\hat{\mathbf{f}}_j = \mathbf{C}_j \mathbf{y}$, and $\mathbf{S} = \mathbf{X} \mathbf{C}_{[0]} + \sum_j \mathbf{C}_j$.
- (b) The **effective degrees of freedom** of the fit and of its terms are

$$\text{df} = \text{tr } \mathbf{S} = \text{tr}(\mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{Z}), \quad \text{df}_j = \text{tr } \mathbf{C}_j = d_j - \lambda_j \text{tr}\{(\mathbf{A}^{-1})_{jj} \mathbf{P}_j\}, \quad (44.1.7)$$

and they add: $\text{df} = p + \sum_j \text{df}_j$. Each df_j decreases from d_j at $\lambda_j = 0$ towards $\dim \mathcal{N}(\mathbf{P}_j)$ as $\lambda_j \rightarrow \infty$.

- (c) If $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, then $\text{Cov}(\hat{\mathbf{y}}) = \sigma^2 \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{Z} \mathbf{A}^{-1}$ and $\text{Cov}(\hat{\mathbf{f}}_j) = \sigma^2 \mathbf{C}_j \mathbf{C}_j^\top$.

Proof.

- (a) Solving [Eq. 44.1.6](#) gives $\hat{\mathbf{y}} = \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{y}$ and $\hat{\mathbf{y}} = \mathbf{Z} \hat{\mathbf{y}} = \mathbf{S} \mathbf{y}$. Symmetry is clear, and $\mathbf{v}^\top \mathbf{S} \mathbf{v} \geq 0$ because $\mathbf{A}^{-1}$ is positive definite. For the upper bound, fix $\mathbf{v}$ and put $\mathbf{u} = \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{v}$, so that $\mathbf{A} \mathbf{u} = \mathbf{Z}^\top \mathbf{v}$. Then

$$\mathbf{v}^\top \mathbf{S} \mathbf{v} = \mathbf{u}^\top \mathbf{A} \mathbf{u} = \|\mathbf{Z} \mathbf{u}\|^2 + \mathbf{u}^\top \mathbf{P} \mathbf{u} \geq \|\mathbf{Z} \mathbf{u}\|^2,$$

while also $\mathbf{v}^\top \mathbf{S} \mathbf{v} = \mathbf{v}^\top (\mathbf{Z} \mathbf{u}) \leq \|\mathbf{v}\| \|\mathbf{Z} \mathbf{u}\| \leq \|\mathbf{v}\| \sqrt{\mathbf{v}^\top \mathbf{S} \mathbf{v}}$ by Cauchy–Schwarz. Dividing by $\sqrt{\mathbf{v}^\top \mathbf{S} \mathbf{v}}$ when it is nonzero gives $\mathbf{v}^\top \mathbf{S} \mathbf{v} \leq \|\mathbf{v}\|^2$, so the eigenvalues lie in $[0, 1]$. Splitting $\mathbf{Z} \hat{\mathbf{y}}$ by blocks gives the last identity.

- (b) $\text{tr } \mathbf{S} = \text{tr}(\mathbf{Z} \mathbf{A}^{-1} \mathbf{Z}^\top) = \text{tr}(\mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{Z})$ by the cyclic property, and $\mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{Z} = \mathbf{A}^{-1}(\mathbf{A} - \mathbf{P}) = \mathbf{I} - \mathbf{A}^{-1} \mathbf{P}$. The j th diagonal block of $\mathbf{A}^{-1} \mathbf{P}$ is $\lambda_j (\mathbf{A}^{-1})_{jj} \mathbf{P}_j$, and the block belonging to the unpenalized columns is zero; taking traces block by block gives both formulas in [Eq. 44.1.7](#) and their sum. Monotonicity in λ_j is [Exercise \(B2\)](#), and as $\lambda_j \rightarrow \infty$ the term is forced into $\mathcal{N}(\mathbf{P}_j)$, which costs $\dim \mathcal{N}(\mathbf{P}_j)$ dimensions.
- (c) Both are immediate from $\text{Cov}(\mathbf{M} \mathbf{Y}) = \mathbf{M} \text{Cov}(\mathbf{Y}) \mathbf{M}^\top$ ([Theorem 2.2.1](#)).

■

Part (b) is the additive-model version of [Theorem 27.2.2\(b\)](#): each term is charged for the dimensions it uses, and the charges add up. The split makes a printed summary readable — “living area: 5.3 degrees of freedom” says at a glance how far from a straight line the curve is — and it is what [Chapter 29](#) needs, since [Definition 29.3.2](#) and [Proposition 29.2.4](#) apply verbatim with df in place of the number of parameters.

Warning. The degrees of freedom of a *term* are not the degrees of freedom of a test: they are a trace computed at a fixed λ , and nothing so far says that df_j is the right

divisor for a sum of squares or the right parameter for a reference distribution. [Section 44.6](#) returns to it.

44.1.4 Exercises

44.1.4.1 A. Check your understanding

Exercise A1.

Repeat the neighbourhood calculation of [Section 44.1](#): what side length does a cube-shaped neighbourhood need in order to contain 1% of n points uniformly spread over the unit cube in q dimensions, for $q = 1, 3, 10$? At what q does the required side exceed 0.5?

44.1.4.2 B. Practice

Exercise B1.

Let $\mathbf{Z}_j$ be a B-spline block with the partition-of-unity property, so $\mathbf{Z}_j \mathbf{1} = \mathbf{1}$, and let $\mathbf{P}_j$ be a difference penalty, so $\mathbf{P}_j \mathbf{1} = \mathbf{0}$. Show that centring the *columns*, that is replacing $\mathbf{Z}_j$ by $(\mathbf{I} - n^{-1} \mathbf{1} \mathbf{1}^\top) \mathbf{Z}_j$, makes $\mathbf{Z}_j^\top \mathbf{Z}_j + \lambda_j \mathbf{P}_j$ singular, while the reparameterization of [Proposition 44.1.1\(c\)](#) does not.

Solution. Write $\tilde{\mathbf{Z}}_j = (\mathbf{I} - n^{-1} \mathbf{1} \mathbf{1}^\top) \mathbf{Z}_j$. Then $\tilde{\mathbf{Z}}_j \mathbf{1} = \mathbf{0}$, so $\mathbf{1}^\top (\tilde{\mathbf{Z}}_j^\top \tilde{\mathbf{Z}}_j + \lambda_j \mathbf{P}_j) \mathbf{1} = 0$ and the matrix is singular. Under (c) the matrix is $\mathbf{U}_j^\top (\mathbf{Z}_j^\top \mathbf{Z}_j + \lambda_j \mathbf{P}_j) \mathbf{U}_j$; if it killed some $\boldsymbol{\alpha} \neq \mathbf{0}$, then $\boldsymbol{\gamma} = \mathbf{U}_j \boldsymbol{\alpha}$ would satisfy $\mathbf{Z}_j \boldsymbol{\gamma} = \mathbf{0}$ and $\mathbf{P}_j \boldsymbol{\gamma} = \mathbf{0}$. The second puts $\boldsymbol{\gamma}$ in the span of the constant, or of the constant and linear sequences for a second-difference penalty, and then $\mathbf{Z}_j \boldsymbol{\gamma} = \mathbf{0}$ forces $\boldsymbol{\gamma} = \mathbf{0}$, since the B-spline basis reproduces those functions exactly.

Exercise B2.

Show that df_j in [Eq. 44.1.7](#) is nonincreasing in λ_j . *Hint:* work with one term and no parametric part first, where $\text{df}(\lambda) = \sum_k \theta_k / (\theta_k + \lambda)$ for the eigenvalues θ_k of $\mathbf{Z}_j^\top \mathbf{Z}_j$ in the metric of $\mathbf{P}_j$.

Solution. Simultaneously diagonalize $\mathbf{Z}_j^\top \mathbf{Z}_j$ and $\mathbf{P}_j$: some nonsingular $\mathbf{T}$ gives $\mathbf{T}^\top \mathbf{Z}_j^\top \mathbf{Z}_j \mathbf{T} = \mathbf{I}$ and $\mathbf{T}^\top \mathbf{P}_j \mathbf{T} = \text{diag}(\nu_k)$, $\nu_k \geq 0$, by [Corollary 1.7.8\(b\)](#). Then $\text{df}(\lambda) = \sum_k 1/(1 + \lambda \nu_k)$, decreasing in λ except where $\nu_k = 0$, which contributes $\dim \mathcal{N}(\mathbf{P}_j)$ whatever λ is. With several terms, argue the same way on the j th block of $\mathbf{A}^{-1} \mathbf{P}$, treating the others as part of $\mathbf{Z}^\top \mathbf{Z}$.

Exercise B3.

In [Definition 44.1.1](#) take $q = 1$ and let $\mathbf{X}$ be a general parametric design. Show that the penalized estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}} = \{\mathbf{X}^\top (\mathbf{I} - \mathbf{S}_1) \mathbf{X}\}^{-1} \mathbf{X}^\top (\mathbf{I} - \mathbf{S}_1) \mathbf{y}$ where $\mathbf{S}_1 = \mathbf{Z}_1 (\mathbf{Z}_1^\top \mathbf{Z}_1 + \lambda_1 \mathbf{P}_1)^{-1} \mathbf{Z}_1^\top$ — the Frisch–Waugh–Lovell form of [Theorem 6.6.2](#) with the smoother in place of a projection. What changes in the proof?

44.1.4.3 C. Going deeper

Exercise C1.

An additive model has no interactions. Show that if the true mean is $f(z_1, z_2) = z_1 z_2$ on $[0, 1]^2$ with z_1, z_2 independent and uniform, the best additive approximation in mean square, $\arg \min_{g_1, g_2} E\{(Z_1 Z_2 - g_1(Z_1) - g_2(Z_2))^2\}$ subject to $E g_1(Z_1) = E g_2(Z_2) = 0$, is $g_1(z) = (z - \frac{1}{2})/2$, $g_2(z) = (z - \frac{1}{2})/2$ plus the constant $1/4$, and compute the mean squared approximation error.

44.2 Backfitting and concavity

Section 44.1 reduced the additive model to one penalized regression with $d = p + \sum_j d_j$ columns. When d is a few dozen, solving Eq. 44.1.6 directly is right and this section is only a change of view. When d runs into the thousands — one coefficient per district, one per subject — or when a term's smoother is not given by a basis at all, an older idea takes over: fit each term in turn to what the others have left behind, and go round again.

44.2.1 The algorithm

Write $\mathbf{S}_j$ for the smoother of the j th term, the linear operator that fits that term alone to a response vector:

$$\mathbf{S}_j = \mathbf{Z}_j (\mathbf{Z}_j^\top \mathbf{Z}_j + \lambda_j \mathbf{P}_j)^{-1} \mathbf{Z}_j^\top. \quad (44.2.1)$$

The **partial residual** for term j is what the response has left once every other part of the model is subtracted, $\mathbf{r}_j = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}} - \sum_{k \neq j} \hat{\mathbf{f}}_k$; backfitting replaces $\hat{\mathbf{f}}_j$ by $\mathbf{S}_j \mathbf{r}_j$ and moves on.

Backfitting.

1. Initialize $\hat{\boldsymbol{\beta}}$ by least squares of $\mathbf{y}$ on $\mathbf{X}$, and $\hat{\mathbf{f}}_j = \mathbf{0}$ for $j = 1, \dots, q$.
2. For $j = 1, \dots, q$ in turn, set $\mathbf{r}_j = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}} - \sum_{k \neq j} \hat{\mathbf{f}}_k$ and $\hat{\mathbf{f}}_j \leftarrow \mathbf{S}_j \mathbf{r}_j$.
3. Update $\hat{\boldsymbol{\beta}} \leftarrow (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top (\mathbf{y} - \sum_k \hat{\mathbf{f}}_k)$, and return to step 2 until the largest change in any $\hat{\mathbf{f}}_j$ is below a tolerance.

Each step is a one-dimensional smoothing problem of the kind Chapter 43 solved; the terms are never assembled into one large matrix; and a smoother *not* of the form Eq. 44.2.1 — a kernel estimate, a monotone fit — drops in unchanged. What is not obvious is that the cycling converges, and to what.

44.2.2 Backfitting is Gauss–Seidel

Theorem 44.2.1 — Backfitting

Consider the criterion Eq. 44.1.4 with blocks $\mathbf{Z}_0 = \mathbf{X}$, $\mathbf{P}_0 = \mathbf{0}$ and $\mathbf{Z}_1, \dots, \mathbf{Z}_q$, and

write $\mathbf{A}_{jj} = \mathbf{Z}_j^\top \mathbf{Z}_j + \lambda_j \mathbf{P}_j$, assumed nonsingular for every j . Let $\mathbf{A} = \mathbf{Z}^\top \mathbf{Z} + \mathbf{P}$ as in Eq. 44.1.6, so that $\mathbf{A}$ is nonnegative definite with diagonal blocks $\mathbf{A}_{jj}$.

- (a) (*Coordinate descent.*) The backfitting update of the j th block is the exact minimizer of Q over $\boldsymbol{\gamma}_j$ with all other blocks held fixed. In particular Q never increases along the iteration.
- (b) (*Gauss–Seidel.*) In terms of coefficients, the update is $\boldsymbol{\gamma}_j \leftarrow \mathbf{A}_{jj}^{-1} \mathbf{Z}_j^\top (\mathbf{y} - \sum_{k \neq j} \mathbf{Z}_k \boldsymbol{\gamma}_k)$, which is one block Gauss–Seidel sweep for the linear system $\mathbf{A} \boldsymbol{\gamma} = \mathbf{Z}^\top \mathbf{y}$. Fix any order of the blocks — the algorithm above takes them in the order $1, \dots, q, 0$ — and write $\mathbf{A} = \mathbf{L} + \mathbf{D} + \mathbf{L}^\top$ with $\mathbf{D}$ the block diagonal and $\mathbf{L}$ the strictly block lower triangular part in that order. One full cycle sends $\boldsymbol{\gamma}$ to $\mathbf{T} \boldsymbol{\gamma} + (\mathbf{D} + \mathbf{L})^{-1} \mathbf{Z}^\top \mathbf{y}$ with

$$\mathbf{T} = \mathbf{I} - (\mathbf{D} + \mathbf{L})^{-1} \mathbf{A}. \quad (44.2.2)$$

- (c) (*Convergence.*) Let $\boldsymbol{\gamma}^{(t)}$ be the iterates from any starting point and let $\hat{\boldsymbol{\gamma}}$ be any solution of $\mathbf{A} \boldsymbol{\gamma} = \mathbf{Z}^\top \mathbf{y}$. Then $\mathbf{A}^{1/2}(\boldsymbol{\gamma}^{(t)} - \hat{\boldsymbol{\gamma}}) \rightarrow \mathbf{0}$ geometrically. Consequently the fitted vector $\mathbf{Z} \boldsymbol{\gamma}^{(t)}$ converges to $\mathbf{Z} \hat{\boldsymbol{\gamma}}$, the criterion $Q(\boldsymbol{\gamma}^{(t)})$ converges to its minimum, and $\boldsymbol{\gamma}^{(t)}$ itself converges to a minimizer of Q , which may depend on the starting point.
- (d) (*Uniqueness.*) If $\mathbf{A}$ is positive definite, the limit is the unique solution $\mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{y}$ of Eq. 44.1.6, and the convergence is geometric in every norm.

Proof.

- (a) As a function of $\boldsymbol{\gamma}_j$ alone, with $\mathbf{r}_j = \mathbf{y} - \sum_{k \neq j} \mathbf{Z}_k \boldsymbol{\gamma}_k$,

$$Q = \|\mathbf{r}_j - \mathbf{Z}_j \boldsymbol{\gamma}_j\|^2 + \lambda_j \boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j + \text{const},$$

strictly convex because $\mathbf{A}_{jj}$ is nonsingular; its gradient vanishes at $\mathbf{A}_{jj} \boldsymbol{\gamma}_j = \mathbf{Z}_j^\top \mathbf{r}_j$, the stated update, and $\mathbf{Z}_j \boldsymbol{\gamma}_j = \mathbf{S}_j \mathbf{r}_j$ by Eq. 44.2.1. Each step minimizes Q in one block, so Q is nonincreasing.

- (b) The j th block row of $\mathbf{A} \boldsymbol{\gamma} = \mathbf{Z}^\top \mathbf{y}$ reads $\mathbf{A}_{jj} \boldsymbol{\gamma}_j + \sum_{k \neq j} \mathbf{Z}_j^\top \mathbf{Z}_k \boldsymbol{\gamma}_k = \mathbf{Z}_j^\top \mathbf{y}$, and solving it for $\boldsymbol{\gamma}_j$ with the other blocks at their current values is the update in (a); taking the *new* values for $k < j$ and the old for $k > j$ is block Gauss–Seidel. Over one full cycle the new iterate satisfies $(\mathbf{D} + \mathbf{L}) \boldsymbol{\gamma}^{\text{new}} = -\mathbf{L}^\top \boldsymbol{\gamma}^{\text{old}} + \mathbf{Z}^\top \mathbf{y}$, which rearranges to Eq. 44.2.2.
- (c) Put $\mathbf{E} = \mathbf{D} + \mathbf{L}$, so that $\mathbf{E} + \mathbf{E}^\top - \mathbf{A} = \mathbf{D}$. The error $\mathbf{e}^{(t)} = \boldsymbol{\gamma}^{(t)} - \hat{\boldsymbol{\gamma}}$ obeys $\mathbf{e}^{(t+1)} = \mathbf{T} \mathbf{e}^{(t)}$. For any $\mathbf{e}$, with $\mathbf{v} = \mathbf{E}^{-1} \mathbf{A} \mathbf{e}$ so that $\mathbf{T} \mathbf{e} = \mathbf{e} - \mathbf{v}$,

$$\mathbf{e}^\top \mathbf{A} \mathbf{e} - (\mathbf{T} \mathbf{e})^\top \mathbf{A} (\mathbf{T} \mathbf{e}) = 2\mathbf{v}^\top \mathbf{A} \mathbf{e} - \mathbf{v}^\top \mathbf{A} \mathbf{v} = 2\mathbf{v}^\top \mathbf{E} \mathbf{v} - \mathbf{v}^\top \mathbf{A} \mathbf{v} = \mathbf{v}^\top (\mathbf{E} + \mathbf{E}^\top - \mathbf{A}) \mathbf{v} = \mathbf{v}^\top \mathbf{D} \mathbf{v}, \quad (44.2.3)$$

using $\mathbf{A} \mathbf{e} = \mathbf{E} \mathbf{v}$ and the symmetry of $\mathbf{A}$. The matrix $\mathbf{D}$ is positive definite, so the $\mathbf{A}$ -seminorm of the error never increases, and it decreases strictly unless $\mathbf{v} = \mathbf{0}$, that is unless $\mathbf{A} \mathbf{e} = \mathbf{0}$.

For geometric decay, set $\mathbf{u} = \mathbf{A}^{1/2} \mathbf{e}$ and $\mathbf{N} = \mathbf{I} - \mathbf{A}^{1/2} \mathbf{E}^{-1} \mathbf{A}^{1/2}$, so that $\mathbf{A}^{1/2} \mathbf{T} \mathbf{e} = \mathbf{N} \mathbf{u}$. In terms of $\mathbf{u}$, Eq. 44.2.3 reads, for *every* $\mathbf{u} \in \mathbb{R}^d$,

$$\|\mathbf{u}\|^2 - \|\mathbf{N} \mathbf{u}\|^2 = \mathbf{v}^\top \mathbf{D} \mathbf{v}, \quad \mathbf{v} = \mathbf{E}^{-1} \mathbf{A}^{1/2} \mathbf{u}. \quad (44.2.4)$$

Now $\mathcal{C}(\mathbf{A}^{1/2})$ is invariant under $\mathbf{N}$, since $\mathbf{N}\mathbf{u} = \mathbf{u} - \mathbf{A}^{1/2}(\mathbf{E}^{-1}\mathbf{A}^{1/2}\mathbf{u})$, and on that subspace $\mathbf{v} = \mathbf{0}$ forces $\mathbf{A}^{1/2}\mathbf{u} = \mathbf{0}$, hence $\mathbf{u} = \mathbf{0}$. So Eq. 44.2.4 gives $\|\mathbf{N}\mathbf{u}\| < \|\mathbf{u}\|$ for every nonzero $\mathbf{u} \in \mathcal{C}(\mathbf{A}^{1/2})$, and its unit sphere is compact, so $\rho := \max\{\|\mathbf{N}\mathbf{u}\| : \mathbf{u} \in \mathcal{C}(\mathbf{A}^{1/2}), \|\mathbf{u}\| = 1\} < 1$. As $\mathbf{u}^{(0)} \in \mathcal{C}(\mathbf{A}^{1/2})$ and the subspace is invariant, $\|\mathbf{A}^{1/2}\mathbf{e}^{(t)}\| \leq \rho^t \|\mathbf{A}^{1/2}\mathbf{e}^{(0)}\|$.

Finally, $\|\mathbf{A}^{1/2}\mathbf{e}\|^2 = \mathbf{e}^\top \mathbf{A} \mathbf{e} = \|\mathbf{Z}\mathbf{e}\|^2 + \mathbf{e}^\top \mathbf{P} \mathbf{e}$, so both terms tend to zero, which gives $\mathbf{Z}\boldsymbol{\gamma}^{(t)} \rightarrow \mathbf{Z}\hat{\boldsymbol{\gamma}}$ and $Q(\boldsymbol{\gamma}^{(t)}) \rightarrow Q(\hat{\boldsymbol{\gamma}})$. For the coefficients themselves,

$$\boldsymbol{\gamma}^{(t+1)} - \boldsymbol{\gamma}^{(t)} = \mathbf{T}\mathbf{e}^{(t)} - \mathbf{e}^{(t)} = -\mathbf{E}^{-1}\mathbf{A}^{1/2}(\mathbf{A}^{1/2}\mathbf{e}^{(t)}),$$

whose norm is at most $\|\mathbf{E}^{-1}\mathbf{A}^{1/2}\| \rho^t \|\mathbf{A}^{1/2}\mathbf{e}^{(0)}\|$. These increments are summable, so $\boldsymbol{\gamma}^{(t)}$ converges to a point $\boldsymbol{\gamma}^\infty$ with $\mathbf{A}\boldsymbol{\gamma}^\infty = \mathbf{Z}^\top \mathbf{y}$: a minimizer of Q .

- (d) If $\mathbf{A}$ is positive definite then $\mathbf{A}^{1/2}$ is nonsingular, $\mathcal{C}(\mathbf{A}^{1/2}) = \mathbb{R}^d$, and the argument above gives $\|\mathbf{e}^{(t)}\| \leq c \rho^t \|\mathbf{e}^{(0)}\|$ for a constant c depending only on the condition number of $\mathbf{A}$.

■

The unpenalized case is the picture Chapter 6 draws.

Corollary 44.2.2 — Backfitting as alternating projection

If $\lambda_j = 0$ for every j and each $\mathbf{Z}_j$ has full column rank, then each $\mathbf{S}_j$ is the orthogonal projection onto $\mathcal{V}_j = \mathcal{C}(\mathbf{Z}_j)$ by Theorem 6.3.3, and backfitting converges to the orthogonal projection of $\mathbf{y}$ onto $\mathcal{V}_0 + \mathcal{V}_1 + \cdots + \mathcal{V}_q$. The fitted components are unique iff the only way to write $\mathbf{0}$ as $\sum_j \mathbf{v}_j$ with $\mathbf{v}_j \in \mathcal{V}_j$ is with every $\mathbf{v}_j = \mathbf{0}$.

Proof. With $\mathbf{P} = \mathbf{0}$ the criterion is $\|\mathbf{y} - \mathbf{Z}\boldsymbol{\gamma}\|^2$ and $\mathbf{A} = \mathbf{Z}^\top \mathbf{Z}$, nonnegative definite with nonsingular diagonal blocks, which is what Theorem 44.2.1(c) needs; its conclusion is $\mathbf{Z}\boldsymbol{\gamma}^{(t)} \rightarrow \mathbf{Z}\hat{\boldsymbol{\gamma}}$, and $\mathbf{Z}\hat{\boldsymbol{\gamma}} = \mathbf{M}\mathbf{y}$ is the projection onto $\mathcal{C}(\mathbf{Z}) = \sum_j \mathcal{V}_j$ by Theorem 6.4.1. The components are the coordinates of that projection in the sum, unique precisely when the sum is direct, which is the stated condition.

■

44.2.3 What it costs, and when to use it

Example. (Backfitting on two P-spline terms)

Two covariates on $[0, 1]$ come from a bivariate normal pair squashed through a hyperbolic tangent, so one correlation ρ controls their dependence; the mean is $3 + f_1(z_1) + f_2(z_2)$, cubic-like in the first component and a bump in the second, with normal errors of standard deviation 0.4. With $n = 400$, 15 cubic B-splines per term, second-difference penalties and $\lambda_1 = \lambda_2 = 8.0$, backfitting and one direct solve of Eq. 44.1.6 agree to 9.4×10^{-14} in the fitted values, as they must, using 11.64 effective degrees of freedom: 1 for the intercept, 5.34 and 5.30 for the two components.

The work is not shared. At $\rho = 0.0$ the backfitting change falls below 10^{-12} after 9

Figure 44.2.1: Backfitting on two P-spline terms. (a) and (b) the fitted components against the truth. (c) the largest change per cycle at three levels of dependence: geometric decay, at a rate that worsens as the terms grow harder to tell apart.

cycles, shrinking by a factor of about 0.015 per cycle; at $\rho = 0.5$ it takes 21 cycles and the factor is 0.240; at $\rho = 0.9$ it takes 121 cycles and the factor is 0.674. Figure 44.2.1 shows the fitted components and the three convergence curves, straight on a logarithmic scale as Theorem 44.2.1(c) predicts.

The blocks used throughout the chapter are built once and reused. A P-spline term is a basis, a difference penalty and the constraint of Proposition 44.1.1(c) absorbed into it:

```
import numpy as np
from scipy.interpolate import BSpline

def bspline_basis(x, n_basis=15, degree=3, lo=None, hi=None):
    """n_basis B-splines of the given degree on equally spaced knots covering the
    data."""
    lo = x.min() if lo is None else lo
    hi = x.max() if hi is None else hi
    inner = np.linspace(lo, hi, n_basis - degree + 1)
    h = inner[1] - inner[0]
    knots = np.r_[lo - h * np.arange(degree, 0, -1), inner, hi + h * np.arange(1,
    degree + 1)]
    return BSpline.design_matrix(np.clip(x, lo, hi), knots, degree, extrapolate=
    False).toarray()

def difference_penalty(d, order=2):
    """K = D'D for the order-th difference matrix D: the P-spline penalty."""
    D = np.diff(np.eye(d), n=order, axis=0)
    return D.T @ D

def spline_term(x, n_basis=15, order=2, weight=None):
    """A P-spline term: its design, its penalty, and the map from new covariate
    values to
    design rows. The constraint  $\sum_i f(x_i) = 0$  is absorbed into the basis, and
    weight = u turns the term into the varying-coefficient term  $f(x) u$ ."""
    lo, hi = x.min(), x.max()
    B = bspline_basis(x, n_basis, lo=lo, hi=hi)
    Q, _ = np.linalg.qr(B.sum(axis=0)[:, None], mode="complete")
    U = Q[:, 1:] # a basis of {gamma : sum_i f(x_i) = 0}
    Z = B if weight is None else B * np.asarray(weight)[:, None]
```

```

def design(xnew, wnew=None):
    Bn = bspline_basis(np.asarray(xnew, float), n_basis, lo=lo, hi=hi)
    return (Bn if wnew is None else Bn * np.asarray(wnew)[: , None]) @ U

return Z @ U, U.T @ difference_penalty(n_basis, order) @ U, design

def spline_block(x, n_basis=15, order=2, weight=None):
    """The (design, penalty) pair of spline_term, without the prediction map."""
    return spline_term(x, n_basis, order, weight)[:2]

```

The data of [Example \(Backfitting on two P-spline terms\)](#) are simulated from two dependent covariates:

```

def simulate(n, rho, seed=20440):
    """Two dependent covariates on [0, 1] and an additive mean with normal errors.
    """
    rng = np.random.default_rng(seed)
    u = rng.normal(size=(n, 2)) @ np.array([[1.0, rho], [0.0, np.sqrt(1 - rho**2)]])
    z1, z2 = 0.5 * (1 + np.tanh(0.8 * u[:, 0])), 0.5 * (1 + np.tanh(0.8 * u[:, 1]))
    f1 = 16.0 * (z1 - 0.5) ** 3 - 0.6 * np.sin(4.5 * z1)
    f2 = 1.4 * np.exp(-25 * (z2 - 0.35) ** 2) - 0.5 * z2
    f1, f2 = f1 - f1.mean(), f2 - f2.mean()
    y = 3.0 + f1 + f2 + rng.normal(scale=0.4, size=n)
    return z1, z2, f1, f2, y

```

Backfitting is a dozen lines, and the direct solve another dozen:

```

def backfit(y, blocks, lambdas, tol=1e-12, maxit=600):
    """Backfitting: cycle over the terms, refitting each to the current partial
    residual."""
    A = [Z.T @ Z + lam * K for (Z, K), lam in zip(blocks, lambdas)]
    f = [np.zeros_like(y) for _ in blocks]
    b0, history = y.mean(), []
    for _ in range(maxit):
        change = 0.0
        for j, (Z, _) in enumerate(blocks):
            r = y - b0 - sum(f[k] for k in range(len(blocks)) if k != j)
            new = Z @ np.linalg.solve(A[j], Z.T @ r) # smooth the partial
            residual
            change = max(change, np.abs(new - f[j]).max())
            f[j] = new
        history.append(change)
        if change < tol:
            break
    return b0, f, np.array(history)

def direct_fit(y, blocks, lambdas):
    """One solve of the penalized normal equations, with an intercept column in
    front."""
    Z = np.column_stack([np.ones(len(y))] + [Zj for Zj, _ in blocks])
    K = np.zeros((Z.shape[1], Z.shape[1]))
    start = 1
    for (_, Kj), lam in zip(blocks, lambdas):
        d = Kj.shape[0]
        K[start:start + d, start:start + d] = lam * Kj
        start += d

```

```

C = np.linalg.solve(Z.T @ Z + K, Z.T) # gamma = C y
edf = [np.trace(Zj @ C[s:s + Zj.shape[1]]) for Zj, s in
        zip([Zj for Zj, _ in blocks], np.cumsum([1] + [Zj.shape[1] for Zj, _ in
        blocks]))]
return Z @ (C @ y), np.trace(Z @ C), edf

```

The two agree, and [Proposition 44.1.2](#) falls out of the direct solve:

```

n, lam = 400, 8.0
z1, z2, f1_true, f2_true, y = simulate(n, rho=0.5)
blocks = [spline_block(z1), spline_block(z2)]
lambdas = [lam, lam]

b0, f, history = backfit(y, blocks, lambdas)
fitted, edf_total, edf = direct_fit(y, blocks, lambdas)
print("cycles:", len(history))
print("largest disagreement:", np.abs(fitted - (b0 + f[0] + f[1])).max())
print(f"edf {edf_total:.3f} = 1 + {edf[0]:.3f} + {edf[1]:.3f}")

```

The direct solve costs $O(nd^2 + d^3)$ and hands over $\mathbf{A}^{-1}$, hence [Proposition 44.1.2](#) and the covariances, free. Backfitting costs $O(\sum_j nd_j^2)$ a cycle, never forms a $d \times d$ matrix and accepts smoothers no penalty produces, but delivers only the fit and takes more cycles the more the terms depend on one another. Modern software solves directly with sparse factorizations; backfitting survives where d is enormous and where the terms are unusual. It is also close kin to the boosting algorithms of [Chapter 30](#), which fit a block to the current residual as backfitting does but damp the update and pick the block greedily instead of cycling ([Theorem 30.4.1](#)).

44.2.4 Concurvity

The rate in [Example \(Backfitting on two P-spline terms\)](#) worsens with ρ for the reason collinearity hurts a linear model: two terms that can each explain the same feature compete for it. Here the competition is between *function spaces*, not columns, and it has its own name.

Definition 44.2.1 — Concurvity

Let $\mathcal{V}_0 = \mathcal{C}(\mathbf{X})$ and $\mathcal{V}_j = \mathcal{C}(\mathbf{Z}_j)$ be the model spaces of the terms, all centred so that $\mathcal{V}_j \subseteq \mathbf{1}^\perp$ for $j \geq 1$. The terms exhibit **exact concurvity** if there exist $\mathbf{v}_j \in \mathcal{V}_j$, not all zero, with $\sum_{j \geq 0} \mathbf{v}_j = \mathbf{0}$. The **concurvity index** of term j is

$$\kappa_j = \max \left\{ \frac{\|\mathbf{M}_{-j} \mathbf{v}\|^2}{\|\mathbf{v}\|^2} : \mathbf{v} \in \mathcal{V}_j, \mathbf{v} \neq \mathbf{0} \right\} \in [0, 1], \quad (44.2.5)$$

where $\mathbf{M}_{-j}$ is the orthogonal projection onto $\sum_{k \neq j} \mathcal{V}_k$. Equivalently κ_j is the largest squared canonical correlation between $\mathcal{V}_j$ and $\sum_{k \neq j} \mathcal{V}_k$, and $\kappa_j = 1$ iff there is exact concurvity involving term j .

Proposition 44.2.3 — What concurvity does

With the notation of [Definition 44.2.1](#) and $\lambda_j = 0$ for all j :

- (a) $\mathbf{A} = \mathbf{Z}^\top \mathbf{Z}$ is singular iff there is exact concurvity. The fitted values are unaffected — they are the projection onto $\sum_j \mathcal{V}_j$ — but the decomposition into components is not unique.
- (b) Assume in addition that there is no exact concurvity and that each $\mathbf{Z}_j$ has full column rank. Then there is a direction $\mathbf{v} \in \mathcal{V}_j$, $\mathbf{v} \neq \mathbf{0}$, with

$$\text{Var}(\mathbf{v}^\top \hat{\mathbf{f}}_j) = \frac{\sigma^2 \|\mathbf{v}\|^2}{1 - \kappa_j}, \quad (44.2.6)$$

against the value $\sigma^2 \|\mathbf{v}\|^2$ that the same functional would have if $\mathcal{V}_j$ were orthogonal to the other spaces. The inflation factor is $1/(1 - \kappa_j)$, and in the single-column case $\mathcal{V}_j = \text{span}\{\mathbf{x}_j\}$ it is the variance inflation factor of [Definition 26.2.1](#), with $\text{Var}(\hat{\beta}_j) = \sigma^2 / \{\|\mathbf{x}_j\|^2(1 - \kappa_j)\}$.

- (c) (*What a penalty repairs.*) With $\lambda_j > 0$ for every j and $\mathcal{N}(\mathbf{Z}_j) \cap \mathcal{N}(\mathbf{P}_j) = \{\mathbf{0}\}$, the matrix $\mathbf{A}$ is nonsingular and the fitted components are unique, whatever κ_j may be.

Proof.

- (a) $\mathbf{Z}^\top \mathbf{Z}$ is singular iff $\mathbf{Z}\boldsymbol{\gamma} = \mathbf{0}$ for some $\boldsymbol{\gamma} \neq \mathbf{0}$, that is iff the vectors $\mathbf{v}_j = \mathbf{Z}_j \boldsymbol{\gamma}_j$ sum to zero without all being zero (if some $\boldsymbol{\gamma}_j \neq \mathbf{0}$ gives $\mathbf{v}_j = \mathbf{0}$, then $\mathbf{Z}_j$ itself is rank deficient, a within-term problem that the constraint of [Proposition 44.1.1\(c\)](#) and the choice of basis exclude). The fitted vector is the projection onto $\mathcal{C}(\mathbf{Z})$, which does not depend on the basis ([Theorem 6.3.6](#)).
- (b) Put $\mathbf{A}_j = \mathbf{Z}_j^\top \mathbf{Z}_j$, $\tilde{\mathbf{Z}}_j = (\mathbf{I} - \mathbf{M}_{-j})\mathbf{Z}_j$ and $\tilde{\mathbf{A}}_j = \tilde{\mathbf{Z}}_j^\top \tilde{\mathbf{Z}}_j$, both positive definite. Writing $\mathbf{v} = \mathbf{Z}_j \mathbf{c}$, [Eq. 44.2.5](#) says that $1 - \kappa_j$ is the minimum of $\mathbf{c}^\top \tilde{\mathbf{A}}_j \mathbf{c} / \mathbf{c}^\top \mathbf{A}_j \mathbf{c}$, attained at a generalized eigenvector $\mathbf{c}$ satisfying $\tilde{\mathbf{A}}_j \mathbf{c} = (1 - \kappa_j) \mathbf{A}_j \mathbf{c}$ by [Corollary 1.7.8](#). Now [Theorem 6.6.2](#) with $\mathbf{X}_1 = \mathbf{Z}_j$ and $\mathbf{X}_2$ the other blocks gives $\hat{\boldsymbol{\gamma}}_j = \tilde{\mathbf{A}}_j^{-1} \tilde{\mathbf{Z}}_j^\top \mathbf{y}$ and $\text{Cov}(\hat{\boldsymbol{\gamma}}_j) = \sigma^2 \tilde{\mathbf{A}}_j^{-1}$. Since $\mathbf{v}^\top \hat{\mathbf{f}}_j = \mathbf{c}^\top \mathbf{A}_j \hat{\boldsymbol{\gamma}}_j$,

$$\text{Var}(\mathbf{v}^\top \hat{\mathbf{f}}_j) = \sigma^2 \mathbf{c}^\top \mathbf{A}_j \tilde{\mathbf{A}}_j^{-1} \mathbf{A}_j \mathbf{c} = \frac{\sigma^2}{1 - \kappa_j} \mathbf{c}^\top \mathbf{A}_j \mathbf{c} = \frac{\sigma^2 \|\mathbf{v}\|^2}{1 - \kappa_j},$$

because the eigenvector relation gives $\tilde{\mathbf{A}}_j^{-1} \mathbf{A}_j \mathbf{c} = \mathbf{c} / (1 - \kappa_j)$. If $\mathcal{V}_j \perp \sum_{k \neq j} \mathcal{V}_k$, then $\tilde{\mathbf{A}}_j = \mathbf{A}_j$, $\kappa_j = 0$ and the variance is $\sigma^2 \|\mathbf{v}\|^2$. For a single column, $\tilde{\mathbf{A}}_j = \|(\mathbf{I} - \mathbf{M}_{-j})\mathbf{x}_j\|^2 = \|\mathbf{x}_j\|^2(1 - \kappa_j)$, which is [Exercise \(B1\)](#).

- (c) Under the stated condition, $\boldsymbol{\gamma}^\top \mathbf{A} \boldsymbol{\gamma} = \|\mathbf{Z}\boldsymbol{\gamma}\|^2 + \boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = 0$ forces $\mathbf{Z}_j \boldsymbol{\gamma}_j = \mathbf{0}$ and $\mathbf{P}_j \boldsymbol{\gamma}_j = \mathbf{0}$ for every j , hence $\boldsymbol{\gamma} = \mathbf{0}$. ■

Part (b) is what “concurvity is collinearity for function spaces” means precisely: the worst direction inside the j th model space pays exactly the inflation factor $1/(1 - \kappa_j)$, and κ_j is computed from the design alone, before any data are seen.

Remark (A penalty restores uniqueness, not precision). Part (c) says nothing about variances, and the usual informal claim — that they blow up as $\kappa_j \rightarrow 1$ — is not a theorem: with $\lambda_j > 0$ fixed, $\mathbf{A}$ stays nonsingular and the variances of [Proposition 44.1.2\(c\)](#) stay bounded. What the penalty does is take over the identification: the closer κ_j is to one, the less of $\hat{\mathbf{f}}_j$ is settled by the data and the more by $\mathbf{P}_j$. Exact variances cost one

Figure 44.2.2: Concurrency. (a) and (b) twenty-five replicate estimates of the first component (truth dashed) under weak and strong dependence. (c) its exact standard deviation at $z_1 = 0.3$ against the concurrency index [Eq. 44.2.5](#).

matrix inverse; compute them and κ_j , and report both.

Example. (Two covariates, one relation)

Let z_1 be uniform on $[0, 1]$ and $z_2 = z_1^{1.5} + \text{noise}$, and fit two P-spline terms with $\lambda = 5.0$ to $n = 300$ observations. The design is fixed and the criterion quadratic, so [Proposition 44.1.2\(c\)](#) gives the exact standard deviation of each component without simulation. As the noise falls from 0.30 through 0.10 to 0.03, the concurrency index of the first term climbs from 0.609 to 0.933 to 0.994, and the standard deviation of the first component at $z_1 = 0.3$ climbs from 0.049 to 0.087 to 0.207, an inflation of 4.2; over the same range the standard deviation of the *fitted mean* there moves only from 0.094 to 0.080. The fit is fine; its attribution to the two covariates is not.

```
def design(n, noise, seed=44012):
    """z2 is a noisy monotone function of z1: small noise means strong concurrency.
    """
    rng = np.random.default_rng(seed)
    z1 = rng.uniform(0, 1, n)
    z2 = np.clip(z1**1.5 + noise * rng.normal(size=n), 0.001, 0.999)
    return z1, z2

def concurrency(Z1, Z2):
    """The largest squared canonical correlation between the two column spaces."""
    Q1, _ = np.linalg.qr(Z1)
    Q2, _ = np.linalg.qr(Z2)
    return np.linalg.svd(Q1.T @ Q2, compute_uv=False)[0] ** 2
```

Warning. Concurrency is harder to spot than collinearity, because it is invisible in pairwise scatterplots and correlations: two covariates can be uncorrelated and still have model spaces that nearly intersect, since κ_j involves *all* smooth functions of each, not just the linear ones ([Exercise \(B3\)](#)). Report κ_j alongside the components, and treat a value near one as a warning that the individual curves, and any story told about them, are not identified by the data even though the predictions are.

44.2.5 Exercises

44.2.5.1 A. Check your understanding

Exercise A1.

Run backfitting with $q = 1$. How many cycles does it take, and why?

Solution. One. With a single block the update sets $\boldsymbol{\gamma}_1 = \mathbf{A}_{11}^{-1} \mathbf{Z}_1^\top \mathbf{y}$, which already solves Eq. 44.1.6; a second cycle reproduces it. In Theorem 44.2.1(b), $\mathbf{L} = \mathbf{0}$, so $\mathbf{T} = \mathbf{I} - \mathbf{A}^{-1} \mathbf{A} = \mathbf{0}$.

44.2.5.2 B. Practice

Exercise B1.

For $q = 2$ with no parametric part, show that the Gauss–Seidel iteration matrix $\mathbf{T}$ of Eq. 44.2.2 has spectral radius equal to the largest eigenvalue of $\mathbf{A}_{11}^{-1} \mathbf{A}_{12} \mathbf{A}_{22}^{-1} \mathbf{A}_{21}$, and that for unpenalized one-column blocks this is the squared correlation between the two columns.

Solution. With $\mathbf{D} + \mathbf{L} = \begin{pmatrix} \mathbf{A}_{11} & \mathbf{0} \\ \mathbf{A}_{21} & \mathbf{A}_{22} \end{pmatrix}$ and $\mathbf{L}^\top = \begin{pmatrix} \mathbf{0} & \mathbf{A}_{12} \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$,

$$\mathbf{T} = -(\mathbf{D} + \mathbf{L})^{-1} \mathbf{L}^\top = - \begin{pmatrix} \mathbf{0} & \mathbf{A}_{11}^{-1} \mathbf{A}_{12} \\ \mathbf{0} & -\mathbf{A}_{22}^{-1} \mathbf{A}_{21} \mathbf{A}_{11}^{-1} \mathbf{A}_{12} \end{pmatrix},$$

block triangular with eigenvalues 0 and those of $\mathbf{A}_{22}^{-1} \mathbf{A}_{21} \mathbf{A}_{11}^{-1} \mathbf{A}_{12}$, whose nonzero eigenvalues are those of $\mathbf{A}_{11}^{-1} \mathbf{A}_{12} \mathbf{A}_{22}^{-1} \mathbf{A}_{21}$. With one column per block and no penalty this is $(\mathbf{x}_1^\top \mathbf{x}_2)^2 / (\|\mathbf{x}_1\|^2 \|\mathbf{x}_2\|^2)$, the squared correlation of centred columns.

Exercise B2.

Modified backfitting. Suppose the smoothers $\mathbf{S}_j$ are not of the form Eq. 44.2.1 but are symmetric with eigenvalues in $[0, 1]$ and satisfy $\mathbf{S}_j \mathbf{1} = \mathbf{1}$. Show that replacing $\mathbf{S}_j$ by $\mathbf{S}_j^c = (\mathbf{I} - n^{-1} \mathbf{1} \mathbf{1}^\top) \mathbf{S}_j$ makes every fitted component sum to zero at each step, and that $\mathbf{A}$ in Theorem 44.2.1 is then replaced by a matrix with the same structure acting on $\mathbf{1}^\perp$.

Exercise B3.

Let z_1 be uniform on $[-1, 1]$ and $z_2 = z_1^2$. Show that $\text{Cov}(z_1, z_2) = 0$, so the two covariates are uncorrelated, and yet the two model spaces of quadratic functions exhibit exact concavity. What does this say about diagnosing concavity by a correlation matrix?

Solution. $E(Z_1 Z_1^2) = E(Z_1^3) = 0 = E(Z_1) E(Z_1^2)$, so the covariance is zero. But $g_1(z_1) = z_1^2$ lies in the first space, $g_2(z_2) = z_2$ in the second, and $g_1(z_{i1}) - g_2(z_{i2}) = 0$ for every i : a nontrivial additive relation, so $\kappa_1 = \kappa_2 = 1$. A correlation sees only the linear part of

the relation between covariates; concurvity sees all of it, so it must be measured on the model spaces.

44.2.5.3 C. Going deeper

Exercise C1.

Population backfitting. Let Z_1, Z_2 be random with $E(Y^2) < \infty$, and consider minimizing $E\{Y - g_1(Z_1) - g_2(Z_2)\}^2$ over centred square-integrable g_1, g_2 . Show that the minimizers satisfy $g_1(z) = E\{Y - g_2(Z_2) \mid Z_1 = z\} - c$ and symmetrically, and that the sample algorithm of this section is the empirical version with conditional expectation replaced by a smoother.

44.3 Varying-coefficient models

The additive model of [Definition 44.1.1](#) has no interactions: whatever z_2 does, the contribution of z_1 is the same curve. Throwing that restriction away brings back the curse of dimensionality, so relax it in one direction at a time. The most useful way keeps a *linear* effect and lets its slope move.

44.3.1 The model

Definition 44.3.1 — Varying-coefficient model

Let $u_1, \dots, u_n$ be the values of an **interaction variable** and $z_1, \dots, z_n$ those of an **effect modifier**. A **varying-coefficient term** is

$$f(z_i) u_i, \quad \sum_{i=1}^n f(z_i) = 0, \quad (44.3.1)$$

and the **varying-coefficient model** is a structured additive model ([Definition 44.1.1](#)) in which one or more of the terms have this form. Combined with a parametric column $\mathbf{u} = (u_1, \dots, u_n)^\top$ carrying a coefficient β_u , the total effect of $\mathbf{u}$ on the response is

$$E(y_i) = \dots + \{\beta_u + f(z_i)\} u_i, \quad (44.3.2)$$

so that $\beta_u + f(z)$ is the **coefficient function**: the slope in u at effect modifier value z . With $u_i \equiv 1$ the term is an ordinary smooth main effect, and with f constrained to be constant it is an ordinary linear effect.

Three readings of the same object:

- **An interaction**, the smooth analogue of the product term β_{uz} of [Section 5.7](#). Where a product term says the slope in u is *linear* in z , this one says only that it is smooth.

- **A factor-by-curve model**, when $\mathbf{u}$ indicates a group: each group gets its own deviation curve in z .
- **A time-varying coefficient**, when z is calendar time: the relationship has drifted, and the model does not say how.

44.3.2 Estimation is the same computation

Varying coefficients cost nothing new because the design of the term is a row-scaled basis.

Proposition 44.3.1 — A varying-coefficient term is an ordinary penalized term

Let $B_1, \dots, B_d$ be a basis for the effect modifier and $\mathbf{P}_0$ the penalty that the corresponding smooth main effect would use. Put $(\mathbf{Z})_{il} = u_i B_l(z_i)$.

- With $f = \sum_l \gamma_l B_l$, the vector of the term's contributions is $\{f(z_i)u_i\}_i = \mathbf{Z}\boldsymbol{\gamma}$, and the roughness of f is $\boldsymbol{\gamma}^\top \mathbf{P}_0 \boldsymbol{\gamma}$ as before. The term is therefore the pair $(\mathbf{Z}, \mathbf{P}_0)$, and everything in [Sections 44.1](#) and [44.2](#) applies unchanged.
- The constraint [Eq. 44.3.1](#) is $\mathbf{c}^\top \boldsymbol{\gamma} = 0$ with $\mathbf{c} = (\sum_i B_1(z_i), \dots, \sum_i B_d(z_i))^\top$ — the *unweighted* column sums of the basis, not of $\mathbf{Z}$ — and is absorbed by [Proposition 44.1.1\(c\)](#). Under it, β_u in [Eq. 44.3.2](#) is the average of the coefficient function over the design points, $\beta_u = n^{-1} \sum_i \{\beta_u + f(z_i)\}$.
- If $u_i \neq 0$ for at least d design points with distinct z_i and the basis is linearly independent there, $\mathbf{Z}$ has full column rank. Observations with $u_i = 0$ contribute nothing to the term: the coefficient function is estimated only where the interaction variable is nonzero.

Proof.

- The i th entry of $\mathbf{Z}\boldsymbol{\gamma}$ is $\sum_l \gamma_l u_i B_l(z_i) = u_i f(z_i)$. The penalty is a statement about f , so it is unchanged by multiplying the term by u_i .
- $\sum_i f(z_i) = \sum_l \gamma_l \sum_i B_l(z_i) = \mathbf{c}^\top \boldsymbol{\gamma}$, which is the stated constraint; [Proposition 44.1.1\(c\)](#) applies verbatim with $\mathbf{c}$ in place of $\mathbf{Z}^\top \mathbf{1}$. The averaging statement is then $n^{-1} \sum_i \{\beta_u + f(z_i)\} = \beta_u + n^{-1} \mathbf{c}^\top \boldsymbol{\gamma} = \beta_u$.
- Suppose $\mathbf{Z}\boldsymbol{\gamma} = \mathbf{0}$. Then $u_i f(z_i) = 0$ for all i , so $f(z_i) = 0$ at the d design points with $u_i \neq 0$; linear independence of the basis at those points forces $\boldsymbol{\gamma} = \mathbf{0}$. The last sentence is the same computation read forwards: rows with $u_i = 0$ are zero rows of $\mathbf{Z}$.

■

Warning. Constraining the *weighted* sum $\sum_i u_i f(z_i) = 0$ instead — what centring the columns of $\mathbf{Z}$ does — also identifies the model, but β_u is then not the average slope, and if $\mathbf{u}$ has been centred it means nothing at all, since $\sum_i u_i = 0$ leaves the constraint silent about the level of f . Use (b).

Figure 44.3.1: A varying coefficient on 50 US states. (a) the coefficient of poverty against the urban percentage, two standard errors wide; dashed, the constant slope from the model that keeps the smooth urban effect. (b) fitted murder rate against poverty at three levels of urbanization.

44.3.3 An example, and how far it can be pushed

Example. (Does poverty matter more in urban states?)

Example (Poverty and murder rates) fitted the murder rate of the 50 US states in 2009 on the poverty rate, the single-parent percentage and the urban percentage, reporting one coefficient for poverty. Here that coefficient may vary smoothly with how urban the state is:

$$\text{murder}_i = \beta_0 + \beta_1 \text{single}_i + \{\beta_2 + f(\text{urban}_i)\} (\text{poverty}_i - \overline{\text{poverty}}) + f_0(\text{urban}_i) + \varepsilon_i,$$

with P-spline terms of 8 basis functions for f and f_0 and smoothing parameters chosen by the restricted-likelihood updates of [Section 44.5](#). The fit uses 6.83 effective degrees of freedom in all, of which 1.82 go to the smooth main effect of urbanization and 2.01 to the coefficient function.

The average poverty slope is 0.250. Keeping the smooth main effect of urbanization but forcing the poverty slope to be constant gives 0.231, and [Example \(Poverty and murder rates\)](#), in which urbanization entered linearly as well, gave 0.2538. The estimated coefficient function rises from -0.034 at 20% urban to 0.364 at 60% and falls back to 0.152 at 90%: on its face, a story in which poverty is associated with homicide in middling states and not in the most rural ones.

That story does not survive its standard errors. The band of ± 2 standard errors in [Figure 44.3.1](#) contains the constant coefficient over the whole range, and the contrast between 60% and 20% urban is 0.398 with a standard error of 0.234 , a ratio of 1.70 . Fifty states and a residual standard deviation of 1.418 murders per 100,000 cannot resolve a coefficient function; they can only say that one is not needed.

Fitting takes no new code, because [Proposition 44.3.1\(a\)](#) has made this an ordinary term: the design is the P-spline basis in the urban percentage scaled row by row by the centred poverty column, the penalty is the same second-difference matrix, and the same solver handles it. The

band is read off the joint covariance of (β_2, γ) with $\beta_2 + f(z)$ evaluated on a grid; the code is `code/ch44/varying_coefficient.py`.

Remark (What a coefficient function means). [Example \(Does poverty matter more in urban states?\)](#) is an observational comparison across states, and [Chapter 25](#) applies to it word for word. A varying coefficient describes how an *association* changes with the modifier. Reading it as “raising poverty by one point in a 60%-urban state would raise the murder rate by 0.36” requires everything [Theorem 25.6.2](#) requires, and requires it separately at each level of the modifier, since the confounding structure may differ across it. The extra flexibility buys a richer description, not weaker causal assumptions.

44.3.4 Where varying coefficients take you

Two extensions use nothing beyond [Proposition 44.3.1](#). With z time and $\mathbf{u}$ a covariate observed repeatedly, $f(t_i)u_i$ is a coefficient drifting over the study; for series data the band must then come from [Part VII](#) rather than from the independence assumption of [Definition 44.1.1](#) ([Exercise \(B1\)](#)). With z a location and a spatial term from [Section 44.4](#) in place of the P-spline, the coefficient varies over a map, which is disease mapping; the same code with a different penalty.

When neither covariate deserves to be the linear one, a genuine bivariate term $f(z_1, z_2)$ is needed. The standard construction is a **tensor-product** basis $B_{lm}(z_1, z_2) = B_l^{(1)}(z_1)B_m^{(2)}(z_2)$ with the penalty

$$\mathbf{P} = \lambda_1(\mathbf{I} \otimes \mathbf{P}^{(1)}) + \lambda_2(\mathbf{P}^{(2)} \otimes \mathbf{I}), \quad (44.3.3)$$

penalizing roughness along each coordinate separately, and so invariant to the units of the two covariates. Everything in this chapter goes through for it, with two smoothing parameters instead of one. The book does not develop the construction further; how to scale the two penalties, how to separate the interaction from its main effects and how to display the surface belong to a book on smoothing, and Wood (2017) is where to find them. [Exercise \(C1\)](#) builds the smallest case by hand.

44.3.5 Exercises

44.3.5.1 A. Check your understanding

Exercise A1.

What does a varying-coefficient term become when (i) $u_i \equiv 1$; (ii) f is forced to be constant; (iii) f is forced to be linear in z ? Which of the three has a familiar name from [Part II](#)?

44.3.5.2 B. Practice

Exercise B1.

A varying-coefficient model is fitted to a time series, but the errors follow $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{V}$ with $\mathbf{V} \neq \mathbf{I}$. Show that the penalized estimate $\hat{\boldsymbol{\gamma}} = \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{y}$ is still unbiased for

the penalized target $\mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{E}(\mathbf{Y})$, but that its covariance is $\sigma^2\mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{V}\mathbf{Z}\mathbf{A}^{-1}$, not $\sigma^2\mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{Z}\mathbf{A}^{-1}$. If $\mathbf{V}$ has positive autocorrelations, in which direction is the naive band wrong?

Solution. Linearity gives both at once: $\mathbf{E}(\mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{Y}) = \mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{E}(\mathbf{Y})$ and $\text{Cov}(\mathbf{A}^{-1}\mathbf{Z}^\top \mathbf{Y}) = \mathbf{A}^{-1}\mathbf{Z}^\top \text{Cov}(\mathbf{Y})\mathbf{Z}\mathbf{A}^{-1}$ (Theorem 2.2.1). Under positive autocorrelation $\mathbf{Z}^\top \mathbf{V}\mathbf{Z} - \mathbf{Z}^\top \mathbf{Z}$ is typically nonnegative definite for smooth columns, so the true variance exceeds the naive one and the band is too narrow, as Theorem 19.2.2 found for a linear model. The repair is Chapter 31, or a random-effect term for the serial structure as in Chapter 33.

Exercise B2.

Show that a model containing both a smooth main effect $f_0(z)$ and a varying-coefficient term $f(z)u$ has exact concurvity (Definition 44.2.1) as soon as u_i is itself a function of z_i , say $u_i = h(z_i)$ with h in the span of the basis. What does this say about the model of Example (Does poverty matter more in urban states?)?

Solution. If $u_i = h(z_i)$ with h in the span, the varying term contributes $f(z_i)h(z_i)$, a function of z_i alone; whenever fh is again in the span, the main-effect term realizes it too, and subtracting gives a nontrivial relation. In Example (Does poverty matter more in urban states?) the poverty rate is *not* a function of the urban percentage, so the concurvity is partial rather than exact; but the two are correlated across states, so the terms compete, which is part of why the bands are wide.

44.3.5.3 C. Going deeper

Exercise C1.

Build the smallest tensor-product term by hand: take $d_1 = d_2 = 3$ basis functions in each coordinate and first-difference penalties $\mathbf{P}^{(1)} = \mathbf{P}^{(2)}$. Write out the 9×9 penalty of Eq. 44.3.3 for $\lambda_1 = \lambda_2 = 1$ and find its null space. Why does that null space make the term identifiable only after the main effects have been constrained away?

44.4 Spatial effects

Many regression data sets carry a location: the district a flat is in, the county a case was reported from, the coordinates of a soil sample. Location is rarely of interest in itself; it stands in for everything unmeasured that varies smoothly over space — climate, soil, infrastructure, local labour markets — and leaving it out puts all of that into the error and biases the coefficient of any spatially patterned covariate. Putting it in needs a design block and a penalty, like any smooth covariate. The only question is what “smooth over space” should mean, and there are two answers, one per kind of location data.

44.4.1 The geoaddivitive model

Definition 44.4.1 — Geoadditive model

Let s_i be the location of observation i . The **geoadditive model** is the additive model Eq. 44.1.1 with one extra term,

$$y_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \sum_{j=1}^q f_j(z_{ij}) + f_{\text{geo}}(s_i) + \varepsilon_i, \quad \sum_i f_{\text{geo}}(s_i) = 0. \quad (44.4.1)$$

Two cases are distinguished by the kind of location.

- (a) (*Areal data.*) $s_i \in \{1, \dots, D\}$ names one of D regions. The design is the **incidence matrix** $\mathbf{Z}_{\text{geo}}$ with $(\mathbf{Z}_{\text{geo}})_{is} = 1$ if $s_i = s$ and 0 otherwise, the coefficient γ_s is the effect of region s , and the penalty is built from a **neighbourhood structure**: a symmetric relation $s \sim t$ saying which regions share a border.
- (b) (*Point-referenced data.*) $s_i \in \mathbb{R}^2$ is a coordinate pair. The design is $(\mathbf{Z}_{\text{geo}})_{il} = r(\|s_i - \kappa_l\|)$ for a set of **knots** $\kappa_1, \dots, \kappa_L$ and a radial function r , and the penalty is $\mathbf{P}_{\text{geo}} = \{r(\|\kappa_l - \kappa_m\|)\}_{lm}$.

In (a) the map is a graph and smoothness means that neighbouring regions do not differ by much; in (b) the map is a plane and smoothness means what it means for a surface. Both are pairs $(\mathbf{Z}_{\text{geo}}, \mathbf{P}_{\text{geo}})$, so Sections 44.1 and 44.2 apply without a word of change.

44.4.2 Markov random fields on a map

For areal data, write n_s for the number of neighbours of region s and define the **neighbourhood penalty**

$$\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = \sum_{s \sim t} (\gamma_s - \gamma_t)^2, \quad K_{st} = \begin{cases} n_s, & t = s, \\ -1, & t \sim s, \\ 0, & \text{otherwise,} \end{cases} \quad (44.4.2)$$

where the sum runs over unordered neighbour pairs: the first-difference penalty of Definition 43.3.1 with “next knot” replaced by “neighbouring region”, the two coinciding exactly on a chain $1 \sim 2 \sim \dots \sim D$.

Example. (Four regions in a row)

Let four districts lie in a row, $1 \sim 2 \sim 3 \sim 4$:

$$\mathbf{P} = \begin{pmatrix} 1 & -1 & 0 & 0 \\ -1 & 2 & -1 & 0 \\ 0 & -1 & 2 & -1 \\ 0 & 0 & -1 & 1 \end{pmatrix},$$

with $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = (\gamma_1 - \gamma_2)^2 + (\gamma_2 - \gamma_3)^2 + (\gamma_3 - \gamma_4)^2$, rank 3 and null space $\text{span}\{\mathbf{1}\}$. If district 4 is instead an island with no neighbours, its row and column vanish, the rank drops to 2 and the null space is spanned by $(1, 1, 1, 0)^\top$ and $(0, 0, 0, 1)^\top$: the island is

not penalized at all and is estimated from its own data alone.

Proposition 44.4.1 — The neighbourhood penalty

Let the regions $1, \dots, D$ carry a symmetric neighbourhood relation with no region its own neighbour, and let $\mathbf{P}$ be as in Eq. 44.4.2.

- (a) $\mathbf{P}$ is symmetric and nonnegative definite, and $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = \sum_{s \sim t} (\gamma_s - \gamma_t)^2$.
- (b) $\mathcal{N}(\mathbf{P})$ is spanned by the indicator vectors of the connected components of the neighbourhood graph. In particular $\text{rank}(\mathbf{P}) = D - c$ where c is the number of components, and $\mathcal{N}(\mathbf{P}) = \text{span}\{\mathbf{1}\}$ iff the graph is connected.
- (c) Treating $\exp\{-\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} / (2\tau^2)\}$ as a density in $\boldsymbol{\gamma}$ on $\mathcal{N}(\mathbf{P})^\perp$, the conditional distribution of γ_s given the others, for a region with $n_s \geq 1$, is normal with mean $n_s^{-1} \sum_{t \sim s} \gamma_t$, the average of its neighbours, and variance τ^2/n_s . The prior is therefore a **Gaussian Markov random field**: each region is shrunk towards its neighbours, and a region with many neighbours is shrunk harder. A region with $n_s = 0$ contributes nothing to the quadratic form: its coefficient is unpenalized, its conditional is flat, and it is estimated from its own data alone (Example (Four regions in a row), Exercise (A1)).

Proof.

- (a) Symmetry is immediate. Each unordered neighbour pair is counted twice in the double sum over ordered pairs, so

$$\sum_{s \sim t} (\gamma_s - \gamma_t)^2 = \frac{1}{2} \sum_s \sum_{t \sim s} (\gamma_s^2 - 2\gamma_s \gamma_t + \gamma_t^2).$$

The first inner sum gives $\sum_s n_s \gamma_s^2$, and so does the third, because $\sum_s \sum_{t \sim s} \gamma_t^2 = \sum_t n_t \gamma_t^2$ by symmetry of the relation. Hence the right-hand side is $\sum_s n_s \gamma_s^2 - \sum_s \sum_{t \sim s} \gamma_s \gamma_t = \boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma}$. Nonnegativity follows because the left-hand side is a sum of squares.

- (b) By (a), $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma} = 0$ iff $\gamma_s = \gamma_t$ across every edge, iff $\boldsymbol{\gamma}$ is constant on each connected component. Since $\mathbf{P}$ is nonnegative definite, that is equivalent to $\mathbf{P} \boldsymbol{\gamma} = \mathbf{0}$ by Theorem 1.7.4, so the null space is the span of the component indicators, which are independent because the components are disjoint.
- (c) If $n_s = 0$ then row s of $\mathbf{P}$ is zero and γ_s does not appear in the quadratic form, which is the last sentence. For $n_s \geq 1$, collect the terms of $\boldsymbol{\gamma}^\top \mathbf{P} \boldsymbol{\gamma}$ that involve γ_s :

$$n_s \gamma_s^2 - 2\gamma_s \sum_{t \sim s} \gamma_t + \text{const} = n_s \left(\gamma_s - \frac{1}{n_s} \sum_{t \sim s} \gamma_t \right)^2 + \text{const}'.$$

Dividing by $2\tau^2$ and exponentiating gives the normal density with the stated mean and variance τ^2/n_s . ■

Part (c) is the reason for the name. The penalty does not shrink a region towards zero — that would be the ridge penalty $\mathbf{P} = \mathbf{I}$ — but towards its neighbourhood, so a district with few

observations borrows strength from those around it while the overall level of the map stays free. That level is the one dimension the centring constraint of [Proposition 44.1.1\(c\)](#) removes on a connected map; it belongs to the intercept.

Remark (Variants). Three variants fit the same framework. Weighting each pair by w_{st} (border length, inverse centroid distance) replaces n_s by $\sum_{t \sim s} w_{st}$ and -1 by $-w_{st}$. Adding $\epsilon \mathbf{I}$ makes the penalty positive definite and the prior proper, at the price of shrinking the map towards zero as well as towards itself. And a *second*, unstructured term with $\mathbf{P} = \mathbf{I}$ on the same regions gives the convolution model of Besag, York and Mollié (1991), separating smooth spatial variation from region-specific noise.

44.4.3 Kriging bases for coordinates

For points rather than regions, smoothness comes from the theory of stationary random fields, which is to say from [Part VII](#). Let the spatial effect be a realization of a mean-zero process $\{U(s)\}$ with $\text{Cov}\{U(s), U(t)\} = \tau^2 r(\|s - t\|)$: a covariance model in the sense of [Definition 33.4.1](#), on a continuous index set.

Proposition 44.4.2 — Low-rank kriging is a penalized term

Let $\mathbf{R} = \{r(\|\kappa_l - \kappa_m\|)\}_{lm}$ be the correlation matrix of the field at L knots, assumed positive definite, and let $\mathbf{u} = \{U(\kappa_1), \dots, U(\kappa_L)\}^\top \sim N_L(\mathbf{0}, \tau^2 \mathbf{R})$.

- (a) The best linear predictor of $U(s)$ from $\mathbf{u}$ is $\hat{U}(s) = \mathbf{r}(s)^\top \mathbf{R}^{-1} \mathbf{u}$ with $\mathbf{r}(s) = \{r(\|s - \kappa_1\|), \dots, r(\|s - \kappa_L\|)\}^\top$. Writing $\boldsymbol{\gamma} = \mathbf{R}^{-1} \mathbf{u}$, the fitted spatial effect at the observations is $\mathbf{Z}_{\text{geo}} \boldsymbol{\gamma}$ with $(\mathbf{Z}_{\text{geo}})_{il} = r(\|s_i - \kappa_l\|)$, and $\boldsymbol{\gamma} \sim N_L(\mathbf{0}, \tau^2 \mathbf{R}^{-1})$.
- (b) Consequently the log-density of $\boldsymbol{\gamma}$ contributes $\boldsymbol{\gamma}^\top \mathbf{R} \boldsymbol{\gamma} / (2\tau^2)$, so the penalized criterion [Eq. 44.1.4](#) with $\mathbf{P}_{\text{geo}} = \mathbf{R}$ and $\lambda_{\text{geo}} = \sigma^2 / \tau^2$ has as its minimizer the posterior mode of $\boldsymbol{\gamma}$ — the kriging predictor restricted to the span of the L knots.
- (c) Taking every distinct location as a knot recovers exact kriging, that is, generalized least squares with the covariance $\tau^2 \mathbf{R} + \sigma^2 \mathbf{I}$ of [Chapter 31](#); taking $L \ll n$ knots is the low-rank approximation that makes the term cheap.

Proof.

- (a) By [Theorem 14.2.8](#) (or [Theorem 32.3.1](#) with $\mathbf{X}$ absent) the best linear predictor is $\text{Cov}\{U(s), \mathbf{u}\} \text{Cov}(\mathbf{u})^{-1} \mathbf{u} = \tau^2 \mathbf{r}(s)^\top (\tau^2 \mathbf{R})^{-1} \mathbf{u}$, the stated formula; evaluating at $s = s_i$ stacks into $\mathbf{Z}_{\text{geo}} \mathbf{R}^{-1} \mathbf{u}$, and the distribution of $\boldsymbol{\gamma} = \mathbf{R}^{-1} \mathbf{u}$ follows from [Theorem 2.2.1](#).
- (b) $-\log$ density of $N_L(\mathbf{0}, \tau^2 \mathbf{R}^{-1})$ is $\boldsymbol{\gamma}^\top \mathbf{R} \boldsymbol{\gamma} / (2\tau^2)$ up to a constant. Adding it to $\|\mathbf{y} - \dots\|^2 / (2\sigma^2)$ and multiplying by $2\sigma^2$ gives [Eq. 44.1.4](#) with the stated λ .
- (c) With $L = n$ distinct locations, $\mathbf{Z}_{\text{geo}} = \mathbf{R}$ and the term contributes $\mathbf{R} \boldsymbol{\gamma} = \mathbf{u}$ with $\mathbf{u}$ penalized by $\mathbf{u}^\top \mathbf{R}^{-1} \mathbf{u}$; minimizing over $\mathbf{u}$ is the mixed model of [Definition 32.2.1](#) with $\mathbf{Z} = \mathbf{I}$, $\mathbf{G} = \tau^2 \mathbf{R}$ and $\mathbf{R} = \sigma^2 \mathbf{I}$, whose marginal covariance is $\tau^2 \mathbf{R} + \sigma^2 \mathbf{I}$ ([Eq. 32.2.2](#)).

■

Figure 44.4.1: A simulated district map, all panels on one colour scale. (a) the surface used to generate the data. (b) unpenalized district effects. (c) the Markov random field Eq. 44.4.2. (d) a kriging term on 21 knots.

Idea. A spatial term is a random effect with a structured covariance — not an analogy: by Proposition 44.4.2 the penalty *is* the inverse prior covariance, and Section 44.5 makes that general. The Markov random field Eq. 44.4.2 says the same with a sparse precision matrix in place of a dense covariance, which is why it is cheap on large maps.

If $\mathbf{R}$ and $\mathbf{Z}_{\text{geo}}$ are to be sparse, the correlation function must have compact support or decay fast. The example below uses the Wendland function $r(h) = (1 - h/\rho)_+^4(1 + 4h/\rho)$, positive definite in two dimensions and zero beyond the range ρ .

44.4.4 A map

Example. (Smoothing a district map)

A simulated country is a 12×12 lattice of 144 districts with between 1 and 8 observations each, 604 in all. The response has mean $2 + 0.7x + \text{surface}(s)$, with x an ordinary covariate and the surface a smooth function of the district centroid that the model does not know; the errors are normal with standard deviation 0.9.

Figure 44.4.1 compares three fits. Unpenalized district effects use 143.0 degrees of freedom and give the noisy map of panel (b), with root mean squared error 0.579 against the true surface. The neighbourhood penalty Eq. 44.4.2, with λ from the restricted likelihood, uses 45.5 and brings that down to 0.170. A kriging term on 21 knots uses 17.7 and gives 0.228: smoother still, and slightly too smooth, because the true surface has features the coarse knot grid cannot represent. The coefficient of x comes out at 0.581 with a standard error of 0.042 — against a true 0.7, about 2.8 standard errors low on this draw — and the residual standard deviation at 0.953.

The map and its penalty are built from the neighbourhood list alone:

```
import numpy as np

def lattice(side):
    """Rook adjacency on a side x side grid of districts, and the district centroids
    . """
    coords = np.array([[c + 0.5, r + 0.5] for r in range(side) for c in range(side)
    ])
```

```

neighbours = []
for s in range(side * side):
    r, c = divmod(s, side)
    nb = [(r + dr) * side + (c + dc) for dr, dc in ((-1, 0), (1, 0), (0, -1),
    (0, 1))
            if 0 <= r + dr < side and 0 <= c + dc < side]
    neighbours.append(sorted(nb))
return coords, neighbours

def neighbourhood_penalty(neighbours):
    """K = D - W: the number of neighbours on the diagonal, -1 for each neighbour
    pair."""
    d = len(neighbours)
    K = np.zeros((d, d))
    for s, nbrs in enumerate(neighbours):
        K[s, s] = len(nbrs)
        for t in nbrs:
            K[s, t] = -1.0
    return K

```

Warning (Spatial confounding). A spatial term competes with every covariate that is itself spatially patterned: they are concure in the sense of [Definition 44.2.1](#). In [Example \(Smoothing a district map\)](#) the covariate x was generated independently of location, so nothing was lost. When a covariate varies smoothly over the map — income across districts, exposure across counties — the spatial term can absorb a large part of its effect, and the fitted coefficient moves, sometimes dramatically, when the term is added. Neither fit is “the” answer: without the spatial term all spatial variation is attributed to the covariate, with it the smooth part goes to location. Which is right is a question about unmeasured confounders, and the fit has no opinion; [Chapter 25](#) has the vocabulary. Report both, and say which unmeasured causes the spatial term stands in for.

44.4.5 Exercises

44.4.5.1 A. Check your understanding

Exercise A1.

A map has two islands, each a connected group of districts, with no neighbour pairs between them. What is $\text{rank}(\mathbf{P})$, what does the penalty leave unidentified, and what does the centring constraint of [Proposition 44.1.1\(c\)](#) fix?

44.4.5.2 B. Practice

Exercise B1.

Show that on a chain $1 \sim 2 \sim \dots \sim D$, the penalty [Eq. 44.4.2](#) equals the first-difference penalty $\boldsymbol{\gamma}^\top \mathbf{D}_1^\top \mathbf{D}_1 \boldsymbol{\gamma}$ of [Definition 43.3.1](#), and that the second-difference penalty is *not* of the form [Eq. 44.4.2](#) for any neighbourhood structure with nonnegative off-diagonal weights.

Exercise B2.

Using [Proposition 44.4.1\(c\)](#), show that if district s has n_s neighbours and its own m_s observations with mean $\bar{y}_s$, and all other effects are held fixed, the penalized criterion is minimized over γ_s at a weighted average of $\bar{y}_s$ and the neighbour mean, with weights m_s and λn_s . What happens when $m_s = 0$?

Solution. Up to constants the terms of [Eq. 44.1.4](#) involving γ_s are $m_s(\bar{y}_s - \gamma_s)^2 + \lambda n_s(\gamma_s - \bar{\gamma}_{(s)})^2$ with $\bar{\gamma}_{(s)} = n_s^{-1} \sum_{t \sim s} \gamma_t$, so $\hat{\gamma}_s = (m_s \bar{y}_s + \lambda n_s \bar{\gamma}_{(s)}) / (m_s + \lambda n_s)$. With $m_s = 0$ the district is set to its neighbour average: the map interpolates over the gap.

44.4.5.3 C. Going deeper**Exercise C1.**

Let $\mathbf{v}$ be the vector of a covariate that is constant within each district, so that $\mathbf{v} \in \mathcal{C}(\mathbf{Z}_{\text{geo}})$ for the incidence design. Show that in the *unpenalized* geoadditive model the coefficient of $\mathbf{v}$ is not identified at all, and that with a penalty it is identified but its estimate depends on λ_{geo} , tending to the no-spatial-term estimate as $\lambda_{\text{geo}} \rightarrow \infty$. What does this say about reporting such a coefficient?

44.5 Structured additive regression

Four kinds of term have appeared: a smooth function of a covariate, a coefficient varying with a modifier, an effect attached to a region of a map, an effect attached to a cluster. Each was a pair $(\mathbf{Z}_j, \mathbf{P}_j)$ — a design block and a nonnegative definite penalty — estimated by the same penalized criterion. This section says that out loud, shows that the framework contains the mixed models of [Chapter 32](#) exactly, and takes from them the thing still missing: a principled way to choose the smoothing parameters.

44.5.1 One predictor

Definition 44.5.1 — Structured additive regression

A structured additive predictor is

$$\boldsymbol{\eta} = \mathbf{X}\boldsymbol{\beta} + \sum_{j=1}^J \mathbf{Z}_j \boldsymbol{\gamma}_j, \quad (44.5.1)$$

where $\mathbf{X}$ collects the unpenalized columns and each term j is a pair $(\mathbf{Z}_j, \mathbf{P}_j)$ with $\mathbf{Z}_j$ an $n \times d_j$ design block and $\mathbf{P}_j$ a symmetric nonnegative definite $d_j \times d_j$ penalty matrix, identified by the constraint $\mathbf{1}^\top \mathbf{Z}_j \boldsymbol{\gamma}_j = 0$ of [Proposition 44.1.1\(c\)](#). A **structured additive regression model** (STAR) fits [Eq. 44.5.1](#) by minimizing the penalized criterion [Eq. 44.1.4](#), with one smoothing parameter $\lambda_j \geq 0$ per term.

The content of the definition is the catalogue of pairs. Everything this chapter and [Chapter 43](#) have built is in [Table 44.5.1](#), and the list is open: a new kind of effect enters as soon as somebody writes down its design and its penalty.

Table 44.5.1. The catalogue of terms. Each row is a design block and a penalty; the last column is the dimension of the part of the term that the penalty never touches, which is what survives as $\lambda_j \rightarrow \infty$ and which the centring constraint reduces by one. In the last row m_1 and m_2 are the null-space dimensions of the two marginal penalties, so 1 for first differences in both coordinates and 4 for second differences.

term	design block $\mathbf{Z}_j$	penalty $\mathbf{P}_j$	$\dim \mathcal{N}(\mathbf{P}_j)$
polynomial of degree d	powers of z	$\mathbf{0}$	$d + 1$
P-spline, difference order r	B-splines at z	$\mathbf{D}_r^\top \mathbf{D}_r$	r
smoothing spline	natural spline basis	$\int B_l'' B_m''$	2
varying coefficient	B-splines times u	as for the P-spline	as for the P-spline
Markov random field	region indicators	Eq. 44.4.2	components of the map
kriging term	radial basis at knots	$\{r(\ \kappa_l - \kappa_m\)\}$	0
random intercept	cluster indicators	$\mathbf{I}$	0
random slope	cluster indicators times u	$\mathbf{I}$	0
tensor-product surface	products of B-splines	Eq. 44.3.3	$m_1 m_2$

Proposition 44.5.1 — When a STAR model is identified

In [Definition 44.5.1](#), assume every $\mathbf{Z}_j$ has full column rank. The penalized criterion has a unique minimizer for every $\lambda_j > 0$ if and only if the only vector $\boldsymbol{\gamma} = (\boldsymbol{\beta}^\top, \boldsymbol{\gamma}_1^\top, \dots)^\top$ with $\mathbf{X}\boldsymbol{\beta} + \sum_j \mathbf{Z}_j \boldsymbol{\gamma}_j = \mathbf{0}$ and $\mathbf{P}_j \boldsymbol{\gamma}_j = \mathbf{0}$ for every j is $\boldsymbol{\gamma} = \mathbf{0}$. Equivalently: there is no exact concurvity among $\mathcal{C}(\mathbf{X})$ and the *unpenalized parts* $\mathbf{Z}_j \mathcal{N}(\mathbf{P}_j)$ of the terms.

Proof. The criterion is the convex quadratic $\|\mathbf{y} - \mathbf{Z}\boldsymbol{\gamma}\|^2 + \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}$ with $\mathbf{P}$ the block penalty [Eq. 44.1.5](#), and its stationarity condition is [Eq. 44.1.6](#) with $\mathbf{A} = \mathbf{Z}^\top \mathbf{Z} + \mathbf{P}$. If $\mathbf{A}$ is positive definite the criterion is strictly convex and [Theorem 30.1.1](#) gives a unique minimizer. Conversely, if $\mathbf{A}$ is singular, pick $\boldsymbol{\gamma}_0 \neq \mathbf{0}$ with $\mathbf{A}\boldsymbol{\gamma}_0 = \mathbf{0}$; expanding the criterion at a minimizer $\hat{\boldsymbol{\gamma}}$ gives $Q(\hat{\boldsymbol{\gamma}} + t\boldsymbol{\gamma}_0) = Q(\hat{\boldsymbol{\gamma}}) + t^2 \boldsymbol{\gamma}_0^\top \mathbf{A}\boldsymbol{\gamma}_0 = Q(\hat{\boldsymbol{\gamma}})$ for every t , so the minimizer is not unique. Uniqueness for every $\lambda_j > 0$ is therefore positive definiteness of $\mathbf{A}$, that is $\boldsymbol{\gamma}^\top \mathbf{A}\boldsymbol{\gamma} = \|\mathbf{Z}\boldsymbol{\gamma}\|^2 + \sum_j \lambda_j \boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j = 0$ forces $\boldsymbol{\gamma} = \mathbf{0}$. Both summands are nonnegative, so the condition is exactly the one stated, and $\boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j = 0$ is equivalent to $\mathbf{P}_j \boldsymbol{\gamma}_j = \mathbf{0}$ by [Theorem 1.7.4](#). ■

Two P-spline terms can therefore be identified even when their spaces nearly intersect, because only their *linear* parts — the null spaces of the second-difference penalties — need be independent. That is far weaker than the requirement for the unpenalized model in [Proposition 44.2.3\(a\)](#), and it explains why penalized additive fits rarely fail outright: they fail softly, through inflated variances.

44.5.2 The mixed-model representation

Proposition 44.5.2 — A STAR model is a linear mixed model

Let $\mathbf{P}_j$ have rank r_j and spectral decomposition $\mathbf{P}_j = \mathbf{Q}_j^+ \mathbf{\Lambda}_j \mathbf{Q}_j^{+\top}$ with $\mathbf{\Lambda}_j = \text{diag}(\nu_{j1}, \dots, \nu_{jr_j})$ positive, and let $\mathbf{Q}_j^0$ be an orthonormal basis of $\mathcal{N}(\mathbf{P}_j)$. Put

$$\mathbf{X}_j^0 = \mathbf{Z}_j \mathbf{Q}_j^0, \quad \mathbf{Z}_j^+ = \mathbf{Z}_j \mathbf{Q}_j^+ \mathbf{\Lambda}_j^{-1/2}, \quad \mathbf{u}_j = \mathbf{\Lambda}_j^{1/2} \mathbf{Q}_j^{+\top} \boldsymbol{\gamma}_j. \quad (44.5.2)$$

- (a) $\mathbf{Z}_j \boldsymbol{\gamma}_j = \mathbf{X}_j^0 \mathbf{b}_j + \mathbf{Z}_j^+ \mathbf{u}_j$ with $\mathbf{b}_j = \mathbf{Q}_j^{0\top} \boldsymbol{\gamma}_j$, and $\boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j = \|\mathbf{u}_j\|^2$.
- (b) With $\tau_j^2 = \sigma^2 / \lambda_j$, the penalized criterion Eq. 44.1.4 divided by σ^2 is the criterion Eq. 32.3.6 of Theorem 32.3.2 for the linear mixed model Eq. 32.2.1 with fixed design $[\mathbf{X}, \mathbf{X}_1^0, \dots, \mathbf{X}_J^0]$, random design $[\mathbf{Z}_1^+, \dots, \mathbf{Z}_J^+]$, $\mathbf{G} = \text{diag}(\tau_1^2 \mathbf{I}_{r_1}, \dots, \tau_J^2 \mathbf{I}_{r_J})$ and $\mathbf{R} = \sigma^2 \mathbf{I}$.
- (c) Consequently the penalized estimate is the BLUP of Theorem 32.3.1; the smoothing parameters are variance ratios, $\lambda_j = \sigma^2 / \tau_j^2$; and the restricted likelihood Eq. 32.4.4 of the transformed model is a likelihood for $(\sigma^2, \tau_1^2, \dots, \tau_J^2)$, hence for $(\lambda_1, \dots, \lambda_J)$.

Proof.

- (a) The columns of $\mathbf{Q}_j^+$ and $\mathbf{Q}_j^0$ form an orthonormal basis of $\mathbb{R}^{d_j}$, so $\boldsymbol{\gamma}_j = \mathbf{Q}_j^0 \mathbf{b}_j + \mathbf{Q}_j^+ \mathbf{Q}_j^{+\top} \boldsymbol{\gamma}_j$ and $\mathbf{Q}_j^+ \mathbf{Q}_j^{+\top} \boldsymbol{\gamma}_j = \mathbf{Q}_j^+ \mathbf{\Lambda}_j^{-1/2} \mathbf{u}_j$. Multiplying by $\mathbf{Z}_j$ gives the first claim. For the second, $\boldsymbol{\gamma}_j^\top \mathbf{P}_j \boldsymbol{\gamma}_j = \boldsymbol{\gamma}_j^\top \mathbf{Q}_j^+ \mathbf{\Lambda}_j \mathbf{Q}_j^{+\top} \boldsymbol{\gamma}_j = \|\mathbf{u}_j\|^2$.
- (b) Substituting (a) into Eq. 44.1.4 turns it into

$$\left\| \mathbf{y} - \mathbf{X} \boldsymbol{\beta} - \sum_j \mathbf{X}_j^0 \mathbf{b}_j - \sum_j \mathbf{Z}_j^+ \mathbf{u}_j \right\|^2 + \sum_j \lambda_j \|\mathbf{u}_j\|^2,$$

and dividing by σ^2 and writing $\lambda_j / \sigma^2 = 1 / \tau_j^2$ gives $\mathbf{R}^{-1} = \sigma^{-2} \mathbf{I}$ in the first term and $\mathbf{G}^{-1}$ in the second, which is Eq. 32.3.6.

- (c) Immediate from Theorem 32.3.2(a)–(b), which identifies the minimizer of Eq. 32.3.6 with $(\hat{\boldsymbol{\beta}}, \hat{\mathbf{u}})$, and from Definition 32.4.1 applied to the transformed model. ■

Idea. A penalty is a prior, and a smoothing parameter is a variance ratio. That one identification does three jobs: the null space of a penalty becomes *fixed* effects, which is why Table 44.5.1 records $\dim \mathcal{N}(\mathbf{P}_j)$; it supplies a likelihood for $\boldsymbol{\lambda}$, which cross-validation does not; and it puts every result of Chapter 32 — BLUP, REML, Henderson's equations, the posterior of Proposition 32.6.1 — at the service of smoothing.

44.5.3 Choosing the smoothing parameters

Two routes are now open. The first is prediction error: Definition 29.3.2 and the information criteria Proposition 29.2.4 apply verbatim with $\text{tr } \mathbf{S}$ in place of the number of parameters, mini-

mized over λ numerically. The second is the restricted likelihood of [Proposition 44.5.2\(c\)](#), usually preferred: it is less prone to the occasional catastrophic undersmoothing cross-validation shows when its criterion is nearly flat, and it comes with the variance interpretation. Both choose from the data the fit uses, so [Proposition 29.5.1](#) applies to both.

Maximizing the restricted likelihood directly is awkward, since each evaluation needs a determinant, and the updates below avoid it. What is proved is that they have the stated fixed points; that those are stationary points of the restricted likelihood is due to Schall (1991), with the general version in Wood and Fasiolo (2017).

Proposition 44.5.3 — Restricted-likelihood updates

In the mixed-model representation of [Proposition 44.5.2](#), the expectation-maximization algorithm for the variance components, with $(\mathbf{b}, \mathbf{u})$ as the missing data, updates

$$\tau_j^{2,\text{new}} = \frac{1}{r_j} \left[\hat{\mathbf{Y}}_j^\top \mathbf{P}_j \hat{\mathbf{Y}}_j + \sigma^2 \text{tr}\{(\mathbf{A}^{-1})_{jj} \mathbf{P}_j\} \right], \quad (44.5.3)$$

where $\hat{\mathbf{Y}}_j$ and $\mathbf{A}$ are computed at the current λ . A pair (τ^2, σ^2) is a fixed point of [Eq. 44.5.3](#) together with the update $\sigma^{2,\text{new}} = \|\mathbf{y} - \hat{\mathbf{y}}\|^2 / (n - \text{df})$ if and only if

$$\hat{\tau}_j^2 = \frac{\hat{\mathbf{Y}}_j^\top \mathbf{P}_j \hat{\mathbf{Y}}_j}{\text{df}_j - m_j}, \quad \hat{\sigma}^2 = \frac{\|\mathbf{y} - \hat{\mathbf{y}}\|^2}{n - \text{df}}, \quad \hat{\lambda}_j = \frac{\hat{\sigma}^2}{\hat{\tau}_j^2}, \quad (44.5.4)$$

with $m_j = d_j - r_j = \dim \mathcal{N}(\mathbf{P}_j)$ and df_j , df the effective degrees of freedom of [Proposition 44.1.2](#).

Proof. [Eq. 44.5.3](#) is the expectation-maximization step for a variance component in a normal linear mixed model: the complete-data estimate of τ_j^2 is $\|\mathbf{u}_j\|^2 / r_j$, whose conditional expectation given $\mathbf{y}$ is $\|\hat{\mathbf{u}}_j\|^2 / r_j + \text{tr}\{\text{Cov}(\mathbf{u}_j \mid \mathbf{y})\} / r_j$. By [Proposition 44.5.2\(a\)](#), $\|\hat{\mathbf{u}}_j\|^2 = \hat{\mathbf{Y}}_j^\top \mathbf{P}_j \hat{\mathbf{Y}}_j$, and by [Proposition 32.6.1\(a\)](#) the conditional covariance of $\mathbf{y}_j$ is $\sigma^2(\mathbf{A}^{-1})_{jj}$, so [Eq. 44.5.2](#) gives

$$\text{tr Cov}(\mathbf{u}_j \mid \mathbf{y}) = \sigma^2 \text{tr}\{\Lambda_j^{1/2} \mathbf{Q}_j^{+\top} (\mathbf{A}^{-1})_{jj} \mathbf{Q}_j^+ \Lambda_j^{1/2}\} = \sigma^2 \text{tr}\{(\mathbf{A}^{-1})_{jj} \mathbf{P}_j\},$$

the trace term as written. (The EM step itself is quoted from the mixed-model literature; what is proved here is its fixed point.)

For the fixed point, [Proposition 44.1.2\(b\)](#) gives $\text{df}_j = d_j - \lambda_j \text{tr}\{(\mathbf{A}^{-1})_{jj} \mathbf{P}_j\}$, that is

$$\text{tr}\{(\mathbf{A}^{-1})_{jj} \mathbf{P}_j\} = \frac{d_j - \text{df}_j}{\lambda_j} = \frac{(d_j - \text{df}_j) \tau_j^2}{\sigma^2}.$$

Substituting into [Eq. 44.5.3](#) and demanding $\tau_j^{2,\text{new}} = \tau_j^2$,

$$r_j \tau_j^2 = \hat{\mathbf{Y}}_j^\top \mathbf{P}_j \hat{\mathbf{Y}}_j + (d_j - \text{df}_j) \tau_j^2,$$

so $\tau_j^2(r_j - d_j + \text{df}_j) = \hat{\mathbf{Y}}_j^\top \mathbf{P}_j \hat{\mathbf{Y}}_j$, and $r_j - d_j = -m_j$ gives the first equation of [Eq. 44.5.4](#). The statement for σ^2 is its own update, and $\lambda_j = \sigma^2 / \tau_j^2$ is [Proposition 44.5.2\(c\)](#).

Read [Eq. 44.5.4](#) as an estimate of a variance: the numerator is the roughness the term shows, the denominator $df_j - m_j$ the number of dimensions it used in showing it, discounting the unpenalized part the penalty cannot see. The solver is one assembly and one solve,

```
import numpy as np

def assemble(blocks, X, lambdas):
    """Stack the parametric columns and the terms into one design and one block
    penalty."""
    Z = np.column_stack([X] + [Zj for Zj, _ in blocks])
    K = np.zeros((Z.shape[1], Z.shape[1]))
    start = X.shape[1]
    for (_, Kj), lam in zip(blocks, lambdas):
        d = Kj.shape[0]
        K[start:start + d, start:start + d] = lam * Kj
        start += d
    return Z, K

class Fit:
    """One penalized solve: coefficients, components, operators and degrees of
    freedom."""

    def __init__(self, y, blocks, X, lambdas, W=None, z=None, operators=True):
        Z, K = assemble(blocks, X, lambdas)
        w = np.ones(len(y)) if W is None else W
        Zw = Z * w[:, None]
        B = Z.T @ Zw                                     # the weighted cross-
        product
        A = B + K
        Ainv = np.linalg.inv(A)
        self.Z, self.K, self.A, self.w = Z, K, A, w
        self.gamma = Ainv @ (Zw.T @ (y if z is None else z))
        self.fitted = Z @ self.gamma
        self.edf_total = np.trace(Ainv @ B)              # tr(S) without
        forming S
        self.parts, self.edf, self.comp = [], [], []
        start = X.shape[1]
        for Zj, _ in blocks:
            sl = slice(start, start + Zj.shape[1])
            self.parts.append(Zj @ self.gamma[sl])
            self.edf.append(np.trace(Ainv[sl] @ B[:, sl]))
            start += Zj.shape[1]
        if operators:                                    # the n x n smoothers
            C = Ainv @ Zw.T
            self.S = Z @ C
            start = X.shape[1]
            for Zj, _ in blocks:
                self.comp.append(Zj @ C[start:start + Zj.shape[1]])
                start += Zj.shape[1]
            self.beta = self.gamma[:X.shape[1]]
```

and the updates themselves are a handful more:

```
def null_dim(K, tol=1e-9):
    """The dimension of the penalty null space: the part of a term that is never
```

```

penalized."""
e = np.linalg.eigvalsh(K)

        lam = new
        if done:
            break
    return lam, Fit(y, blocks, X, lam), sigma2

```

Example. (Four kinds of term at once)

A simulated data set of 1200 observations has a binary covariate with a linear effect, a smooth effect of z_1 , a coefficient of u varying with z_2 , an areal effect on an 8×8 map of 64 districts and a random intercept for 40 clusters: four terms, 132 coefficients, smoothing parameters from [Eq. 44.5.4](#).

The fit recovers the residual standard deviation as 0.713 (true 0.7) and the linear effect as 0.770 (true 0.8). The four terms take 7.86, 5.13, 42.92 and 36.48 effective degrees of freedom, 94.40 out of 132, with implied variance components 0.1609, 0.0170, 0.2002 and 0.2646 — the last the variance of the random intercept, truly 0.25. Root mean squared errors against the truth are 0.031, 0.045, 0.129 and 0.119, against a noise standard deviation of 0.7. [Figure 44.5.1](#) shows all four.

The shrinkage in panels (c) and (d) is not a defect but [Theorem 32.3.1](#): a predictor of a random effect trades bias for variance, and the slope of predicted against true falls below one by exactly the amount the estimated variance ratio dictates.

44.5.4 The Bayesian reading

[Proposition 44.5.2](#) already contains it. Give each term the prior

$$\pi(\gamma_j \mid \tau_j^2) \propto (\tau_j^2)^{-r_j/2} \exp\left\{-\frac{1}{2\tau_j^2} \gamma_j^\top \mathbf{P}_j \gamma_j\right\}, \quad (44.5.5)$$

Figure 44.5.1: One structured additive fit with four kinds of term. (a) the smooth term against the truth. (b) the estimated coefficient function. (c) and (d) fitted district and cluster effects against the truth, with the line of equality; both are shrunk, as a best linear unbiased predictor must be.

normal on $\mathcal{N}(\mathbf{P}_j)^\perp$ and flat on the null space, give $\boldsymbol{\beta}$ a flat prior, and the penalized estimate is the posterior mode (Definition 39.4.1); with $\boldsymbol{\lambda}$ fixed the posterior of $\boldsymbol{\gamma}$ is normal with covariance $\sigma^2 \mathbf{A}^{-1}$ by Proposition 32.6.1(a). That covariance produces the bands in this chapter's figures: the Wahba–Nychka bands of Theorem 43.6.1, with their caveat that they are honest about bias averaged over the curve, not pointwise, and condition on $\boldsymbol{\lambda}$ as though it were known. Treating $\boldsymbol{\tau}^2$ and σ^2 as unknown too gives a fully Bayesian model, sampled as in Section 39.4 (Definition 39.4.2), whose advantage is precisely that it propagates the uncertainty in $\boldsymbol{\lambda}$ into the bands instead of ignoring it.

Warning (Improper priors on variance components). The prior Eq. 44.5.5 is improper on $\mathcal{N}(\mathbf{P}_j)$, which is harmless: that part is a fixed effect with a flat prior. The prior on τ_j^2 is not harmless. An inverse-gamma prior with both parameters tending to zero, or a flat prior on τ_j^2 , can produce an improper posterior, and the symptom in a sampler is not a crash but a chain that drifts towards zero variance and never settles (Proposition 39.5.1). Use a proper prior whose scale is set on the scale of the data, and check the sampler, never the fit alone.

44.5.5 Exercises

44.5.5.1 A. Check your understanding

Exercise A1.

For each of the following, give the design block and the penalty: (i) a random slope of a covariate u within K clusters; (ii) a linear effect that is not to be penalized at all; (iii) a smooth term that is to be penalized towards a straight line rather than towards a constant.

44.5.5.2 B. Practice

Exercise B1.

Take one term with $\mathbf{Z} = \mathbf{D}$ the $n \times K$ matrix of cluster indicators and $\mathbf{P} = \mathbf{I}$. Show that the penalized estimate of the cluster effects is $\hat{\gamma}_k = m_k \bar{r}_k / (m_k + \lambda)$, where m_k is the cluster size and $\bar{r}_k$ the mean residual in cluster k , and identify this with Theorem 32.3.1

for the one-way random effects model of [Definition 32.1.1](#).

Solution. With the other effects fixed the criterion is $\sum_k \sum_{i \in k} (r_i - \gamma_k)^2 + \lambda \sum_k \gamma_k^2$, which separates over k and gives $\hat{\gamma}_k = m_k \bar{r}_k / (m_k + \lambda)$. With $\lambda = \sigma^2 / \tau^2$ that is $\bar{r}_k m_k \tau^2 / (m_k \tau^2 + \sigma^2)$, the shrinkage factor of [Theorem 32.3.1](#) for the one-way model.

Exercise B2.

Write the generalized cross-validation criterion [Definition 29.3.2](#) for a STAR fit as $\text{GCV}(\lambda) = n \|\mathbf{y} - \mathbf{S}\mathbf{y}\|^2 / (n - \text{tr } \mathbf{S})^2$. Show that it is minimized where σ^2 of [Eq. 44.5.4](#) is stationary in a particular sense, and explain why the two criteria nevertheless disagree in general.

44.5.5.3 C. Going deeper

Exercise C1.

The updates [Eq. 44.5.4](#) are a fixed-point iteration, not a descent method, and they are not guaranteed to converge from every start. Construct a two-term model in which the restricted likelihood has a stationary point at $\tau_1^2 = 0$ (the term is smoothed away), verify that this is a fixed point of [Eq. 44.5.4](#), and explain how a run that lands there should be reported.

Solution. Let the first term be a P-spline in a covariate with no effect and the second anything. If the data show no roughness in that term, $\hat{\gamma}_1^\top \mathbf{P}_1 \hat{\gamma}_1 \rightarrow 0$ while $\text{df}_1 \rightarrow m_1$, so [Eq. 44.5.4](#) sends $\tau_1^2 \rightarrow 0$ and $\lambda_1 \rightarrow \infty$, and there the update reproduces itself because the numerator stays zero. This is the boundary of the parameter space, where [Theorem 32.5.2](#) says the usual asymptotics for a test of $\tau_1^2 = 0$ fail; the honest report is “the term was smoothed to its null space”, not “significant at 0 degrees of freedom”.

44.6 Generalized additive models

Everything so far assumed a normal response and an identity link. Lifting that costs one paragraph, because [Part VIII](#) did the work: a generalized linear model is fitted by repeated weighted least squares ([Theorem 34.4.1](#)), and repeated *penalized* weighted least squares is what this chapter has been doing throughout. Put the two together and the model class that carries the name appears.

44.6.1 The model and its fit

Theorem 44.6.1 — Generalized additive models

Let $y_1, \dots, y_n$ be independent from an exponential dispersion family in the sense of [Definition 34.2.1](#), with dispersion ϕ , variance function V , link g and mean $\mu_i = g^{-1}(\eta_i)$, and let $\boldsymbol{\eta} = \mathbf{Z}\boldsymbol{\gamma}$ be the structured additive predictor [Eq. 44.5.1](#) with block penalty $\mathbf{P}$ as

in Eq. 44.1.5. Define the **penalized deviance**

$$Q(\boldsymbol{\gamma}) = D(\boldsymbol{\gamma}) + \boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}, \quad (44.6.1)$$

with D the deviance of Definition 34.5.1, and let $\hat{\boldsymbol{\gamma}}$ minimize it.

- (a) Minimizing Eq. 44.6.1 is the same as maximizing the **penalized log-likelihood** $\ell(\boldsymbol{\gamma}) - (2\phi)^{-1}\boldsymbol{\gamma}^\top \mathbf{P}\boldsymbol{\gamma}$. Neither the minimizer nor the iteration below depends on ϕ .
- (b) (*Penalized IRLS.*) With $\mathbf{W}$ the working weights and $\mathbf{z}$ the working response of Eq. 34.4.1, both evaluated at $\boldsymbol{\gamma}^{(t)}$, the Fisher scoring step for Eq. 44.6.1 is

$$\boldsymbol{\gamma}^{(t+1)} = (\mathbf{Z}^\top \mathbf{W}\mathbf{Z} + \mathbf{P})^{-1} \mathbf{Z}^\top \mathbf{W}\mathbf{z}, \quad (44.6.2)$$

that is, the penalized weighted least squares fit of the working response on the same design. At a fixed point the unpenalized columns satisfy $\mathbf{X}^\top \mathbf{W}\mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$, where $\mathbf{D} = \text{diag}\{h'(\eta_i)\}$; for the canonical link with prior weights $w_i \equiv 1$ this is $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$.

- (c) (*Degrees of freedom.*) At convergence, with $\mathbf{A} = \mathbf{Z}^\top \mathbf{W}\mathbf{Z} + \mathbf{P}$, the effective degrees of freedom are $\text{df} = \text{tr}(\mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{W}\mathbf{Z})$ and split over terms exactly as in Proposition 44.1.2(b). The approximate covariance of $\hat{\boldsymbol{\gamma}}$ is $\phi \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{W}\mathbf{Z} \mathbf{A}^{-1}$ in its frequentist form and $\phi \mathbf{A}^{-1}$ in the Bayesian form of Proposition 44.5.2.
- (d) (*Inference for a term.*) Let $\mathbf{V}_j = \phi(\mathbf{A}^{-1})_{jj}$ and let $\mathbf{V}_j^{r-}$ be the rank- r pseudo-inverse of $\mathbf{V}_j$ with r the integer nearest to df_j . Under $f_j \equiv 0$, and treating $\boldsymbol{\lambda}$ as fixed and ϕ as known, $T_j = \hat{\boldsymbol{\gamma}}_j^\top \mathbf{V}_j^{r-} \hat{\boldsymbol{\gamma}}_j$ has approximately the $\chi^2(r)$ distribution; with ϕ estimated, T_j/r is referred to $F(r, n - \text{df})$. This is an approximation, stated here without proof; see the notes.

Proof.

- (a) By Definition 34.5.1, $D(\boldsymbol{\gamma}) = 2\phi\{\ell_{\text{sat}} - \ell(\boldsymbol{\gamma})\}$ with ℓ_{sat} free of $\boldsymbol{\gamma}$; dividing Eq. 44.6.1 by 2ϕ and dropping the constant gives the stated criterion, and rescaling an objective by a positive constant does not move its minimizer.
- (b) Let $\mathbf{U} = \partial\ell/\partial\boldsymbol{\gamma}$ and $\mathcal{I} = \mathbf{Z}^\top \mathbf{W}\mathbf{Z}/\phi$ be the score and expected information of the unpenalized model (Theorem 34.3.1), so $\partial D/\partial\boldsymbol{\gamma} = -2\phi\mathbf{U}$ and $\text{E}(\partial^2 D/\partial\boldsymbol{\gamma}\partial\boldsymbol{\gamma}^\top) = 2\mathbf{Z}^\top \mathbf{W}\mathbf{Z}$. Fisher scoring for Eq. 44.6.1 therefore takes

$$\begin{aligned} \boldsymbol{\gamma}^{(t+1)} &= \boldsymbol{\gamma}^{(t)} - (2\mathbf{Z}^\top \mathbf{W}\mathbf{Z} + 2\mathbf{P})^{-1}(-2\phi\mathbf{U} + 2\mathbf{P}\boldsymbol{\gamma}^{(t)}) \\ &= \mathbf{A}^{-1}\{\mathbf{A}\boldsymbol{\gamma}^{(t)} + \phi\mathbf{U} - \mathbf{P}\boldsymbol{\gamma}^{(t)}\}, \end{aligned}$$

and $\mathbf{A}\boldsymbol{\gamma}^{(t)} - \mathbf{P}\boldsymbol{\gamma}^{(t)} = \mathbf{Z}^\top \mathbf{W}\mathbf{Z}\boldsymbol{\gamma}^{(t)} = \mathbf{Z}^\top \mathbf{W}\boldsymbol{\eta}^{(t)}$, while $\phi\mathbf{U} = \mathbf{Z}^\top \mathbf{W}\mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu})$ by Theorem 34.3.1. Adding,

$$\boldsymbol{\gamma}^{(t+1)} = \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{W}\{\boldsymbol{\eta}^{(t)} + \mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu})\} = \mathbf{A}^{-1} \mathbf{Z}^\top \mathbf{W}\mathbf{z}^{(t)},$$

which is Eq. 44.6.2; ϕ has cancelled, proving the last claim of (a). At a fixed point the gradient of Eq. 44.6.1 vanishes, that is $\mathbf{Z}^\top \mathbf{W}\mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{P}\boldsymbol{\gamma}$; the rows of $\mathbf{P}$ belonging to $\mathbf{X}$ are zero, so those components read $\mathbf{X}^\top \mathbf{W}\mathbf{D}^{-1}(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$. For the canonical link $\mathbf{W}\mathbf{D}^{-1} = \text{diag}\{w_i h'(\eta_i)/V(\mu_i)\}$ reduces to $\text{diag}(w_i)$, since $h'(\eta) = V(\mu)$ there (Theorem 34.3.1(d)), and with $w_i \equiv 1$ the identity becomes $\mathbf{X}^\top(\mathbf{y} - \boldsymbol{\mu}) = \mathbf{0}$.

- (c) At convergence the fitted linear predictor is $\mathbf{Z}\mathbf{A}^{-1}\mathbf{Z}^\top\mathbf{W}\mathbf{z}$, of the same form as in [Proposition 44.1.2](#); its trace is $\text{tr}(\mathbf{Z}\mathbf{A}^{-1}\mathbf{Z}^\top\mathbf{W}) = \text{tr}(\mathbf{A}^{-1}\mathbf{Z}^\top\mathbf{W}\mathbf{Z})$ ([Theorem 1.6.1](#)), and the block decomposition of [Proposition 44.1.2\(b\)](#) goes through with $\mathbf{Z}^\top\mathbf{W}\mathbf{Z}$ in place of $\mathbf{Z}^\top\mathbf{Z}$. Treating $\mathbf{z}$ as a response with covariance $\phi\mathbf{W}^{-1}$, as in [Theorem 34.4.1](#), gives $\text{Cov}(\hat{\gamma}) \approx \phi\mathbf{A}^{-1}\mathbf{Z}^\top\mathbf{W}\mathbf{Z}\mathbf{A}^{-1}$; the Bayesian form is [Proposition 44.5.2](#) with $\mathbf{R} = \phi\mathbf{W}^{-1}$.
- (d) Not proved here; see the notes.

■

Idea. Penalized IRLS is the whole algorithm: a generalized additive model is a generalized linear model whose weighted least squares step has acquired a penalty. Deviance, residuals, dispersion, offsets, the canonical-link orthogonality all survive, because the working problem is the same working problem.

What Hastie and Tibshirani (1990) called **local scoring** differs only in solving the inner penalized weighted least squares problem by backfitting ([Theorem 44.2.1](#)) rather than by one direct solve — essential when a $d \times d$ solve was expensive, a matter of taste now. [Exercise \(B1\)](#) works out the correspondence.

The inner loop needs one addition to the toolkit: the working weights and the working response. The first cell below repeats, unchanged, the term constructor of [Section 44.2](#) and the solver of [Section 44.5](#), so that this page runs on its own; the second is the new part.

44.6.2 Choosing the smoothing parameters, and the dispersion

Eq. 44.5.4 was derived for a normal response. The standard device, the *performance iteration* of Gu (1992), applies it to the working problem: at each penalized IRLS step treat $\mathbf{z}$ as a normal response with covariance $\phi \mathbf{W}^{-1}$, update $\boldsymbol{\lambda}$ by Eq. 44.5.4 with the weights in place, and continue. That is what `irls_reml` does above. Recomputing $\boldsymbol{\lambda}$ by maximizing a properly defined restricted likelihood for the generalized model at every step is more stable and is what modern software does; Wood (2011) gives it.

One choice there matters more than it looks. For a Poisson or binomial response the nominal dispersion is $\phi = 1$, and taking that at face value when the data are overdispersed makes $\lambda_j = \hat{\phi}/\hat{\tau}_j^2$ too small by the factor $\hat{\phi}$, so every curve is undersmoothed. Chapter 38 built the repair: estimate ϕ by the Pearson statistic over the residual degrees of freedom (Proposition 38.3.2) and use *that* in the update, which is the quasi-likelihood position of Definition 38.2.1.

Example. (Physician visits, with two smooth terms)

Example (Physician visits in a health insurance experiment) fitted a Poisson log-linear model to the RAND Health Insurance Experiment, $n = 20190$ person-years, with every regressor entering linearly — among them a general disease index, which has no reason to be linear on the log scale. Take that index and one further variable of the same kind, the log of the participation incentive payment, and give each a P-spline term of 12 basis functions, keeping the coinsurance, deductible-plan, physical-limitation and health-status regressors linear: that is a generalized additive model, fitted by Eq. 44.6.2. Its baseline throughout is the **linear fit**, meaning the same list of regressors with the disease index and the incentive payment entering linearly too.

The disease term takes 9.11 effective degrees of freedom and the incentive term 4.48, out of 20.59 for the whole model. The estimated dispersion is 6.22, so these data are as overdispersed as Chapter 37 found them; the smoothing parameters, 1.16 and 103.94, were chosen with that dispersion in place. The coefficient of log coinsurance is -0.1146 , a rate ratio of 0.8917, against -0.0874 in the linear fit and -0.0712 in the smaller model of Example (Physician visits in a health insurance experiment), which carried no incentive-payment term at all; self-reported physical limitation still multiplies the rate by $e^{0.2777}$.

The deviance falls from 84378 for the linear fit to 83619, at a cost of 11.59 degrees of freedom. Scaling by the dispersion gives a quasi- F statistic of 10.54 on 11.59 and 20169 degrees of freedom, whose nominal p -value is 1.6×10^{-20} . The deviance difference is the statistic of Theorem 34.5.5(a), but its reference distribution there assumed a fixed nested pair, and here the larger model was smoothed. Read as a rough diagnostic rather than as a test, it says what panel (a) of Figure 44.6.1 shows: the effect of the disease index is far from linear — it rises steeply over the first half of the range and then flattens — and no straight line would do.

Figure 44.6.1: A Poisson generalized additive model for physician visits. (a) and (b) the two smooth terms, with two-standard-error bands and a rug of covariate quantiles. (c) and (d) observed mean, and observed variance, against fitted mean over twenty bins, the last with the Poisson and quasi-Poisson lines.

The same panel is a warning. Above a disease index of 40 lie 55 person-years, 0.3% of the sample, and the curve there swings by more than a unit on the log scale with a standard error of 0.347, against 0.011 at the median. That wiggle is an artefact of a handful of observations and a globally chosen smoothing parameter; report it as “no information above 40”, not as a finding.

44.6.3 What the p-values are worth

Warning (Inference after choosing the smoothing parameters). The statistic in [Theorem 44.6.1\(d\)](#) and the quasi- F of [Example \(Physician visits, with two smooth terms\)](#) both treat λ as a constant. It is not: it was chosen from the same data, by minimizing a criterion that rewards fitting those data well — [Proposition 29.5.1](#) in a new costume. Three consequences, in order of importance:

1. The reference distribution is approximate even when everything else is right. How good the approximation of [Theorem 44.6.1\(d\)](#) is depends on the term; Wood (2013) reports both the cases where it works and the cases where it fails, and simulation is the only way to know which one is at hand.
2. A term that the smoothing-parameter selection has pushed to the boundary $\lambda_j = \infty$ — smoothed to a straight line, or to zero — sits on the edge of the parameter space, where [Theorem 32.5.2](#) says the usual asymptotics fail.
3. A p -value for a term that was *selected* into the model by the same fit is not a p -value at all.

Use these numbers to rank terms and to screen, nothing more. For a claim that matters, hold out data, or put the whole fitting procedure — smoothing-parameter selection included — inside the resampling loop of [Chapter 23](#).

44.6.4 Checking the fit

The model is still a generalized linear model at heart, so the diagnostics of [Chapter 39](#) transfer unchanged; panels (c) and (d) of [Figure 44.6.1](#) show two of them, binned by fitted mean. Panel (c) is the binned analogue of the exact recalibration identity [Proposition 35.4.2](#), which a penalized fit no longer satisfies exactly, since the score identity of [Theorem 44.6.1\(b\)](#) holds only for the unpenalized columns. Panel (d) puts the observed variance in the same bins against the fitted mean: far above the Poisson line $\sigma^2 = \mu$ and close to $\hat{\phi}\mu$, so the mean model is adequate, the variance model is not, and every standard error must carry the dispersion ([Definition 38.2.1](#)). One check is specific to these models: a term whose effective degrees of freedom sit close to $d_j - 1$, the most its basis allows, is asking for more basis functions; refit with more and see whether the curve moves.

A smoothing parameter shrinks a term towards its penalty null space but not through it: however large λ_j grows, a P-spline term with a second-difference penalty keeps a straight line and never leaves the model. Both standard repairs are penalties, so both live inside [Definition 44.5.1](#): a second penalty on the null space, letting the restricted likelihood shrink the term to zero (Marra and Wood, 2011; [Exercise \(B2\)](#)); or a penalty that is not differentiable at zero, the group lasso of [Section 30.3](#) with each term a group, which removes terms exactly.

44.6.5 Where this leaves the book

Part IX set out to drop the linear predictor, and it has. A modern additive fit is a linear model in a basis, with a quadratic penalty per term, a variance ratio per penalty and a mixed model underneath; the response may come from any exponential dispersion family, and the terms may be curves, surfaces, maps or clusters.

One assumption has survived it all. Every model in this book, from [Chapter 5](#) to this page, has modelled the *mean* of the response and treated the rest of its distribution as a nuisance — σ^2 , or ϕ , or a variance function fixed by the family. When the spread or the shape is itself the object of interest, that is not enough. [Chapter 45](#), the last of the book, gives up the mean: it estimates quantiles directly, and then lets *every* parameter of a response distribution carry a structured additive predictor of its own ([Definition 45.5.1](#)) — this chapter’s machinery, run once per parameter.

44.6.6 Exercises

44.6.6.1 A. Check your understanding

Exercise A1.

In [Theorem 44.6.1\(a\)](#) the dispersion cancels from the iteration but not from the smoothing-parameter update. Explain the difference, and say what happens to the fitted curves if $\phi = 1$ is assumed when in truth $\phi = 6$.

Solution. Given λ , ϕ only rescales [Eq. 44.6.1](#), so the minimizer is unchanged. The update $\lambda_j = \phi/\tau_j^2$ compares the penalty term with the noise level, so getting the noise level wrong by a factor of six makes every λ_j six times too small: undersmoothed curves, too many effective degrees of freedom, bands too narrow.

44.6.6.2 B. Practice

Exercise B1.

Local scoring. Show that replacing the direct solve in [Eq. 44.6.2](#) by one or more backfitting cycles on the weighted penalized normal equations gives the local scoring algorithm of Hastie and Tibshirani, and that [Theorem 44.2.1](#) applies to the inner loop with $\mathbf{Z}_j^\top \mathbf{Z}_j$ replaced by $\mathbf{Z}_j^\top \mathbf{W} \mathbf{Z}_j$. What must be true of $\mathbf{W}$ for the convergence proof to go through?

Solution. [Eq. 44.6.2](#) is $\mathbf{A}\boldsymbol{\gamma} = \mathbf{Z}^\top \mathbf{W} \mathbf{z}$ with $\mathbf{A} = \mathbf{Z}^\top \mathbf{W} \mathbf{Z} + \mathbf{P}$: the structure of [Eq. 44.1.6](#) with the inner product $\langle \mathbf{u}, \mathbf{v} \rangle_{\mathbf{W}} = \mathbf{u}^\top \mathbf{W} \mathbf{v}$ in place of the Euclidean one, so backfitting on it is block Gauss–Seidel, which is local scoring. The proof of [Theorem 44.2.1](#) needs $\mathbf{A}$ symmetric nonnegative definite with positive definite diagonal blocks, hence $\mathbf{W}$ nonnegative definite — working weights are, being $h'(\eta_i)^2/V(\mu_i) \geq 0$ — and positive on enough observations to keep each $\mathbf{Z}_j^\top \mathbf{W} \mathbf{Z}_j + \lambda_j \mathbf{P}_j$ nonsingular.

Exercise B2.

Shrinking a whole term away. Let $\mathbf{P}_j$ have null space of dimension m_j with orthonormal basis $\mathbf{Q}_j^0$, and replace the penalty by $\mathbf{P}_j + \epsilon \mathbf{Q}_j^0 \mathbf{Q}_j^{0\top}$ for a small $\epsilon > 0$. Show that the new penalty is positive definite, that $\lambda_j \rightarrow \infty$ now shrinks the whole term to zero, and that $\text{df}_j \rightarrow 0$.

Solution. Split $\boldsymbol{\gamma} = \boldsymbol{\gamma}^+ + \boldsymbol{\gamma}^0$ over the range and null space of $\mathbf{P}_j$; the new quadratic form is $\boldsymbol{\gamma}^{+\top} \mathbf{P}_j \boldsymbol{\gamma}^+ + \epsilon \|\boldsymbol{\gamma}^0\|^2$, zero only if both pieces vanish, so it is positive definite with null space $\{\mathbf{0}\}$. By [Proposition 44.1.2\(b\)](#) the term's degrees of freedom then fall to 0 as $\lambda_j \rightarrow \infty$, with $\hat{\boldsymbol{\gamma}}_j \rightarrow \mathbf{0}$: the restricted likelihood can select the term out, which is what [Eq. 44.5.4](#) does when it explains nothing.

44.6.6.3 C. Going deeper**Exercise C1.**

In [Example \(Physician visits, with two smooth terms\)](#) the curve above a disease index of 40 rests on 55 observations. Suppose all of them were deleted. Using the fact that the P-spline penalty of [Definition 43.3.1](#) has the straight lines as its null space, describe exactly what the fitted curve does over the empty range, and compute the limit of its variance as the range of emptiness grows.

44.7 Summary and Notes

44.7.1 Summary

Idea.

1. Additivity is the structural assumption that makes nonparametric regression possible in more than one or two dimensions. The model is [Definition 44.1.1](#); its components are fixed only up to constants until centred ([Proposition 44.1.1](#)), a constraint best absorbed into the basis.
2. In a basis, an additive model is one penalized regression with a block-diagonal penalty: [Eq. 44.1.4](#) and the penalized normal equations [Eq. 44.1.6](#). The fit is a linear smoother, its effective degrees of freedom are $\text{tr } \mathbf{S}$, and they split over the terms ([Proposition 44.1.2](#)).
3. Backfitting — smooth each term against the partial residual, and cycle — is block Gauss–Seidel on those equations and block coordinate descent on the criterion, converging geometrically to the unique fit when the penalized cross-product is positive definite and to a minimizer otherwise ([Theorem 44.2.1](#)); unpenalized, it is alternating projection ([Corollary 44.2.2](#)).
4. Concurvity is collinearity between function spaces ([Definition 44.2.1](#)). It leaves the fitted mean alone, inflates the variance of the components by $1/(1 - \kappa_j)$ in the worst direction ([Proposition 44.2.3](#)), and is invisible in a correlation matrix.
5. A varying-coefficient term $f(z)u$ is an ordinary penalized term whose design is the

basis scaled row by row ([Definition 44.3.1](#), [Proposition 44.3.1](#)): smooth interactions, factor-by-curve models and time-varying coefficients at no extra cost.

6. A spatial effect is a term too ([Definition 44.4.1](#)): for areal data the penalty [Eq. 44.4.2](#), with one null direction per connected component and a conditional reading as shrinkage towards the neighbour mean ([Proposition 44.4.1](#)); for coordinates a kriging basis penalized by the correlation matrix at the knots ([Proposition 44.4.2](#)), the mixed model of Part VII in disguise.
7. Structured additive regression ([Definition 44.5.1](#)) is the whole catalogue in one predictor. It is identified whenever the *unpenalized parts* of its terms are ([Proposition 44.5.1](#)), it is a linear mixed model after one orthogonal transformation ([Proposition 44.5.2](#)), and its smoothing parameters are variance ratios estimated by [Eq. 44.5.4](#) ([Proposition 44.5.3](#)).
8. With a link and an exponential dispersion family the fit is penalized IRLS ([Theorem 44.6.1](#)): [Chapter 34](#)'s algorithm with the penalty added. Degrees of freedom, dispersion and [Chapter 39](#)'s diagnostics carry over, and the dispersion belongs in the smoothing-parameter update or every curve is undersmoothed.
9. Inference for a smooth term is approximate, and doubly so because the smoothing parameters were chosen from the same data. The p -values rank terms; they do not test them.

44.7.2 Notes and sources

Additive models and backfitting. The additive model and backfitting come from Friedman and Stuetzle (1981), where the cycling served projection pursuit regression, and from Breiman and Friedman (1985). The definitive analysis is Buja, Hastie and Tibshirani (1989): the Gauss–Seidel reading, the convergence theory for symmetric shrinking smoothers, concurvity, and the distinction between convergence of the fit and of the components are all theirs. [Theorem 44.2.1](#) is that theory for penalized smoothers, where the argument reduces to the Ostrowski–Reich theorem (Golub and Van Loan, 2013, chapter 11); Hastie and Tibshirani (1990) made the models widely used. The order here reverses the historical one: because [Chapter 43](#) built its smoothers from bases and penalties, the direct solve is available from the start and backfitting becomes an algorithm for large problems rather than the definition of the estimator. Wood (2017) takes the same view and is the standard modern reference for the chapter. A fourth route, met in [Chapter 30](#) rather than here, is componentwise boosting: fit a block to the current residual as backfitting does, but damp the step and pick the block greedily instead of cycling ([Theorem 30.4.1](#)).

Concurvity. The word and the phenomenon are from Buja, Hastie and Tibshirani (1989); measuring it by canonical correlations between the component spaces, as in [Definition 44.2.1](#), and reporting it routinely follow Wood (2017). Ramsay, Burnett and Krewski (2003) document how badly it distorts component estimates in air-pollution time-series studies, where pollution, temperature and season are nearly functions of one another.

Varying coefficients. Hastie and Tibshirani (1993) introduced these models in the generality used here; the tensor-product construction is developed in Wood (2017).

Spatial terms. The Markov random field penalty and its conditional reading are due to Besag (1974); the intrinsic form used here, with the convolution model that adds an unstructured region effect, is Besag, York and Mollié (1991), and Rue and Held (2005) is the systematic treatment. The kriging side goes back to Matheron (1963); the low-rank penalized version of

[Proposition 44.4.2](#), and the name *geoadditive model*, are from Kammann and Wand (2003), and Wendland (1995) constructed the compactly supported radial functions used in the example. Reich, Hodges and Zadnik (2006) sharpen the spatial-confounding warning: a spatial random effect can move a fixed-effect estimate substantially, in a direction that is hard to predict.

Structured additive regression. The name and the framework are from Fahrmeir, Kneib and Lang (2004) and Brezger and Lang (2006); the presentation in Fahrmeir, Kneib, Lang and Marx (2021, chapter 9) is the one this chapter is answerable to. The mixed-model representation is older: Verbyla et al. (1999) developed it and Ruppert, Wand and Carroll (2003) built a book on it. The updates [Eq. 44.5.4](#) are Schall (1991), analysed in their modern form by Wood and Fasiolo (2017) as the Fellner–Schall method. The fully Bayesian version is Lang and Brezger (2004); the warning about improper posteriors from vague priors on variance components is Hobert and Casella (1996), with Gelman (2006) on which proper priors behave well.

Generalized additive models. Local scoring is Hastie and Tibshirani (1986, 1990). The direct penalized-IRLS form of [Theorem 44.6.1](#), which is what software now uses, is developed in Wood (2017, chapter 6); the performance iteration is Gu (1992), and the more stable outer iteration, which differentiates a properly defined restricted likelihood, is Wood (2011). The approximate reference distribution quoted without proof in [Theorem 44.6.1\(d\)](#) is derived, with simulation evidence for its accuracy and its failure modes, in Wood (2013). The bands come from the Bayesian argument of Wahba (1983) and Nychka (1988) through [Theorem 43.6.1](#); Marra and Wood (2012) find their coverage survives averaged over the curve but not pointwise. Term selection by an extra penalty on the null space is Marra and Wood (2011).

Two threads the book does not develop. Smoothing-spline analysis of variance, Gu (2013), builds additive and interaction models from reproducing-kernel Hilbert spaces rather than from bases and difference penalties, reaching the same models by a more elegant and more demanding route. And the theory of *rates*: the optimal rate quoted in [Section 44.1](#) is Stone (1980), and the fact that each additive component can still be estimated at the one-dimensional rate whatever q is — so that additivity defeats the curse of dimensionality rather than merely dodging it — is Stone (1985), with the sharp version for backfitting in Opsomer and Ruppert (1997). Those proofs need empirical-process tools this book does not assume.

Chapter 45

Quantile Regression and GAMLSS

Forty-four chapters have been spent on one number. Least squares estimates a conditional mean; the generalized linear model estimates a transformed conditional mean; splines and additive models let that mean bend. Everything else about the conditional distribution of the response — its spread, its skewness, its tails — entered as an assumption to be checked, a nuisance to be corrected for, or a reason to widen a standard error. This last chapter turns the nuisance into the subject.

There are two ways to do it. One drops the parametric model and estimates the conditional quantiles directly, each level fitted by its own criterion: that is quantile regression, whose loss function is as simple as squared error and as easy to justify. The other keeps a parametric family but lets *every* parameter of it carry its own structured additive predictor: that is GAMLSS. Between them sits expectile regression, which buys a differentiable loss at the price of a less transparent interpretation. The chapter ends where a book about models should end: with how to tell whether one estimated distribution is better than another.

What you need. [Chapter 5](#) and [Chapter 6](#) (the linear model, least squares and the best linear predictor [Theorem 6.11.1](#)), [Chapter 21](#) (heteroscedasticity, weighted least squares and the sandwich [Definition 21.4.1](#)), [Chapter 22](#) ([Definition 22.2.1](#), the older route to a well-behaved response), [Chapter 23](#) (the bootstrap [Definition 23.1.1](#) and the permutation schemes [Definition 23.5.1](#)), [Chapter 25](#) (what a fitted curve does and does not mean), [Chapter 29](#) (cross-validation [Theorem 29.3.2](#), AIC [Proposition 29.2.4](#), selection bias [Proposition 29.5.1](#)), [Chapter 30](#) (penalized fitting [Definition 30.1.1](#)) and [Chapter 34](#) (the generalized linear model [Definition 34.2.1](#) and its iteratively reweighted least squares [Theorem 34.4.1](#)). The last two sections use the penalized splines of [Chapter 43](#) and the structured additive predictors of [Chapter 44](#); the M-estimation machinery of [Section 20.6](#) ([Proposition 20.6.1](#)) is the ancestor of two algorithms below.

45.0.1 Roadmap

- [Why model more than the mean](#)
- [Quantile regression](#)
- [Inference for quantile regression](#)
- [Expectile regression](#)
- [Models for location, scale and shape](#)
- [Comparing distributional models](#)

- [Summary and notes](#)

45.1 Why model more than the mean

A fitted regression is usually reported as a curve with a band around it. The curve estimates $E(Y | \mathbf{x})$; the band says how far individual responses fall from it. In every model this book has built, the curve has been the object of study and the band an afterthought, computed from one variance parameter, one variance function or one sandwich correction. That division of labour is a modelling decision, and often a bad one.

45.1.1 What the mean model promises

Take the model of [Chapter 5](#) in its strongest form: $Y = \mathbf{x}^\top \boldsymbol{\beta} + \varepsilon$ with ε independent of $\mathbf{x}$. Write

$$Q_Y(\tau | \mathbf{x}) = \inf\{q : P(Y \leq q | \mathbf{x}) \geq \tau\}$$

for the conditional quantile function. A homoscedastic model makes it a rigid object: all its level curves are one curve, shifted.

Lemma 45.1.1 — Quantiles follow monotone maps

Let Y be a random variable and h a strictly increasing, left-continuous function on the range of Y . Then $Q_{h(Y)}(\tau) = h(Q_Y(\tau))$ for every $\tau \in (0, 1)$.

Proof. Write F for the distribution function of Y and $q_0 = Q_Y(\tau)$. Strict monotonicity gives $\{y : h(y) \leq h(q_0)\} = \{y : y \leq q_0\}$, so $P\{h(Y) \leq h(q_0)\} = F(q_0) \geq \tau$ and $h(q_0)$ is admissible in the infimum defining $Q_{h(Y)}(\tau)$. For the reverse inequality the infimum runs over all real c , not only over values of h , and that is where left-continuity is needed. Take $c < h(q_0)$ and put $b = \sup\{y : h(y) \leq c\}$; if that set is empty then $P\{h(Y) \leq c\} = 0 < \tau$ at once. Otherwise $h(b) = \lim_{y \uparrow b} h(y) \leq c$ by left-continuity, so the set is $(-\infty, b]$ and $P\{h(Y) \leq c\} = F(b)$; and $h(b) \leq c < h(q_0)$ forces $b < q_0$, whence $F(b) < \tau$ by the definition of q_0 . No $c < h(q_0)$ is admissible, so the two infima agree. ■

Proposition 45.1.2 — What a mean model does and does not say

Let $\mathbf{x}$ be a covariate vector and ε a random variable with quantile function q_ε , independent of $\mathbf{x}$.

- Location model.** If $Y = \mathbf{x}^\top \boldsymbol{\beta} + \varepsilon$, then $Q_Y(\tau | \mathbf{x}) = \mathbf{x}^\top \boldsymbol{\beta} + q_\varepsilon(\tau)$. Every conditional quantile curve is the regression curve shifted by a constant, so the effect of a covariate on the τ -quantile is $\boldsymbol{\beta}$, the same for every τ , and the conditional distribution has the same shape and the same spread everywhere.
- Location-scale model.** If $Y = \mathbf{x}^\top \boldsymbol{\beta} + \exp(\mathbf{x}^\top \boldsymbol{\alpha})\varepsilon$, then

$$Q_Y(\tau | \mathbf{x}) = \mathbf{x}^\top \boldsymbol{\beta} + \exp(\mathbf{x}^\top \boldsymbol{\alpha}) q_\varepsilon(\tau), \quad (45.1.1)$$

so $\partial Q_Y(\tau | \mathbf{x}) / \partial \mathbf{x} = \boldsymbol{\beta} + q_\varepsilon(\tau) \exp(\mathbf{x}^\top \boldsymbol{\alpha}) \boldsymbol{\alpha}$ does depend on τ . The quantile curves are no longer parallel, but they are still generated by one curve q_ε stretched by one positive function.

- (c) **Beyond scale.** In (b) the standardized response $\{Y - \mathbf{x}^\top \boldsymbol{\beta}\} \exp(-\mathbf{x}^\top \boldsymbol{\alpha})$ has a distribution free of $\mathbf{x}$. Any feature of the conditional law that is invariant under location and scale changes — skewness, kurtosis, the ratio of any two central moments of the same degree — is therefore constant in $\mathbf{x}$. A model of the mean and the variance cannot represent a conditional distribution whose *shape* moves with $\mathbf{x}$.

Proof. Parts (a) and (b) are [Lemma 45.1.1](#) applied conditionally on $\mathbf{x}$ to the strictly increasing map $h(e) = \mathbf{x}^\top \boldsymbol{\beta} + ce$ with $c = 1$ and $c = \exp(\mathbf{x}^\top \boldsymbol{\alpha}) > 0$; the derivative in (b) is immediate from [Eq. 45.1.1](#). For (c), write $Z = \{Y - \mathbf{x}^\top \boldsymbol{\beta}\} \exp(-\mathbf{x}^\top \boldsymbol{\alpha})$. By construction $Z = \varepsilon$, whose law does not involve $\mathbf{x}$, and any location-scale invariant functional of the conditional law of Y equals the same functional of the law of Z . ■

In plain words: quoting one residual standard deviation asserts that the poorest household's food budget is as predictable as the richest one's, and that a covariate moving the median moves the tenth and ninetieth percentiles by exactly the same amount. Those are claims about the world, rarely examined and often false.

45.1.2 Heteroscedasticity is a finding

[Chapter 21](#) treated non-constant variance as a problem to be managed: test for it ([Theorem 21.2.2](#)), fix the standard errors ([Definition 21.4.1](#)), or reweight ([Theorem 21.3.1](#)). All three treat $\text{Var}(Y | \mathbf{x})$ as a nuisance, yet the variance function is often the more interesting half of the model. If the spread of insurance claims grows faster than their mean, that is the fact the insurer is pricing; if the variability of a child's height at a given age defines the reference band, the band *is* the model.

Example. (Engel's budgets, one more time)

Engel's 1857 survey of 235 Belgian working-class households records annual income and annual food expenditure; the same data supported the diagnostics of [Chapter 20](#) and the tests of [Section 21.2](#). Least squares gives a slope of 0.4852 and a single residual standard deviation of 114.1 francs. Split the households into thirds by income: the residual standard deviations within the thirds are 48.6, 74.8 and 171.6 francs, a ratio of 3.53 from the poorest third to the richest.

The consequence for a prediction interval is immediate. The nominal 95% interval from the homoscedastic normal model contains 1.000 of the poorest third, 1.000 of the middle third and 0.911 of the richest — far too wide where the data are tight and too narrow where they are loose — while the overall figure of 0.970 looks respectable. Averaging over the design hides the error that matters to each household.

Figure 45.1.1: Engel's budget survey. (a) The least squares line with the 95% prediction band of a homoscedastic normal model. (b) Residuals by income fifth.

Shape moves too. The quartile coefficient of skewness, $(q_{0.75} + q_{0.25} - 2q_{0.5}) / (q_{0.75} - q_{0.25})$, is -0.23 for the residuals of the poorest fifth of households and 0.40 for the richest fifth, and the interquartile range grows by a factor of 3.75 between them (Figure 45.1.1).

```
import numpy as np
import statsmodels.api as sm
from scipy import stats
data = sm.datasets.engel.load_pandas().data

income = data["income"].to_numpy()
food = data["foodexp"].to_numpy()
n = len(income)
X = np.column_stack([np.ones(n), income])

beta, *_ = np.linalg.lstsq(X, food, rcond=None)
resid = food - X @ beta
sigma = np.sqrt(resid @ resid / (n - 2))          # one number for every household

# a 95% prediction interval from the homoscedastic normal model
t = stats.t.ppf(0.975, n - 2)
lev = np.einsum("ij,jk,ik->i", X, np.linalg.inv(X.T @ X), X)
half = t * sigma * np.sqrt(1 + lev)
inside = (food >= X @ beta - half) & (food <= X @ beta + half)

# split the households into income thirds and look at the spread in each
edges = np.quantile(income, [1 / 3, 2 / 3])
third = np.digitize(income, edges)
spread = [resid[third == k].std(ddof=1) for k in range(3)]
covered = [inside[third == k].mean() for k in range(3)]

print(f"residual sd by income third: {spread[0]:.1f}, {spread[1]:.1f}, {spread[2]:.1f}")
print(f"inside the 95% band: {covered[0]:.3f}, {covered[1]:.3f}, {covered[2]:.3f}")
```

45.1.3 Questions that need a distribution

Some questions cannot even be stated in terms of a conditional mean. *What share of a poor household's income goes on food?* asks for a low quantile, because policy is written about the vulnerable. *What is the tenth percentile of birth weight at this gestational age?* asks for a paediatric reference chart, a grid of conditional quantiles. *How much capital must be held against this portfolio?* asks for a value at risk, a conditional quantile and not a multiple of a conditional standard deviation unless the shape is known. *Has inequality in wages changed, or only the average wage?* compares quantile curves at different levels, which is where quantile regression entered economics.

45.1.4 Three routes

The three sections that follow take three strategies, in increasing order of what they assume: estimate each quantile separately by an asymmetrically weighted absolute deviation; estimate each expectile separately by an asymmetrically weighted *squared* deviation, buying a differentiable loss at the price of a fitted quantity that is harder to describe; or model the whole conditional law by giving every parameter of a parametric family its own structured additive predictor. A fourth route was taken long ago — transform the response until a homoscedastic model fits, as in [Definition 22.2.1](#) — but one power must serve the whole design, and [Section 22.5](#) recorded what that costs when the answer is wanted on the original scale. Because the routes answer different questions, they are compared in [Section 45.6](#) by which produces the better predictive distribution.

45.1.5 Exercises

45.1.5.1 A. Check your understanding

Exercise A1.

In a homoscedastic linear model with normal errors, by how much does the 0.9 conditional quantile exceed the 0.5 conditional quantile? Show that the answer does not depend on $\mathbf{x}$, and say which part of [Proposition 45.1.2](#) this illustrates.

Solution. The difference is $\sigma\{\Phi^{-1}(0.9) - \Phi^{-1}(0.5)\} = \sigma\Phi^{-1}(0.9)$, with $\Phi^{-1}(0.9) \approx 1.2816$. By [Proposition 45.1.2\(a\)](#) the two quantile curves are the regression curve shifted by constants, so their difference is a constant free of $\mathbf{x}$.

45.1.5.2 B. Practice

Exercise B1.

Let $\log Y \mid x \sim N(\alpha + \beta x, \sigma^2)$ with σ constant. Show that the conditional quantiles of Y are *not* parallel, that the conditional coefficient of variation is constant, and that the conditional skewness is constant. Which parts of [Proposition 45.1.2](#) apply to Y , and which to $\log Y$?

Solution. By Lemma 45.1.1 with $h = \exp$, $Q_Y(\tau | x) = \exp\{\alpha + \beta x + \sigma\Phi^{-1}(\tau)\}$, so the ratio of two quantile curves is constant while their difference is not: the curves fan out. $E(Y | x) = \exp(\alpha + \beta x + \sigma^2/2)$ and $\text{Var}(Y | x) = E(Y | x)^2(e^{\sigma^2} - 1)$, so the coefficient of variation is $(e^{\sigma^2} - 1)^{1/2}$, free of x ; the skewness of a lognormal depends only on σ . Thus $\log Y$ obeys part (a) and Y obeys part (b) with $\exp(\mathbf{x}^\top \boldsymbol{\alpha})$ proportional to $\exp(\beta x)$: a covariate-dependent scale but a frozen shape.

Exercise B2.

In Example (Engel's budgets, one more time) the homoscedastic 95% prediction interval has half-width close to 2×114.1 francs for every household. Using the within-third standard deviations, say roughly what nominal level that half-width actually attains in the poorest third and in the richest third, if the conditional law were normal with the within-third standard deviation. Comment on the direction of both errors.

45.2 Quantile regression

Least squares answers a question about a loss function: which constant minimizes expected squared error? Change the loss and the answer changes. The median minimizes expected absolute error, and one modification of absolute error — weighting the two sides differently — picks out any quantile at all. Koenker and Bassett (1978) built a regression method on that observation.

45.2.1 The check loss

Definition 45.2.1 — Check loss and quantile regression

For $\tau \in (0, 1)$ the **check function** is

$$\rho_\tau(u) = u\{\tau - 1\{u < 0\}\} = \begin{cases} \tau u, & u \geq 0, \\ (\tau - 1)u, & u < 0, \end{cases} \quad (45.2.1)$$

a convex, piecewise linear, nonnegative function with a kink at the origin, equal to $|u|/2$ when $\tau = 1/2$. The **linear quantile regression model** at level τ asserts

$$Q_Y(\tau | \mathbf{x}) = \mathbf{x}^\top \boldsymbol{\beta}_\tau,$$

and given data $(y_i, \mathbf{x}_{(i)})$, $i = 1, \dots, n$, a **τ -regression quantile** is any minimizer

$$\hat{\boldsymbol{\beta}}_\tau \in \arg \min_{\mathbf{b} \in \mathbb{R}^p} R_\tau(\mathbf{b}) = \sum_{i=1}^n \rho_\tau(y_i - \mathbf{x}_{(i)}^\top \mathbf{b}). \quad (45.2.2)$$

The subscript τ is there because the coefficients may differ from level to level: the model is a separate statement for each τ , not one model with a nuisance parameter. Nothing is assumed

about the shape of the conditional distribution, not even that it has a density.

45.2.2 What the check loss estimates

Theorem 45.2.1 — The check loss elicits the quantile

Let Y be a random variable with distribution function F and $E|Y| < \infty$, and let $G(q) = E\rho_\tau(Y - q)$.

- (a) **Population characterization.** G is finite and convex, and for $q < q'$

$$G(q') - G(q) = \int_q^{q'} \{F(s) - \tau\} ds. \quad (45.2.3)$$

Consequently the set of minimizers of G is exactly the set of τ -quantiles of F , that is $\{q : F(q^-) \leq \tau \leq F(q)\}$.

- (b) **Linear program.** Writing $u_i = (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})_+$ and $v_i = (\mathbf{x}_{(i)}^\top \mathbf{b} - y_i)_+$, problem Eq. 45.2.2 is equivalent to

$$\min_{\mathbf{b}, \mathbf{u}, \mathbf{v}} \{\tau \mathbf{1}^\top \mathbf{u} + (1 - \tau) \mathbf{1}^\top \mathbf{v}\} \quad \text{subject to} \quad \mathbf{X}\mathbf{b} + \mathbf{u} - \mathbf{v} = \mathbf{y}, \quad \mathbf{u} \geq \mathbf{0}, \quad \mathbf{v} \geq \mathbf{0}, \quad (45.2.4)$$

a linear program in $2n + 2p$ nonnegative variables with n equality constraints.

- (c) **Equivariance of the estimate.** Let $\hat{\beta}_\tau(\mathbf{y}, \mathbf{X})$ denote any solution of Eq. 45.2.2. For $a > 0$, $\boldsymbol{\gamma} \in \mathbb{R}^p$ and nonsingular $\mathbf{A}$,

$$\begin{aligned} \hat{\beta}_\tau(a\mathbf{y}, \mathbf{X}) &= a \hat{\beta}_\tau(\mathbf{y}, \mathbf{X}), & \hat{\beta}_\tau(-\mathbf{y}, \mathbf{X}) &= -\hat{\beta}_{1-\tau}(\mathbf{y}, \mathbf{X}), \\ \hat{\beta}_\tau(\mathbf{y} + \mathbf{X}\boldsymbol{\gamma}, \mathbf{X}) &= \hat{\beta}_\tau(\mathbf{y}, \mathbf{X}) + \boldsymbol{\gamma}, \\ \hat{\beta}_\tau(\mathbf{y}, \mathbf{X}\mathbf{A}) &= \mathbf{A}^{-1} \hat{\beta}_\tau(\mathbf{y}, \mathbf{X}). \end{aligned}$$

- (d) **Equivariance under monotone maps.** For strictly increasing left-continuous h , $Q_{h(Y)}(\tau | \mathbf{x}) = h\{Q_Y(\tau | \mathbf{x})\}$.

Proof.

- (a) Split the loss at the kink: $\rho_\tau(u) = \tau u_+ + (1 - \tau)u_-$, where $u_- = (-u)_+$, so $G(q) = \tau E(Y - q)_+ + (1 - \tau) E(q - Y)_+$, finite because both terms are bounded by $E|Y| + |q|$. By Fubini's theorem,

$$E(Y - q)_+ = \int_q^\infty \{1 - F(s)\} ds, \quad E(q - Y)_+ = \int_{-\infty}^q F(s) ds.$$

Subtracting the two expressions for q' and q gives

$$\begin{aligned} G(q') - G(q) &= -\tau \int_q^{q'} \{1 - F(s)\} ds + (1 - \tau) \int_q^{q'} F(s) ds \\ &= \int_q^{q'} \{F(s) - \tau\} ds, \end{aligned}$$

which is Eq. 45.2.3; convexity follows because the integrand is nondecreasing. Let $q_\tau = \inf\{q : F(q) \geq \tau\}$. If $q < q_\tau$ then $F(s) < \tau$ for every $s < q_\tau$, so $G(q) - G(q_\tau) = \int_q^{q_\tau} \{\tau - F(s)\} ds > 0$ and q is not a minimizer. If $q > q_\tau$ then $F(s) \geq F(q_\tau) \geq \tau$ for $s \geq q_\tau$ by right continuity, so $G(q) \geq G(q_\tau)$, with equality if and only if $F \equiv \tau$ almost everywhere on (q_τ, q) , that is $F(q^-) = \tau$. Hence q_τ is a minimizer and the minimizers are exactly the points with $F(q^-) \leq \tau \leq F(q)$.

- (b) For any $\mathbf{b}$ the choices $u_i = (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})_+$ and $v_i = (\mathbf{x}_{(i)}^\top \mathbf{b} - y_i)_+$ are feasible with objective value $R_\tau(\mathbf{b})$, so the linear program's optimum is at most $\min_{\mathbf{b}} R_\tau(\mathbf{b})$. Conversely, if $(\mathbf{b}, \mathbf{u}, \mathbf{v})$ is feasible then $u_i - v_i = y_i - \mathbf{x}_{(i)}^\top \mathbf{b}$, and for a fixed difference the sum $\tau u_i + (1 - \tau)v_i$ is minimized by $\min(u_i, v_i) = 0$, which gives exactly $\rho_\tau(y_i - \mathbf{x}_{(i)}^\top \mathbf{b})$. The two problems therefore have the same value and the same optimal $\mathbf{b}$.
- (c) For $a > 0$, $\rho_\tau(au) = a\rho_\tau(u)$, so $R_\tau(\mathbf{b}; a\mathbf{y}) = aR_\tau(\mathbf{b}/a; \mathbf{y})$ and the minimizers correspond under $\mathbf{b} \mapsto a\mathbf{b}$. A direct check on Eq. 45.2.1 gives $\rho_\tau(-u) = \rho_{1-\tau}(u)$, whence $R_\tau(\mathbf{b}; -\mathbf{y}) = R_{1-\tau}(-\mathbf{b}; \mathbf{y})$ and the second identity. For the shift, $y_i + \mathbf{x}_{(i)}^\top \boldsymbol{\gamma} - \mathbf{x}_{(i)}^\top \mathbf{b} = y_i - \mathbf{x}_{(i)}^\top (\mathbf{b} - \boldsymbol{\gamma})$, so the objective is the old one at $\mathbf{b} - \boldsymbol{\gamma}$. For the reparameterization, the residuals of $\mathbf{X}\mathbf{A}$ at $\mathbf{b}$ are those of $\mathbf{X}$ at $\mathbf{A}\mathbf{b}$.
- (d) This is Lemma 45.1.1 applied conditionally on $\mathbf{x}$.

■

Part (a) is the whole justification of the method, and it needs remarkably little: no density, no moments beyond the first, no continuity. Part (d) is a property least squares does not have: the median of $\log Y$ is the logarithm of the median of Y , while the mean of $\log Y$ is not the logarithm of the mean, the retransformation problem of Section 22.5. A quantile regression fitted on the log scale reads back without a smearing correction.

Remark (The influence of one observation). Away from the kink $\rho'_\tau(u) = \tau - 1\{u < 0\}$ takes only the values τ and $\tau - 1$, so an observation enters the estimating equation *only through the sign of its residual*: moving one response from $+10$ to $+10^6$ changes nothing. This is the bounded-influence property that made the median robust in Section 20.6. It buys nothing against a bad *design* point, whose $\mathbf{x}_{(i)}$ enters unbounded.

Remark (Without moments). Minimizing $G_0(q) = E\{\rho_\tau(Y - q) - \rho_\tau(Y)\}$ instead removes the moment condition: since $|\rho_\tau(u - v) - \rho_\tau(u)| \leq \max(\tau, 1 - \tau)|v|$, this is finite whatever the tails of Y , and differs from G by a constant whenever G is finite, so (a) holds verbatim.

45.2.3 Solving the problem

Proposition 45.2.2 — Interpolation and counting

Let $\text{rank}(\mathbf{X}) = p$ and let $\hat{\boldsymbol{\beta}}_\tau$ minimize Eq. 45.2.2.

- (a) There is a minimizer whose residual vector vanishes at p observations whose rows of $\mathbf{X}$ are linearly independent: the fit passes exactly through p of the data points.
- (b) If $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, then for *any* minimizer, with n_-, n_0, n_+ the numbers of negative, zero and positive residuals,

$$n_- \leq \tau n \leq n_- + n_0. \quad (45.2.5)$$

Proof.

- (a) Let $\mathbf{b}$ be any minimizer, $H = \{i : y_i = \mathbf{x}_{(i)}^\top \mathbf{b}\}$ the interpolated set, and suppose $\{\mathbf{x}_{(i)} : i \in H\}$ spans a space of dimension less than p . Choose $\mathbf{d} \neq \mathbf{0}$ orthogonal to all of them. For small t the residuals in H stay zero and no other residual changes sign, so

$$R_\tau(\mathbf{b} + t\mathbf{d}) = \sum_{i \notin H} (r_i - t\mathbf{x}_{(i)}^\top \mathbf{d}) \{\tau - 1\{r_i < 0\}\}, \quad r_i = y_i - \mathbf{x}_{(i)}^\top \mathbf{b},$$

which is affine in t . An affine function minimized at $t = 0$ is constant, so R_τ stays minimal as t grows, until some residual outside H reaches zero. Because $\text{rank}(\mathbf{X}) = p$ and $\mathbf{d} \neq \mathbf{0}$, some $\mathbf{x}_{(i)}^\top \mathbf{d} \neq 0$, so such a t exists and is finite; there the interpolated set is strictly larger and the objective still minimal. Repeating raises the rank of $\{\mathbf{x}_{(i)} : i \in H\}$ to p .

- (b) Let $\mathbf{1} = \mathbf{X}\mathbf{c}$ and consider $\phi(t) = R_\tau(\hat{\boldsymbol{\beta}}_\tau + t\mathbf{c})$, which shifts every fitted value by t and so every residual by $-t$. For $t > 0$ small, an observation with $r_i > 0$ contributes $\tau(r_i - t)$, one with $r_i \leq 0$ contributes $(\tau - 1)(r_i - t)$; hence $\phi'(0^+) = -\tau n_+ + (1 - \tau)(n_- + n_0)$. Similarly $\phi'(0^-) = -\tau(n_+ + n_0) + (1 - \tau)n_-$. Minimality forces $\phi'(0^+) \geq 0$ and $\phi'(0^-) \leq 0$. The first gives $\tau n_+ \leq (1 - \tau)(n_- + n_0)$; adding $\tau(n_- + n_0)$ to both sides and using $n_+ + n_- + n_0 = n$ yields $\tau n \leq n_- + n_0$. The second gives $\tau(n_+ + n_0) \geq (1 - \tau)n_-$, and adding τn_- to both sides yields $\tau n \geq n_-$. ■

Part (b) says the fitted surface has about τn observations below it, which is what the name promises; part (a) says it is pinned to p of the data points, as the median of an odd number of points is one of the points. Together they make the fit a combinatorial object: finitely many candidate hyperplanes, one per choice of p rows, and the optimum is one of them. Hence the simplex method of Koenker and d'Orey (1987) rather than differentiation, or the interior-point route of Portnoy and Koenker (1997), which makes quantile regression competitive in cost with least squares for large n .

Example. (Seven quantile lines for Engel's budgets)

Fitting Eq. 45.2.4 at seven levels gives slopes rising steadily with τ :

τ	0.05	0.10	0.25	0.50	0.75	0.90	0.95
slope	0.3434	0.4018	0.4741	0.5602	0.6440	0.6863	0.7091
intercept	124.9	110.1	95.5	81.5	62.4	67.4	64.1

The least squares slope, 0.4852, sits between the quartiles. A household at the tenth percentile of its income group spends about 0.4018 of each extra franc on food, one at the ninetieth 0.6863; at an income of 1000 francs the fitted median budget share is 0.642 and the tenth-percentile share 0.512. Every fit interpolates 2 observations and satisfies Eq. 45.2.5, as the listings verify.

```

import numpy as np
import statsmodels.api as sm
from scipy.optimize import linprog
data = sm.datasets.engel.load_pandas().data
TAUS = (0.05, 0.10, 0.25, 0.50, 0.75, 0.90, 0.95)

income = data["income"].to_numpy()
food = data["foodexp"].to_numpy()
n = len(food)
X = np.column_stack([np.ones(n), income])

def check_loss(u, tau):
    """The check function rho_tau applied elementwise."""
    return u * (tau - (u < 0))

def qreg(X, y, tau):
    """Quantile regression by linear programming.

    Variables are (b+, b-, u, v), all nonnegative, with beta = b+ - b- and
    u - v = y - X beta the positive and negative parts of the residual.
    """
    n, p = X.shape
    cost = np.concatenate([np.zeros(2 * p), tau * np.ones(n), (1 - tau) * np.ones(n)
    ])
    A = np.hstack([X, -X, np.eye(n), -np.eye(n)])
    out = linprog(cost, A_eq=A, b_eq=y, bounds=(0, None), method="highs")
    return out.x[:p] - out.x[p:2 * p]

beta = {tau: qreg(X, food, tau) for tau in TAUS}
for tau in (0.10, 0.50, 0.90):
    print(f"tau = {tau:.2f}:  intercept {beta[tau][0]:8.2f}    slope {beta[tau][1]:.4f}")

for tau in TAUS:
    r = food - X @ beta[tau]
    n_zero = np.sum(np.abs(r) < 1e-8)
    n_neg = np.sum(r < -1e-8)
    assert n_zero == X.shape[1] # p residuals vanish exactly
    assert n_neg <= tau * n <= n_neg + n_zero # the counting identity
    print(f"at every tau: 2 residuals are zero and #negative <= tau*n <= #negative + 2")

```

Koenker and Machado (1999) proposed the analogue of R^2 : with $\hat{V}(\tau)$ the minimized check loss and $\tilde{V}(\tau)$ its value in the intercept-only model, $R_1(\tau) = 1 - \hat{V}(\tau)/\tilde{V}(\tau)$. For Engel's data it rises from 0.474 at $\tau = 0.05$ to 0.805 at $\tau = 0.95$: income explains far more about the upper tail than about the lower. Like R^2 it says nothing about whether the linear specification is right.

45.2.4 Reading a coefficient

The coefficient $\beta_{\tau j}$ is the derivative of the τ -quantile of the conditional distribution with respect to x_j . It is *not* the effect of x_j on the household that happens to sit at rank τ .

Remark (Quantiles of distributions, not of people). Suppose incomes rise by one franc for every household. The 0.9-quantile of the new conditional distribution exceeds the

Figure 45.2.1: (a) Seven fitted quantile lines for Engel's budgets, least squares dashed. (b) The fitted slope against τ .

old by $\beta_{0.9}$; but the household at rank 0.9 before need not be there after, and nothing in the data says what happened to it. Reading β_τ as an individual effect assumes the change preserves ranks — the kind of untestable structure Chapter 25 insists on making explicit (Definition 25.2.1). Without it, quantile regression describes how a *distribution* moves, which is usually the question anyway.

Two cautions carry over: extrapolation is as unsafe as in Section 12.3, and Section 45.3 shows it is the first place quantile curves misbehave; and linearity of $Q_Y(\tau | \mathbf{x})$ is an assumption, testable in the spirit of Theorem 14.6.2.

45.2.5 Exercises

45.2.5.1 A. Check your understanding

Exercise A1.

A quantile regression with an intercept and one regressor is fitted at $\tau = 0.25$ to $n = 40$ observations. How many residuals can be negative, and how many are exactly zero? Use Proposition 45.2.2.

Solution. Generic data give $n_0 = p = 2$, and Eq. 45.2.5 reads $n_- \leq 10 \leq n_- + 2$, so $n_- \in \{8, 9, 10\}$.

45.2.5.2 B. Practice

Exercise B1.

Take $\mathbf{X} = \mathbf{1}$, so that the problem is to fit one number. Show that the minimizers of $\sum_i \rho_\tau(y_i - b)$ are exactly the τ -quantiles of the empirical distribution of $y_1, \dots, y_n$, and that for τn not an integer the minimizer is the unique order statistic $y_{(\lceil \tau n \rceil)}$.

Solution. Apply [Theorem 45.2.1\(a\)](#) to the empirical distribution F_n , which is legitimate because F_n is a distribution function with finite mean. The minimizers are $\{b : F_n(b^-) \leq \tau \leq F_n(b)\}$. If $\tau n \notin \mathbb{Z}$, no order statistic has F_n equal to τ , and the condition picks out the single point $y_{(\lceil \tau n \rceil)}$; if τn is an integer, the whole interval $[y_{(\tau n)}, y_{(\tau n+1)}]$ minimizes.

Exercise B2.

Write down the dual of the linear program [Eq. 45.2.4](#) and show that it is

$$\max_{\mathbf{d}} \mathbf{y}^\top \mathbf{d} \quad \text{subject to} \quad \mathbf{X}^\top \mathbf{d} = \mathbf{0}, \quad \mathbf{d} \in [\tau - 1, \tau]^n,$$

or, after the shift $\mathbf{a} = \mathbf{d} + (1 - \tau)\mathbf{1}$, $\max\{\mathbf{y}^\top \mathbf{a} : \mathbf{X}^\top \mathbf{a} = (1 - \tau)\mathbf{X}^\top \mathbf{1}, \mathbf{a} \in [0, 1]^n\}$. Show that at an optimum $a_i = 1$ for a positive residual and $a_i = 0$ for a negative one, so that $\mathbf{a}$ records the “signs” of the residuals, and explain why these are the raw material of the rank tests of [Section 45.3](#).

45.2.5.3 C. Going deeper

Exercise C1.

Show that the set of minimizers of R_τ is a convex polyhedron, and that if it contains two distinct points then R_τ is constant on the segment joining them. Deduce that a unique solution is the generic case: non-uniqueness requires a coincidence in the data, such as $p + 1$ observations lying on one hyperplane.

45.3 Inference for quantile regression

The estimator of [Section 45.2](#) minimizes a criterion with no derivative at the kink and no closed form, yet its large-sample behaviour is as clean as that of least squares, with one new ingredient: the asymptotic variance involves the *density* of the response at the fitted quantile, which is hard to estimate well. Everything practical below is an attempt either to estimate that density or to avoid it.

45.3.1 An identity of Knight’s

The analysis rests on an exact decomposition of the increment of the check loss into a linear part and a controllable remainder.

Lemma 45.3.1 — Knight’s identity

For all real u and v , with $\psi_\tau(u) = \tau - 1\{u < 0\}$,

$$\rho_\tau(u - v) - \rho_\tau(u) = -v \psi_\tau(u) + \int_0^v \{1\{u \leq s\} - 1\{u \leq 0\}\} ds. \quad (45.3.1)$$

Proof. Both sides vanish at $v = 0$, so it suffices to check four cases. Suppose first $u > 0$. If $0 < v \leq u$ the left side is $\tau(u-v) - \tau u = -\tau v$ and the integrand vanishes for $s \leq v < u$, so the right side is $-\tau v$ too. If $v > u$ the left side is $(\tau - 1)(u - v) - \tau u = -u - \tau v + v$, while the integral contributes $v - u$, giving $-\tau v + (v - u)$: the same. If $v < 0$ the integral runs backwards over $s \in (v, 0)$, where $s < 0 < u$ makes the integrand zero, and the left side is $-\tau v$ again.

Now suppose $u \leq 0$, so $\psi_\tau(u) = \tau - 1$ and $1\{u \leq 0\} = 1$. If $v > 0$ then for $s \in (0, v)$ we have $u \leq 0 < s$, the integrand is zero, and both sides equal $-v(\tau - 1)$. If $u \leq v < 0$ the same computation holds with the integral over $(v, 0)$, where $u \leq v < s$ again makes the integrand vanish. If $v < u \leq 0$, the left side is $\tau(u - v) - u(\tau - 1) = u - \tau v$; the integrand equals -1 on (v, u) and 0 on $(u, 0)$, so the backwards integral contributes $u - v$, and the right side is $-v(\tau - 1) + (u - v) = u - \tau v$. ■

45.3.2 The limiting distribution

Theorem 45.3.2 — Asymptotic normality of a regression quantile

Fix τ and suppose the rows $\mathbf{x}_{(i)}$ are fixed and the errors $u_i = y_i - \mathbf{x}_{(i)}^\top \boldsymbol{\beta}_\tau$ are independent with distribution functions F_i satisfying $F_i(0) = \tau$. Assume

- (C1) each F_i has a density f_i in a neighbourhood of zero with $f_i(0) > 0$; the f_i are equicontinuous at zero, that is $\sup_i \sup_{|s| \leq t} |f_i(s) - f_i(0)| \rightarrow 0$ as $t \downarrow 0$; and $\sup_i \sup_{|s| < \epsilon} f_i(s) < \infty$ for some $\epsilon > 0$;
- (C2) $n^{-1} \sum_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \rightarrow \mathbf{D}_0$ and $n^{-1} \sum_i f_i(0) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \rightarrow \mathbf{D}_1$, both positive definite;
- (C3) $n^{-1/2} \max_i \|\mathbf{x}_{(i)}\| \rightarrow 0$.

Then

$$\sqrt{n}(\hat{\boldsymbol{\beta}}_\tau - \boldsymbol{\beta}_\tau) \xrightarrow{d} N_p(\mathbf{0}, \tau(1 - \tau) \mathbf{D}_1^{-1} \mathbf{D}_0 \mathbf{D}_1^{-1}). \quad (45.3.2)$$

If the errors are identically distributed with density f , then $\mathbf{D}_1 = f(0) \mathbf{D}_0$ and the covariance collapses to

$$\frac{\tau(1 - \tau)}{f(0)^2} \mathbf{D}_0^{-1} = \tau(1 - \tau) s(\tau)^2 \mathbf{D}_0^{-1}, \quad s(\tau) = \frac{1}{f\{F^{-1}(\tau)\}}, \quad (45.3.3)$$

where s is the **sparsity function**, the derivative of the quantile function.

Proof. Write $\boldsymbol{\delta} \in \mathbb{R}^p$, $c_i = \mathbf{x}_{(i)}^\top \boldsymbol{\delta} / \sqrt{n}$ and

$$Z_n(\boldsymbol{\delta}) = \sum_{i=1}^n \{\rho_\tau(u_i - c_i) - \rho_\tau(u_i)\},$$

a convex function of δ minimized at $\hat{\delta}_n = \sqrt{n}(\hat{\beta}_\tau - \beta_\tau)$. By Eq. 45.3.1,

$$Z_n(\delta) = -\delta^\top \mathbf{w}_n + R_n(\delta), \quad \mathbf{w}_n = \frac{1}{\sqrt{n}} \sum_i \mathbf{x}_{(i)} \psi_\tau(u_i),$$

$$R_n(\delta) = \sum_i \int_0^{c_i} \{1\{u_i \leq s\} - 1\{u_i \leq 0\}\} ds.$$

Because F_i is continuous at zero and $F_i(0) = \tau$, the variables $\psi_\tau(u_i)$ are independent with mean zero and variance $\tau(1 - \tau)$, and they are bounded. Condition (C3) makes the Lindeberg condition hold for $\mathbf{w}_n$, which by (C2) and the Cramér–Wold device gives $\mathbf{w}_n \xrightarrow{d} N_p\{\mathbf{0}, \tau(1 - \tau)\mathbf{D}_0\}$.

For the remainder, $E R_n(\delta) = \sum_i \int_0^{c_i} \{F_i(s) - F_i(0)\} ds$. By the equicontinuity in (C1), $F_i(s) - F_i(0) = f_i(0)s + o(s)$ uniformly in i , and $\max_i |c_i| \leq n^{-1/2} \|\delta\| \max_i \|\mathbf{x}_{(i)}\| \rightarrow 0$ by (C3), so

$$\begin{aligned} E R_n(\delta) &= \sum_i \left\{ \frac{1}{2} f_i(0) c_i^2 + o(c_i^2) \right\} \\ &= \frac{1}{2} \delta^\top \left\{ \frac{1}{n} \sum_i f_i(0) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right\} \delta + o(1) \rightarrow \frac{1}{2} \delta^\top \mathbf{D}_1 \delta. \end{aligned}$$

Each summand of R_n is bounded in absolute value by $|c_i| 1\{|u_i| \leq |c_i|\}$, whose second moment is at most $c_i^2 \cdot 2|c_i| \sup f_i$ once $|c_i| < \epsilon$. Summing the independent terms,

$$\text{Var } R_n(\delta) \leq 2 \left(\sup_i \sup_{|s| < \epsilon} f_i(s) \right) \max_i |c_i| \sum_i c_i^2 \rightarrow 0,$$

because $\sum_i c_i^2 \rightarrow \delta^\top \mathbf{D}_0 \delta$ and $\max_i |c_i| \rightarrow 0$. Hence $R_n(\delta) \rightarrow \frac{1}{2} \delta^\top \mathbf{D}_1 \delta$ in probability, and for each fixed δ ,

$$\begin{aligned} Z_n(\delta) &\xrightarrow{d} Z(\delta) = -\delta^\top \mathbf{w} + \frac{1}{2} \delta^\top \mathbf{D}_1 \delta, \\ \mathbf{w} &\sim N_p\{\mathbf{0}, \tau(1 - \tau)\mathbf{D}_0\}, \end{aligned}$$

jointly over finitely many δ , since $\mathbf{w}_n$ is the only random part in the limit. The limit Z is a strictly convex quadratic with unique minimizer $\mathbf{D}_1^{-1} \mathbf{w}$.

The last step is the one this book takes on trust. Each Z_n is convex, so pointwise convergence in distribution to a limit with a unique minimizer implies convergence in distribution of the minimizers: this is the convexity lemma of Pollard (1991), proved there from the fact that convex functions converging pointwise on a dense set converge uniformly on compacta. Applying it, $\hat{\delta}_n \xrightarrow{d} \mathbf{D}_1^{-1} \mathbf{w}$, whose covariance is Eq. 45.3.2. The identically distributed case follows by substituting $f_i = f$ and noting that $s(\tau) = 1/f\{F^{-1}(\tau)\}$ is the derivative of F^{-1} at τ .

■

Warning (What the sparsity function does to precision). In Eq. 45.3.3 the factor $\tau(1 - \tau)$ shrinks as τ approaches 0 or 1, suggesting that extreme quantiles are estimated *more* precisely. They are not: $s(\tau)^2$ blows up faster, because the tail density is small. For a standard normal $\tau(1 - \tau)s(\tau)^2$ is $0.25/\varphi(0)^2 \approx 1.571$ at the median and about 13.9 at $\tau = 0.99$. Extreme conditional quantiles need far more data, or a model that borrows strength across levels.

45.3.3 Estimating the sparsity function

The iid formula [Eq. 45.3.3](#) requires $f\{F^{-1}(\tau)\}$, a density at a point. The standard device replaces it by a difference quotient of the empirical quantile function of the residuals,

$$\hat{s}(\tau) = \frac{\hat{F}_n^{-1}(\tau + h_n) - \hat{F}_n^{-1}(\tau - h_n)}{2h_n}, \quad (45.3.4)$$

with a bandwidth $h_n \rightarrow 0$ slowly; Hall and Sheather (1988) derived the choice $h_n = n^{-1/3} z_\alpha^{2/3} \{1.5\varphi(z_\tau)^2 / (2z_\tau^2 + 1)\}^{1/3}$ from an Edgeworth expansion for studentized quantiles. The non-identically-distributed case needs $\mathbf{D}_1$, estimated by replacing $f_i(0)$ with a kernel estimate of the density of the i th residual at zero, in the form Koenker (2005, chapter 4) attributes to Powell. Both involve a bandwidth and both converge slowly, which is the reason for the alternatives below.

Example. (Three standard errors for one slope)

At $\tau = 0.5$ the fitted income slope is 0.5602, and the three routes give very different precisions:

method	$\tau = 0.5$	$\tau = 0.9$
iid formula Eq. 45.3.3	0.0121	0.0143
sandwich Eq. 45.3.2	0.0308	0.0300
pairs bootstrap, $B = 999$	0.0344	0.0264

At the median the iid formula is optimistic by a factor of 2.5 against the sandwich and rather more against the bootstrap, which is no surprise: [Example \(Engel's budgets, one more time\)](#) showed that these errors are anything but identically distributed. The least squares slope has standard error 0.0144 under the same false assumption. The estimated sparsity is 192.2 francs at $\tau = 0.5$ and 378.9 at $\tau = 0.9$.

```

45.3.4 Avoiding the density

Two families of methods sidestep [Eq. 45.3.4](#) altogether.

Rank-score tests. The dual variables of [Eq. 45.2.4](#), described in [Exercise \(B2\)](#), are a regression analogue of ranks: they depend on the data only through each observation's position relative to the fitted hyperplanes. Gutenbrunner and Jurečková (1992) showed that tests built from them are distribution-free in the sense classical rank tests are, and intervals follow by inverting the test over a grid. No density is estimated, which is why Koenker (2005, chapter 3) makes them the default; the cost is a grid search per interval.

The bootstrap. Resampling $(y_i, \mathbf{x}_{(i)})$ pairs — the case bootstrap of [Definition 23.1.1\(b\)](#) —

needs only independence of the pairs, and Hahn (1995) proved that the bootstrap distribution of $\sqrt{n}(\hat{\beta}_\tau^* - \hat{\beta}_\tau)$ has the same limit as that of $\sqrt{n}(\hat{\beta}_\tau - \beta_\tau)$. Resampling *residuals* is not valid here, for the reason [Section 23.1](#) gave in the heteroscedastic linear model: it imposes the identical-distribution structure quantile regression was chosen to avoid.

Example. (Which interval keeps its promise)

Generate $n = 150$ observations from $y = 1 + x + (0.2 + 1.2x)\varepsilon$ with x uniform on $(0, 2)$ and ε standard normal, so the true slope of the τ -quantile is $1 + 1.2z_\tau$: 1.000 at the median, 2.538 at $\tau = 0.9$. Over 800 replicates (150 for the bootstrap, $B = 99$), the nominal 95% intervals cover:

method	$\tau = 0.5$	$\tau = 0.9$
iid formula	0.899	0.911
sandwich	0.965	0.911
pairs bootstrap	0.933	0.940

The iid formula undercovers at both levels, as it must. The sandwich is conservative at the median (mean width 0.989 against 0.743) and no better than the iid formula at $\tau = 0.9$, where its kernel estimate of $\mathbf{D}_1$ is fed by few residuals near zero. The bootstrap is the steadiest, at B extra linear programs.

45.3.5 Quantile curves that cross

Nothing in separate fitting forces the fitted curves to be ordered, yet the objects they estimate certainly are.

Proposition 45.3.3 — Ordering, and how to restore it

- (a) Let $\bar{\mathbf{x}} = n^{-1} \sum_i \mathbf{x}_{(i)}$ and let $\hat{\beta}_\tau$ solve [Eq. 45.2.2](#). Then $\tau \mapsto \bar{\mathbf{x}}^\top \hat{\beta}_\tau$ is nondecreasing: at the average design point the fitted quantiles never cross.
- (b) Fix $\mathbf{x}$ and levels $\tau_1 < \dots < \tau_m$, let $q_j = \mathbf{x}^\top \hat{\beta}_{\tau_j}$ be the fitted values and let $q_{(1)} \leq \dots \leq q_{(m)}$ be the same numbers sorted. For any nondecreasing sequence $g_1 \leq \dots \leq g_m$ and any $p \geq 1$,

$$\sum_{j=1}^m |q_{(j)} - g_j|^p \leq \sum_{j=1}^m |q_j - g_j|^p. \quad (45.3.5)$$

Sorting the fitted quantiles therefore moves them no further from the true quantile curve, in every L^p sense at once.

Proof.

- (a) Split the check loss as $\rho_\tau(u) = \tau u + u_-$, where $u_- = (-u)_+$; this is an identity, since for $u \geq 0$ both sides are τu and for $u < 0$ both are $\tau u - u$. Summing over

the residuals at $\mathbf{b}$,

$$R_\tau(\mathbf{b}) = \tau \sum_i (y_i - \mathbf{x}_{(i)}^\top \mathbf{b}) + S(\mathbf{b}) = \tau n(\bar{y} - \bar{\mathbf{x}}^\top \mathbf{b}) + S(\mathbf{b}), \quad S(\mathbf{b}) = \sum_i (\mathbf{x}_{(i)}^\top \mathbf{b} - y_i)_+.$$

Let $\tau_1 < \tau_2$ and abbreviate $\hat{\boldsymbol{\beta}}_j = \hat{\boldsymbol{\beta}}_{\tau_j}$. Optimality gives $R_{\tau_2}(\hat{\boldsymbol{\beta}}_2) \leq R_{\tau_2}(\hat{\boldsymbol{\beta}}_1)$ and $R_{\tau_1}(\hat{\boldsymbol{\beta}}_1) \leq R_{\tau_1}(\hat{\boldsymbol{\beta}}_2)$. Adding the two inequalities, the terms $S(\hat{\boldsymbol{\beta}}_1)$, $S(\hat{\boldsymbol{\beta}}_2)$ and $\bar{y}$ cancel and there remains

$$-\tau_2 \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_2 - \tau_1 \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_1 \leq -\tau_2 \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_1 - \tau_1 \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_2,$$

that is $(\tau_2 - \tau_1)(\bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_1 - \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_2) \leq 0$. Since $\tau_2 > \tau_1$, $\bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_1 \leq \bar{\mathbf{x}}^\top \hat{\boldsymbol{\beta}}_2$.

- (b) Sorting a finite sequence is a finite composition of transpositions of adjacent inverted pairs, so it suffices to show that exchanging one inverted pair does not increase the sum. Suppose $i < j$ and $q_i > q_j$, and write $\phi(t) = |t|^p$, which is convex. Put $a = q_j - g_j$, $b = q_i - g_i$, $a' = q_i - g_j$, $b' = q_j - g_i$. Then $a' + b' = a + b$, and since $g_i \leq g_j$ and $q_j < q_i$ both a' and b' lie between $\min(a, b)$ and $\max(a, b)$. Two numbers with the same sum lying inside the interval spanned by another two can be written as $a' = \lambda a + (1 - \lambda)b$ and $b' = (1 - \lambda)a + \lambda b$ for some $\lambda \in [0, 1]$, so convexity gives $\phi(a') + \phi(b') \leq \phi(a) + \phi(b)$. Exchanging the pair replaces $\phi(b) + \phi(a)$ by $\phi(a') + \phi(b')$ and leaves every other term alone.

■

Part (b) is the **rearrangement** repair of Chernozhukov, Fernández-Val and Galichon (2010): fit the levels separately, then sort the fitted values at each $\mathbf{x}$. It costs nothing, can only help, and produces a genuine quantile function. Other repairs impose the ordering during fitting — He (1997) through a location-scale model, Bondell, Reich and Wang (2010) through linear constraints — at the price of a stronger model or a larger optimization.

Example. (Where Engel's lines cross)

The seven fitted lines of [Example \(Seven quantile lines for Engel's budgets\)](#) are not parallel, so every neighbouring pair crosses somewhere: at incomes of 252, 203, 163, 228, −117 and 143 francs. The smallest income in the data is 377, so every crossing lies outside the data, where the model was never tested ([Figure 45.3.1\(b\)](#)). Crossing reaches inside when the predictor is more flexible: adding a quadratic term in income leaves the curves out of order on 0.035 of a grid spanning the lowest 99% of incomes, beginning at the very edge. Rearranging repairs the ordering and moves the curves by at most 4.0 francs.

```
TAUS = (0.05, 0.10, 0.25, 0.50, 0.75, 0.90, 0.95)
beta = {tau: qreg(X, food, tau) for tau in TAUS}
crossings = {}
for lo, hi in zip(TAUS[:-1], TAUS[1:]):
    d0, d1 = beta[hi] - beta[lo]
    crossings[(lo, hi)] = -d0 / d1 # where two fitted lines meet
print(f"incomes in the data run from {income.min():.0f} to {income.max():.0f}")
print("neighbouring fitted lines meet at income",
      " ".join(f"{v:.0f}" for v in crossings.values()))
```

Figure 45.3.1: (a) The fitted income slope against τ , with pointwise 95% pairs-bootstrap bands and the least squares slope. (b) The seven fitted lines extended left of the smallest observed income: the fan closes and crosses.

45.3.6 Two extensions, briefly

A Bayesian reading. Minimizing Eq. 45.2.2 maximizes the likelihood of an asymmetric Laplace density with location $\mathbf{x}_{(i)}^\top \boldsymbol{\beta}_\tau$ and asymmetry τ , so a flat prior makes the regression quantile a posterior mode and Chapter 39 (Definition 39.4.1, Definition 39.4.2) applies (Yu and Moyeed 2001; Kozumi and Kobayashi 2011 give a scale mixture yielding conditionally normal Gibbs steps). Only one τ can have the assumed error law, so the credible intervals deserve the scepticism due to any misspecified likelihood.

Nonlinear predictors. A roughness penalty on the check loss gives additive quantile regression — a linear program under an L^1 penalty (Koenker, Ng and Portnoy 1994), a quadratic program under the penalties of Chapter 43 — and structured additive predictors (Definition 44.5.1) carry over. The difficulty is the smoothing parameter: Theorem 29.3.2 needs a quadratic criterion, so cross-validation must refit, or the problem must be handed to Section 45.5.

45.3.7 Exercises

45.3.7.1 A. Check your understanding

Exercise A1.

Use Eq. 45.3.3 to show that for iid normal errors the asymptotic variance of a regression median exceeds that of least squares by the factor $\pi/2$. Which assumption of Theorem 45.3.2 is doing the work?

Solution. With $f(0) = 1/(\sigma\sqrt{2\pi})$ and $\tau = 1/2$, Eq. 45.3.3 gives $(1/4) 2\pi\sigma^2 \mathbf{D}_0^{-1} = (\pi/2)\sigma^2 \mathbf{D}_0^{-1}$, against $\sigma^2 \mathbf{D}_0^{-1}$ for least squares. The identical-distribution assumption is what makes the comparison meaningful; under heteroscedasticity the comparison can go the other way, as Example (Three standard errors for one slope) shows in reverse.

45.3.7.2 B. Practice

Exercise B1.

For a standard normal error law, compute $\tau(1-\tau)s(\tau)^2$ at $\tau = 0.5, 0.9, 0.99$ and confirm the claim in the warning above that precision deteriorates in the tail. At which τ is the factor smallest?

Solution. $s(\tau) = 1/\varphi\{\Phi^{-1}(\tau)\}$, so the factor is $\tau(1-\tau)/\varphi\{\Phi^{-1}(\tau)\}^2$. At $\tau = 0.5$ it is $0.25/(0.3989)^2 \approx 1.571$; at $\tau = 0.9$, $0.09/(0.1755)^2 \approx 2.92$; at $\tau = 0.99$, $0.0099/(0.0267)^2 \approx 13.9$. Differentiating shows the minimum is at $\tau = 1/2$ by symmetry.

Exercise B2.

Two fitted quantile lines $a_1 + b_1x$ and $a_2 + b_2x$ with $b_1 < b_2$ cross at $x^* = -(a_2 - a_1)/(b_2 - b_1)$. Using the numbers of [Example \(Seven quantile lines for Engel's budgets\)](#), verify the crossing income of the $\tau = 0.05$ and $\tau = 0.10$ lines, and explain why [Proposition 45.3.3\(a\)](#) guarantees that x^* cannot lie at the mean income.

45.3.7.3 C. Going deeper

Exercise C1.

Use [Eq. 45.3.1](#) to show that the estimating equation for β_τ in the population is $E\{\mathbf{x} \psi_\tau(Y - \mathbf{x}^\top \beta_\tau)\} = \mathbf{0}$, and that this is the exact analogue of the normal equations with ψ_τ in place of the identity. Compare with the estimating-function framework of [Chapter 38](#) ([Definition 38.2.1](#)): is ψ_τ a quasi-score?

45.4 Expectile regression

The check loss buys freedom from distributional assumptions at the price of a kink, and the kink makes the estimator awkward: no closed form, no hat matrix, no leverage shortcut for cross-validation ([Theorem 29.3.2](#)), no easy way to attach the quadratic penalties that [Chapter 30](#) and [Chapter 43](#) are built on. Newey and Powell (1987) replaced the absolute deviation by a squared one, keeping the asymmetry. The answer is a family of location measures called expectiles, fitted by weighted least squares.

45.4.1 Asymmetric squared loss

Definition 45.4.1 — Expectiles and expectile regression

For $\tau \in (0, 1)$ define the **asymmetric squared loss**

$$\rho_\tau^E(u) = |\tau - 1\{u < 0\}| u^2 = \begin{cases} \tau u^2, & u \geq 0, \\ (1 - \tau)u^2, & u < 0. \end{cases} \quad (45.4.1)$$

For a random variable Y with $EY^2 < \infty$, the τ -**expectile** μ_τ is a minimizer of $S(\mu) = E\rho_\tau^E(Y - \mu)$. The **expectile regression** model at level τ asserts that the τ -expectile of the conditional law of Y is $\mathbf{x}^\top \boldsymbol{\beta}_\tau$, and the estimate is

$$\hat{\boldsymbol{\beta}}_\tau^E \in \arg \min_{\mathbf{b}} \sum_{i=1}^n \rho_\tau^E(y_i - \mathbf{x}_{(i)}^\top \mathbf{b}). \quad (45.4.2)$$

The weight τ applies above the fit and $1 - \tau$ below, as in the check loss; only the power has changed, and at $\tau = 1/2$ problem [Eq. 45.4.2](#) is least squares.

45.4.2 What an expectile is

Proposition 45.4.1 — Properties of expectiles

Let $EY^2 < \infty$ and let Y be non-degenerate.

- (a) **Existence, uniqueness, monotonicity.** S is finite, differentiable and strictly convex, and μ_τ is its unique stationary point, characterized by

$$\tau E(Y - \mu_\tau)_+ = (1 - \tau) E(\mu_\tau - Y)_+. \quad (45.4.3)$$

The map $\tau \mapsto \mu_\tau$ is strictly increasing on $(0, 1)$.

- (b) **The mean is an expectile.** $\mu_{1/2} = EY$.
- (c) **The level of a point.** For every μ with $P(Y < \mu) > 0$ and $P(Y > \mu) > 0$ — equivalently, every μ interior to the convex hull of the support of Y — there is exactly one τ with $\mu_\tau = \mu$, namely

$$\tau = \frac{E(\mu - Y)_+}{E|Y - \mu|}. \quad (45.4.4)$$

- (d) **Equivariance.** For $a > 0$ and $b \in \mathbb{R}$, $\mu_\tau(aY + b) = a\mu_\tau(Y) + b$, and $\mu_\tau(-Y) = -\mu_{1-\tau}(Y)$. Expectiles are *not* equivariant under nonlinear increasing transformations.

Proof.

- (a) Write $S(\mu) = \tau E(Y - \mu)_+^2 + (1 - \tau) E(\mu - Y)_+^2$, finite because $(y - \mu)^2 \leq 2y^2 + 2\mu^2$. The loss is continuously differentiable with $\rho_\tau^{E'}(u) = 2u|\tau - 1\{u < 0\}|$, continuous at the origin because both one-sided derivatives vanish, and nondecreasing, so ρ_τ^E is convex. Dominated convergence permits differentiation under the expectation, giving

$$\frac{1}{2}S'(\mu) = -\tau E(Y - \mu)_+ + (1 - \tau) E(\mu - Y)_+ =: -H(\mu).$$

Now H is continuous, and for $\mu < \mu'$,

$$\begin{aligned} H(\mu) - H(\mu') &= \tau \mathbb{E}\{(Y - \mu)_+ - (Y - \mu')_+\} \\ &\quad + (1 - \tau) \mathbb{E}\{(\mu' - Y)_+ - (\mu - Y)_+\} \geq 0, \end{aligned}$$

each expectation being nonnegative because $t \mapsto (y - t)_+$ is nonincreasing and $t \mapsto (t - y)_+$ nondecreasing, and strict unless Y puts no mass outside $[\mu, \mu']$ on either side, which a non-degenerate Y cannot do for every pair. Moreover, as $\mu \rightarrow -\infty$ monotone convergence gives $\mathbb{E}(\mu - Y)_+ \downarrow 0$, while $\mathbb{E}(Y - \mu)_+ \geq \mathbb{E}Y - \mu \rightarrow +\infty$, so $H(\mu) \rightarrow +\infty$; the same argument reflected gives $H(\mu) \rightarrow -\infty$ as $\mu \rightarrow +\infty$. So H has a unique zero, S is strictly convex there, and [Eq. 45.4.3](#) is exactly $H(\mu_\tau) = 0$. For monotonicity, let $\tau < \tau'$ and write H_τ for the function above. Then

$$\begin{aligned} H_{\tau'}(\mu_\tau) &= H_\tau(\mu_\tau) + (\tau' - \tau) \mathbb{E}|Y - \mu_\tau| \\ &= (\tau' - \tau) \mathbb{E}|Y - \mu_\tau| > 0, \end{aligned}$$

using $\mathbb{E}(Y - \mu)_+ + \mathbb{E}(\mu - Y)_+ = \mathbb{E}|Y - \mu|$; since $H_{\tau'}$ is decreasing with a unique zero, that zero $\mu_{\tau'}$ lies to the right of μ_τ .

- (b) At $\tau = 1/2$, [Eq. 45.4.3](#) reads $\mathbb{E}(Y - \mu)_+ = \mathbb{E}(\mu - Y)_+$, that is $\mathbb{E}(Y - \mu) = 0$.
- (c) Put $N = \mathbb{E}(Y - \mu)_+$ and $P = \mathbb{E}(\mu - Y)_+$; both are strictly positive under the stated condition on μ , so $N + P = \mathbb{E}|Y - \mu| > 0$. Equation [Eq. 45.4.3](#) says $\tau N = (1 - \tau)P$, hence $\tau(N + P) = P$, and [Eq. 45.4.4](#) follows. Conversely, given such a μ , the ratio $P/(N + P)$ lies strictly between 0 and 1 and solves the equation, and by (a) the solution for that τ is unique.
- (d) For $a > 0$, $\rho_\tau^E(au) = a^2 \rho_\tau^E(u)$, so $\mathbb{E} \rho_\tau^E(aY + b - \mu) = a^2 \mathbb{E} \rho_\tau^E\{Y - (\mu - b)/a\}$ and the minimizers correspond as claimed; $\rho_\tau^E(-u) = \rho_{1-\tau}^E(u)$ gives the reflection. For the failure under nonlinear maps it is enough to look at $\tau = 1/2$: by (b) the 1/2-expectile is the mean, and for strictly convex h Jensen's inequality gives $\mathbb{E} h(Y) > h(\mathbb{E} Y)$, so $\mu_{1/2}\{h(Y)\} \neq h\{\mu_{1/2}(Y)\}$.

■

Part (c) says what level an expectile sits at. Compare the two characterizations:

$$\tau = \frac{\mathbb{E} \mathbf{1}\{Y \leq q_\tau\}}{\mathbb{E} \mathbf{1}} \quad (\text{quantile}), \quad \tau = \frac{\mathbb{E}(\mu_\tau - Y)_+}{\mathbb{E}|Y - \mu_\tau|} \quad (\text{expectile}).$$

A quantile counts the mass below the point; an expectile weighs it, by distance. So an expectile depends on the *entire* distribution and has none of the robustness of [Definition 45.2.1](#): one response moved to $+10^6$ moves every expectile. In exchange it is smooth.

Remark (Expectiles as quantiles of another law). Since [Eq. 45.4.4](#) determines τ from μ and F , the expectiles of F are the quantiles of another distribution built from F by partial moments — the observation of Jones (1994). The catch is that the relabelling depends on F : the τ -quantile is at level τ for every distribution, while the τ -expectile is at a level only the distribution can tell you.

Example. (Which quantile is the nine-tenths expectile?)

For a standard normal the 0.9-expectile sits at the 0.806-quantile and the 0.5-expectile at the 0.500-quantile, as symmetry requires. For a lognormal with log-scale 0.8 the 0.9-expectile sits at the 0.892-quantile: the heavy right tail drags it further out. For

the residuals of the least squares fit to Engel's budgets the 0.9-expectile sits at the 0.851-quantile and the 0.1-expectile at the 0.170-quantile (Figure 45.4.1(b)). Three distributions, three answers to the same question.

45.4.3 Fitting by weighted least squares

Proposition 45.4.2 — The estimating equation and its iteration

Let $\text{rank}(\mathbf{X}) = p$ and $Q(\mathbf{b}) = \sum_i \rho_\tau^E(y_i - \mathbf{x}_{(i)}^\top \mathbf{b})$.

- (a) Q is continuously differentiable and strictly convex, so it has a unique minimizer, characterized by

$$\mathbf{X}^\top \mathbf{W}(\mathbf{b})(\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{0}, \quad \mathbf{W}(\mathbf{b}) = \text{diag}\{w_i(\mathbf{b})\}, \quad w_i(\mathbf{b}) = |\tau - 1\{y_i < \mathbf{x}_{(i)}^\top \mathbf{b}\}|. \quad (45.4.5)$$

- (b) The **iterated weighted least squares** step $\mathbf{b}^{(t+1)} = \{\mathbf{X}^\top \mathbf{W}(\mathbf{b}^{(t)})\mathbf{X}\}^{-1} \mathbf{X}^\top \mathbf{W}(\mathbf{b}^{(t)})\mathbf{y}$ has the property that if $\mathbf{W}(\mathbf{b}^{(t+1)}) = \mathbf{W}(\mathbf{b}^{(t)})$, then $\mathbf{b}^{(t+1)}$ is the exact global minimizer of Q .

Proof.

- (a) The scalar loss is continuously differentiable with derivative $2u|\tau - 1\{u < 0\}|$, which is strictly increasing, so ρ_τ^E is strictly convex; composing with the affine map $\mathbf{b} \mapsto y_i - \mathbf{x}_{(i)}^\top \mathbf{b}$ and summing gives a convex Q , strictly convex because $\text{rank}(\mathbf{X}) = p$ makes $\mathbf{b} \mapsto \mathbf{X}\mathbf{b}$ injective. It is also coercive: $\rho_\tau^E(u) \geq \min(\tau, 1 - \tau)u^2$ gives $Q(\mathbf{b}) \geq \min(\tau, 1 - \tau)\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$, which tends to infinity as $\|\mathbf{b}\| \rightarrow \infty$ because $\mathbf{X}$ has full column rank, so a minimizer exists, and strict convexity makes it unique. The chain rule gives $\nabla Q(\mathbf{b}) = -2\mathbf{X}^\top \mathbf{W}(\mathbf{b})(\mathbf{y} - \mathbf{X}\mathbf{b})$, and for a differentiable convex function a stationary point is a global minimum.
- (b) The weighted least squares step solves $\mathbf{X}^\top \mathbf{W}_t \mathbf{X}\mathbf{b} = \mathbf{X}^\top \mathbf{W}_t \mathbf{y}$ with $\mathbf{W}_t = \mathbf{W}(\mathbf{b}^{(t)})$, so $\mathbf{X}^\top \mathbf{W}_t(\mathbf{y} - \mathbf{X}\mathbf{b}^{(t+1)}) = \mathbf{0}$. If $\mathbf{W}(\mathbf{b}^{(t+1)}) = \mathbf{W}_t$, this is Eq. 45.4.5 at $\mathbf{b}^{(t+1)}$, so $\nabla Q(\mathbf{b}^{(t+1)}) = \mathbf{0}$ and by (a) the point is the global minimizer. ■

Warning (What is not proved here). Part (b) says the iteration is *correct when it stops*, not that it stops. The weights depend on $\mathbf{b}$ only through the signs of the residuals, so the step is a Newton step for a piecewise linear system with finitely many weight patterns; global convergence is not proved in this book. In practice it is fast: for the seven fits below none needed more than 6 reweightings from a least squares start. Compare Proposition 20.6.1, whose majorization argument does give a descent guarantee but requires $\rho(u) = g(u^2)$ with g concave, which Eq. 45.4.1 is not.

Example. (Expectile lines for Engel's budgets)

The same 235 households, fitted at the same seven levels by Eq. 45.4.2:

Figure 45.4.1: (a) Seven fitted expectile lines for Engel's budgets. (b) The quantile level at which the τ -expectile sits, for three laws; the diagonal is where the levels agree.

τ	0.05	0.10	0.25	0.50	0.75	0.90	0.95
slope	0.3617	0.3830	0.4293	0.4852	0.5454	0.6017	0.6322
intercept	157.9	162.6	159.0	147.5	128.8	109.0	99.8

The level $\tau = 1/2$ reproduces least squares exactly, slope 0.4852. The fan opens in the same direction as the quantile fan of [Example \(Seven quantile lines for Engel's budgets\)](#) but less widely, from 0.3617 to 0.6322 against 0.3434 to 0.7091 — not a discrepancy, since by [Example \(Which quantile is the nine-tenths expectile?\)](#) the level 0.9 means a more central position for an expectile.

```

45.4.4 When to prefer an expectile

The case for expectiles is about what a differentiable loss makes possible.

Penalties and smoothing. A penalized spline turns [Eq. 45.4.2](#) into penalized weighted least squares, which is [Definition 30.1.1](#) with weights. Every step is a linear smoother, so the effective degrees of freedom is a trace and generalized cross-validation [Definition 29.3.2](#) can choose the smoothing parameter through the leverage shortcut [Theorem 29.3.2](#) without refitting. Schnabel and Eilers (2009) built expectile smoothing on this, and Sobotka and Kneib (2012) extended it to structured additive predictors, where the smoothing parameters go to the mixed-model representation ([Theorem 43.6.1](#), using [Definition 32.4.1](#)). None of this is available for the check loss without approximation.

Efficiency and risk. The expectile estimator uses the magnitude of every residual, the quantile estimator only its sign, whose asymptotic variance carries the sparsity factor of [Eq. 45.3.3](#). Which is the more precise depends on the error law, and the comparison is meaningful only at matched levels, since at a common τ the two estimate different functionals; Newey and Powell (1987, §3) give the asymptotic variance from which such comparisons are made. A functional is *elicitable* if it minimizes an expected loss — the mean by squared error, quantiles by the check loss ([Theorem 45.2.1](#)), expectiles by [Eq. 45.4.1](#) — and Ziegel (2016) showed that the τ -expectiles with $\tau \geq 1/2$ are the only law-invariant coherent risk measures that are also elicitable, which is what put them into financial risk management.

The case against is short and serious: nobody can say in one sentence what the 0.9-expectile is. “Ninety per cent of households fall below this line” a reader understands; “the lower partial moment at this line is nine times the upper one” is not.

45.4.5 Exercises

45.4.5.1 A. Check your understanding

Exercise A1.

Let Y take the values 0 and 1 with probability $1/2$ each. Compute μ_τ from [Eq. 45.4.3](#) as a function of τ , and compare with the τ -quantile.

Solution. For $\mu \in (0, 1)$, $E(Y - \mu)_+ = (1 - \mu)/2$ and $E(\mu - Y)_+ = \mu/2$, so [Eq. 45.4.3](#) gives $\tau(1 - \mu) = (1 - \tau)\mu$, that is $\mu_\tau = \tau$. The expectile moves continuously from 0 to 1, while the τ -quantile jumps from 0 to 1 at $\tau = 1/2$. Expectiles smooth over the gaps of a discrete law.

45.4.5.2 B. Practice

Exercise B1.

For $Y \sim N(0, 1)$, show that [Eq. 45.4.3](#) becomes $\tau\{\varphi(\mu) - \mu(1 - \Phi(\mu))\} = (1 - \tau)\{\varphi(\mu) + \mu\Phi(\mu)\}$, and verify numerically that $\mu_{0.9} = 0.8616$ lies at the 0.806-quantile, as reported in [Example \(Which quantile is the nine-tenths expectile?\)](#).

Solution. For the standard normal, $E(Y - \mu)_+ = \varphi(\mu) - \mu\{1 - \Phi(\mu)\}$ and $E(\mu - Y)_+ = \varphi(\mu) + \mu\Phi(\mu)$, both by integration by parts. Substituting into [Eq. 45.4.3](#) gives the stated identity; solving it numerically at $\tau = 0.9$ gives $\mu_{0.9} = 0.8616$, and $\Phi(0.8616) = 0.806$.

Exercise B2.

Show that if the law of Y is symmetric about m , then $\mu_\tau + \mu_{1-\tau} = 2m$, and that the τ -expectile lies at the $\alpha(\tau)$ -quantile with $\alpha(1/2) = 1/2$. Does symmetry force $\alpha(\tau) = \tau$?

45.4.5.3 C. Going deeper

Exercise C1.

Let Y have a Cauchy distribution. Which of the objects in this chapter still exist: the conditional mean, the τ -quantiles, the τ -expectiles? What does this say about the price of the smooth loss?

Solution. Quantiles exist and are finite for every $\tau \in (0, 1)$, since [Theorem 45.2.1\(a\)](#) needs only a distribution function (and the remark after it removes even the moment condition). The mean does not exist, so neither does the $1/2$ -expectile; indeed [Definition 45.4.1](#)

assumes $EY^2 < \infty$, and $E|Y| = \infty$ already destroys [Eq. 45.4.3](#), whose two sides are both infinite. The smooth loss buys computation at the cost of moments.

45.5 Models for location, scale and shape

Quantile and expectile regression estimate one feature of the conditional law at a time and never write the law down. The opposite strategy writes it down in full: choose a parametric family with enough parameters to bend as the data require, and let every one of them depend on the covariates through its own structured additive predictor. Rigby and Stasinopoulos (2005) named the result generalized additive models for location, scale and shape.

The gain is a likelihood, and with it penalized estimation, effective degrees of freedom, AIC and Bayesian posteriors. The cost is a parametric assumption about the shape of the conditional distribution, which the data must be allowed to contradict — the subject of [Section 45.6](#).

45.5.1 The model

Definition 45.5.1 — Generalized additive model for location, scale and shape

Let $D(\theta_1, \dots, \theta_K)$ be a family of distributions on the response space with density or mass function $d(y; \theta_1, \dots, \theta_K)$; in this chapter θ_k denotes the k th parameter of that family, not the natural parameter of [Definition 34.2.1](#). A **GAMLSS** asserts that the responses $Y_1, \dots, Y_n$ are independent with

$$Y_i \sim D(\theta_{i1}, \dots, \theta_{iK}), \quad g_k(\theta_{ik}) = \eta_{ik}, \quad k = 1, \dots, K,$$

where each g_k is a strictly increasing **link** mapping the admissible range of θ_k onto $\mathbb{R}$ (the identity for an unrestricted parameter, the logarithm for a positive one, the logit for one in $(0, 1)$), and each η_{ik} is a structured additive predictor ([Definition 44.5.1](#))

$$\eta_{ik} = \beta_{0k} + \sum_{j=1}^{J_k} f_{jk}(v_{ij}), \quad f_{jk}(\cdot) \text{ represented by } \mathbf{Z}_{jk} \boldsymbol{\gamma}_{jk}, \quad (45.5.1)$$

with each $\boldsymbol{\gamma}_{jk}$ carrying a quadratic penalty $\lambda_{jk} \boldsymbol{\gamma}_{jk}^\top \mathbf{P}_{jk} \boldsymbol{\gamma}_{jk}$. The predictors for different parameters may use different covariates and different amounts of structure.

Taking $K = 1$ with D an exponential dispersion family and η linear recovers [Definition 34.2.1](#); with additive η it recovers [Theorem 44.6.1](#). The new content is $K > 1$: the scale, and the shape, become regression problems.

Example. (The heteroscedastic normal model)

The smallest interesting case has $K = 2$, $D = N(\mu, \sigma^2)$, identity link on μ and log link on σ :

$$Y_i \sim N(\mu_i, \sigma_i^2), \quad \mu_i = \eta_{i1}, \quad \log \sigma_i = \eta_{i2}. \quad (45.5.2)$$

The log link keeps $\sigma_i > 0$ whatever the predictor does, as it kept a Poisson mean positive in [Chapter 37](#). With both predictors linear this is [Proposition 45.1.2\(b\)](#) with normal ε ; with penalized splines it is the fit of [Example \(Mean and scale together\)](#).

45.5.2 Estimation

Theorem 45.5.1 — Penalized likelihood and block-wise Fisher scoring

Write $\ell_i(\boldsymbol{\theta}_i) = \log d(y_i; \theta_{i1}, \dots, \theta_{iK})$ and collect the coefficients of predictor k into $\boldsymbol{\gamma}_k$ with design $\mathbf{Z}_k$, penalty matrix $\mathbf{P}_k$ and smoothing parameter λ_k , so that $\boldsymbol{\eta}_k = \mathbf{Z}_k \boldsymbol{\gamma}_k$. The **penalized log-likelihood** is

$$\ell_p(\boldsymbol{\gamma}_1, \dots, \boldsymbol{\gamma}_K) = \sum_{i=1}^n \ell_i(\boldsymbol{\theta}_i) - \frac{1}{2} \sum_{k=1}^K \lambda_k \boldsymbol{\gamma}_k^\top \mathbf{P}_k \boldsymbol{\gamma}_k. \quad (45.5.3)$$

- (a) **Score.** With $u_{ik} = \partial \ell_i / \partial \eta_{ik}$ and $\mathbf{u}_k = (u_{1k}, \dots, u_{nk})^\top$,

$$\frac{\partial \ell_p}{\partial \boldsymbol{\gamma}_k} = \mathbf{Z}_k^\top \mathbf{u}_k - \lambda_k \mathbf{P}_k \boldsymbol{\gamma}_k. \quad (45.5.4)$$

- (b) **Fisher scoring is penalized weighted least squares.** Let $w_{ik} = -E(\partial^2 \ell_i / \partial \eta_{ik}^2)$ and $\mathbf{W}_k = \text{diag}(w_{1k}, \dots, w_{nk})$. Updating block k with the others held fixed by one Fisher scoring step gives

$$\boldsymbol{\gamma}_k^{\text{new}} = (\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k + \lambda_k \mathbf{P}_k)^{-1} \mathbf{Z}_k^\top \mathbf{W}_k \mathbf{z}_k, \quad \mathbf{z}_k = \boldsymbol{\eta}_k + \mathbf{W}_k^{-1} \mathbf{u}_k, \quad (45.5.5)$$

the penalized version of the iteratively reweighted least squares of [Theorem 34.4.1](#), with $\mathbf{z}_k$ the working response for parameter k . Cycling over $k = 1, \dots, K$ until nothing changes is backfitting ([Theorem 44.2.1](#)) applied to the K blocks.

- (c) **The normal location-scale model is orthogonal.** For [Eq. 45.5.2](#),

$$u_{i1} = \frac{y_i - \mu_i}{\sigma_i^2}, \quad w_{i1} = \frac{1}{\sigma_i^2}, \quad u_{i2} = \frac{(y_i - \mu_i)^2}{\sigma_i^2} - 1, \quad w_{i2} = 2, \quad (45.5.6)$$

and the expected cross-information $-E(\partial^2 \ell_i / \partial \eta_{i1} \partial \eta_{i2})$ is zero. The two blocks are therefore orthogonal: neither Fisher scoring step needs the other's derivatives, the working response for μ is $\mathbf{z}_1 = \mathbf{y}$, and the working response for $\log \sigma$ is $\mathbf{z}_2 = \boldsymbol{\eta}_2 + \frac{1}{2} \mathbf{u}_2$.

Proof.

- (a) By the chain rule $\partial \ell_i / \partial \boldsymbol{\gamma}_k = (\partial \ell_i / \partial \eta_{ik}) \partial \eta_{ik} / \partial \boldsymbol{\gamma}_k$, and $\partial \eta_{ik} / \partial \boldsymbol{\gamma}_k$ is the i th row of $\mathbf{Z}_k$. Summing u_{ik} times that row over i gives $\mathbf{Z}_k^\top \mathbf{u}_k$, and differentiating the quadratic penalty gives $-\lambda_k \mathbf{P}_k \boldsymbol{\gamma}_k$.
- (b) Differentiating [Eq. 45.5.4](#) once more, the contribution of observation i to the second

derivative within block k is $\partial^2 \ell_i / \partial \eta_{ik}^2$ times the outer product of the i th row of $\mathbf{Z}_k$ with itself; taking expectations and summing over the independent responses gives $-\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k - \lambda_k \mathbf{P}_k$. A Fisher scoring step therefore reads

$$\boldsymbol{\gamma}_k^{\text{new}} = \boldsymbol{\gamma}_k + (\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k + \lambda_k \mathbf{P}_k)^{-1} (\mathbf{Z}_k^\top \mathbf{u}_k - \lambda_k \mathbf{P}_k \boldsymbol{\gamma}_k).$$

Adding and subtracting $\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k \boldsymbol{\gamma}_k$ inside the bracket turns the right side into $(\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k + \lambda_k \mathbf{P}_k)^{-1} \mathbf{Z}_k^\top \mathbf{W}_k (\mathbf{Z}_k \boldsymbol{\gamma}_k + \mathbf{W}_k^{-1} \mathbf{u}_k)$, which is [Eq. 45.5.5](#).

- (c) With $\ell_i = -\log \sigma_i - (y_i - \mu_i)^2 / (2\sigma_i^2) - \frac{1}{2} \log(2\pi)$, $\mu_i = \eta_{i1}$ and $\sigma_i = e^{\eta_{i2}}$, direct differentiation gives $\partial \ell_i / \partial \eta_{i1} = (y_i - \mu_i) / \sigma_i^2$ and

$$\frac{\partial \ell_i}{\partial \eta_{i2}} = \sigma_i \frac{\partial \ell_i}{\partial \sigma_i} = \sigma_i \left\{ -\frac{1}{\sigma_i} + \frac{(y_i - \mu_i)^2}{\sigma_i^3} \right\} = \frac{(y_i - \mu_i)^2}{\sigma_i^2} - 1.$$

Differentiating again, $\partial^2 \ell_i / \partial \eta_{i1}^2 = -1 / \sigma_i^2$, which is already non-random, so $w_{i1} = 1 / \sigma_i^2$; and $\partial^2 \ell_i / \partial \eta_{i2}^2 = -2(y_i - \mu_i)^2 / \sigma_i^2$, whose expectation is -2 , so $w_{i2} = 2$. Finally $\partial^2 \ell_i / \partial \eta_{i1} \partial \eta_{i2} = -2(y_i - \mu_i) / \sigma_i^2$, with expectation zero because $E(Y_i - \mu_i) = 0$. The working responses follow from $\mathbf{z}_k = \boldsymbol{\eta}_k + \mathbf{W}_k^{-1} \mathbf{u}_k$: for $k = 1$, $z_{i1} = \mu_i + \sigma_i^2 (y_i - \mu_i) / \sigma_i^2 = y_i$.

■

Idea. A GAMLSS fit is a stack of weighted smoothers. Each parameter's block is updated by the same penalized weighted least squares step that fitted a generalized additive model, with weights and working responses supplied by the log-likelihood of the chosen family. The rest is bookkeeping, which is why the framework accommodates any family whose derivatives can be written down.

Orthogonality in part (c) is special to this parameterization of the normal family; for most families the cross-information is not zero, and cycling over blocks then converges more slowly or must give way to a joint Newton step. The effective degrees of freedom of a block is the trace $\text{tr}\{(\mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k + \lambda_k \mathbf{P}_k)^{-1} \mathbf{Z}_k^\top \mathbf{W}_k \mathbf{Z}_k\}$ that [Theorem 27.2.2](#) attached to ridge regression and [Definition 30.1.1](#) to penalized least squares; the total of these traces goes into AIC ([Proposition 29.2.4](#)).

45.5.3 Choosing the family

The distribution is a modelling choice on a par with the link, made from what the response is. Positive with a right tail: gamma, inverse Gaussian, lognormal. Positive with adjustable skewness: the Box–Cox family, whose third parameter is a power estimated rather than assumed, generalizing [Definition 22.2.1](#). Heavy tailed: a t family with the degrees of freedom as a third parameter. Counts with too many zeros: a zero-inflated or hurdle family ([Definition 37.5.1](#)). Proportions: a beta family reparameterized into a mean and a precision.

The ancestor is the LMS method of Cole and Green (1992) for growth charts: a Box–Cox power, a median and a coefficient of variation, each a smooth function of age — a three-parameter GAMLSS written a decade before the name, and still how paediatric reference charts are built.

45.5.4 Warnings

Warning (Identifiability). Each predictor in [Eq. 45.5.1](#) contains an intercept and several smooth terms, and a constant moves freely between them. The remedy is that of [Chapter 44](#): constrain every smooth term to sum to zero over the data ([Definition 44.1.1](#)), separately in every predictor. Without the constraints the penalized information is singular in as many directions as there are smooth terms. When the *same* covariate enters two predictors, the concurvity of [Proposition 44.2.3](#) appears between parameters, and no ceteris paribus reading of a single parameter's curve survives.

Warning (The likelihood is unbounded). Let the mean predictor be flexible enough to interpolate one observation, say $\mu(x_1) = y_1$, and the scale predictor flexible enough to be small near x_1 and unchanged elsewhere. The contribution of observation 1 to [Eq. 45.5.3](#) is then $-\log \sigma(x_1)$, which grows without bound as $\sigma(x_1) \rightarrow 0$ while the others stay finite: the unpenalized likelihood of a flexible location-scale model has no maximum. What stops the fit running away is the penalty, so the smoothing parameters are what make the problem well posed — and they cannot be chosen by maximizing the same likelihood.

Example. (Watching it happen)

Fitting [Eq. 45.5.2](#) to Engel's budgets with the scale penalty set to 0.01 instead of the chosen 10.0 raises the in-sample log-likelihood from 277.4 to 282.9, a gain a naive search would take. The ten-fold cross-validated log score — minus the mean predictive log density, so that smaller is better ([Definition 45.6.1](#) and the remark in [Section 45.6](#)) — tells the truth: it moves from -1.1102 to 59.9 . The wilder scale curve dips towards zero where the mean spline interpolates, and a held-out household near such a dip is assigned a density indistinguishable from zero.

45.5.5 A location-scale fit to Engel's budgets

Example. (Mean and scale together)

Take [Eq. 45.5.2](#) with a cubic B-spline basis of 12 columns for each predictor — knots at income quantiles, second-difference penalties ([Definition 43.3.1](#)) — and measure income and food expenditure in thousands of francs. The two smoothing parameters are chosen by ten-fold cross-validation of the log score over a grid, giving 31.6 for the mean and 10.0 for the scale, with effective degrees of freedom 8.75 and 5.59, 14.33 in all.

The fitted scale rises from 40.5 francs at an income of 500 to 184.5 at an income of 2000, a ratio of 4.55; the single constant the homoscedastic model fits is 107.4 francs, wrong in both directions at once. At an income of 1000 francs the fitted mean budget is 645.3 francs and the fitted ninetieth percentile 746.5. With the response in thousands of francs the AIC is -526.1 against -368.0 for the same mean spline with a constant scale, and the cross-validated log score -1.1102 against -0.6938 : most of what a homoscedastic model gets wrong here is the scale. The implied quantile curves $\hat{\mu}(x) + \hat{\sigma}(x)z_\tau$ cannot cross, one clear advantage over the separate fits of [Section 45.3](#).

Figure 45.5.1: A normal location-scale GAMLSS for Engel's budgets, both predictors penalized splines in income. (a) The implied 0.1, 0.5 and 0.9 quantile curves. (b) The fitted scale against the homoscedastic constant.

45.5.6 Variations

Bayesian GAMLSS. Every quadratic penalty is a normal prior on the coefficients ([Proposition 39.5.1](#)), so [Eq. 45.5.3](#) is a log posterior up to the smoothing-parameter priors, and [Section 39.4](#) transfers whole, with those parameters sampled rather than tuned (Klein, Kneib, Lang and Sohn 2015). **Boosting.** Feeding a GAMLSS log-likelihood to the componentwise boosting of [Section 30.4](#) gives an algorithm that also selects which terms enter which predictor (Mayr, Fenske, Hofner, Kneib and Schmid 2012). **Multivariate responses.** With a multivariate family the dependence parameters become regression problems too; [Section 45.7](#) points at the literature.

45.5.7 Exercises

45.5.7.1 A. Check your understanding

Exercise A1.

In [Example \(Mean and scale together\)](#) the mean block has 12 basis columns and effective degrees of freedom 8.75. What are the two extreme values the effective degrees of freedom of that block could take, and which smoothing parameters produce them?

Solution. As $\lambda_\mu \rightarrow 0$ the trace tends to 12, the number of columns; as $\lambda_\mu \rightarrow \infty$ it tends to the dimension of the null space of the second-difference penalty, namely 2 (constants and straight lines). The fitted value 8.75 is much nearer the flexible end.

45.5.7.2 B. Practice

Exercise B1.

For a gamma response with mean μ and shape ν , density $d(y) = \{\nu/\mu\}^\nu y^{\nu-1} e^{-\nu y/\mu} / \Gamma(\nu)$, with log links on both parameters, compute u_{i1} and w_{i1} of [Theorem 45.5.1\(b\)](#) for the mean block. Is the model orthogonal in the sense of part (c)?

Solution. With $\eta_1 = \log \mu$, $\partial \ell / \partial \mu = \nu(y - \mu)/\mu^2$, so $u_1 = \mu \partial \ell / \partial \mu = \nu(y - \mu)/\mu$. Then $\partial^2 \ell / \partial \eta_1^2 = -\nu y/\mu$, with expectation $-\nu$, so $w_1 = \nu$. The cross derivative $\partial^2 \ell / \partial \eta_1 \partial \eta_2$ involves $\nu(y - \mu)/\mu$ times ν , whose expectation is zero, so the gamma model with these links is also orthogonal — a fact the algorithm exploits, and one that does not extend to three-parameter families.

Exercise B2.

Verify from [Eq. 45.5.6](#) that the working response for the scale block of the normal location-scale model is $z_{i2} = \log \sigma_i + \frac{1}{2} \{(y_i - \mu_i)^2 / \sigma_i^2 - 1\}$, and show that the scale step

is therefore an ordinary penalized least squares smooth of the squared standardized residuals, shifted and halved.

45.5.7.3 C. Going deeper

Exercise C1.

Show that the normal family parameterized by (μ, σ) is orthogonal for *any* increasing link on σ , not just the logarithm, and find a parameterization of the normal family in which it is not. What does orthogonality buy in [Theorem 45.5.1\(b\)](#)?

45.6 Comparing distributional models

Three fits to the same data now sit side by side: a homoscedastic linear model, a family of quantile regressions, and a location-scale GAMLSS. They estimate different things, so none can be judged by how well it hits its own target. What they share is that each delivers, at every covariate value, a predictive distribution for the response. That is the object to score.

45.6.1 Scoring rules

Definition 45.6.1 — Scoring rule, propriety

A **scoring rule** is a function $S(F, y)$ assigning a penalty when the predictive distribution F is issued and the value y is observed; smaller is better. Write $S(F, G) = \mathbb{E}_{Y \sim G} S(F, Y)$ for its expectation when Y really follows G . The rule is **proper** relative to a class of distributions if

$$S(G, G) \leq S(F, G) \quad \text{for all } F, G \text{ in the class,} \quad (45.6.1)$$

and **strictly proper** if equality forces $F = G$. A **consistent scoring function** for a functional T is a function $s(x, y)$ with $\mathbb{E}_G s\{T(G), Y\} \leq \mathbb{E}_G s(x, Y)$ for every x ; a functional admitting one is called **elicitable**.

Propriety is the minimal honesty requirement: under a rule that is not proper a forecaster does better by misreporting, and a comparison of methods rewards whoever misreports most skilfully. Three consistent scoring functions have already appeared: squared error for the mean, the check loss for the τ -quantile by [Theorem 45.2.1\(a\)](#), and [Eq. 45.4.1](#) for the τ -expectile by [Proposition 45.4.1\(a\)](#). Each scores a single number; the next result scores a whole distribution and ties it back to the check loss.

Proposition 45.6.1 — The continuous ranked probability score and the probability integral transform

For a distribution function F with finite mean and a real y , define

$$\text{CRPS}(F, y) = \int_{-\infty}^{\infty} \{F(s) - 1\{y \leq s\}\}^2 ds. \quad (45.6.2)$$

- (a) $\text{CRPS}(F, y)$ is finite, and for any G with finite mean

$$\mathbb{E}_{Y \sim G} \text{CRPS}(F, Y) = \int \{F(s) - G(s)\}^2 ds + \int G(s)\{1 - G(s)\} ds. \quad (45.6.3)$$

Hence the CRPS is a strictly proper scoring rule on the distributions with finite mean.

- (b) If F is continuous and strictly increasing with finite mean, then

$$\text{CRPS}(F, y) = 2 \int_0^1 \rho_\tau \{y - F^{-1}(\tau)\} d\tau : \quad (45.6.4)$$

the CRPS is the check loss averaged over all levels.

- (c) If $Y \sim F$ with F continuous, then $U = F(Y)$ is uniform on $(0, 1)$. If the predictive distributions $F_1, \dots, F_n$ are the true conditional distributions of independent $Y_1, \dots, Y_n$ and each is continuous, then the **probability integral transforms** $U_i = F_i(Y_i)$ are independent and uniform.

Proof.

- (a) The integrand of Eq. 45.6.2 is bounded by one and vanishes outside the region where $F(s)$ and $1\{y \leq s\}$ disagree, which lies in the set where $\min\{F(s), 1 - F(s)\} > 0$ together with a bounded interval; a finite mean makes $\int \min\{F, 1 - F\} ds < \infty$, so the score is finite. For fixed s , $1\{Y \leq s\}$ is Bernoulli with mean $G(s)$, so

$$\mathbb{E}_G \{F(s) - 1\{Y \leq s\}\}^2 = \{F(s) - G(s)\}^2 + G(s)\{1 - G(s)\}.$$

Integrating over s (Tonelli, the integrand being nonnegative) gives Eq. 45.6.3. The second term does not involve F , so the expectation is minimized exactly when $\int (F - G)^2 = 0$, that is when $F = G$ almost everywhere, and two right-continuous distribution functions agreeing almost everywhere are equal.

- (b) Write $q_\tau = F^{-1}(\tau)$ and $u = F(y)$, and split both sides at y . For the left side, $F(s) - 1\{y \leq s\}$ equals $F(s)$ for $s < y$ and $F(s) - 1$ for $s \geq y$, so $\text{CRPS}(F, y) = \int_{-\infty}^y F^2 + \int_y^\infty (1 - F)^2$. Substituting $s = q_\tau$ and integrating by parts,

$$\begin{aligned} \int_{-\infty}^y F(s)^2 ds &= \int_0^u \tau^2 dq_\tau = u^2 y - 2 \int_0^u \tau q_\tau d\tau, \\ \int_y^\infty \{1 - F\}^2 ds &= 2 \int_u^1 (1 - \tau) q_\tau d\tau - (1 - u)^2 y, \end{aligned}$$

the boundary terms at 0 and 1 vanishing because the mean is finite. For the right side, $q_\tau \leq y$ exactly when $\tau \leq u$, so $\rho_\tau(y - q_\tau) = \tau(y - q_\tau)$ for $\tau < u$ and

$(1 - \tau)(q_\tau - y)$ for $\tau > u$. Hence

$$\begin{aligned} 2 \int_0^1 \rho_\tau(y - q_\tau) d\tau &= 2y \int_0^u \tau d\tau - 2 \int_0^u \tau q_\tau d\tau \\ &\quad + 2 \int_u^1 (1 - \tau) q_\tau d\tau - 2y \int_u^1 (1 - \tau) d\tau, \end{aligned}$$

and $2 \int_0^u \tau d\tau = u^2$, $2 \int_u^1 (1 - \tau) d\tau = (1 - u)^2$. The two expressions agree term by term.

- (c) For continuous F and $u \in (0, 1)$, the set $\{y : F(y) \leq u\}$ is the interval $(-\infty, q_u]$ up to endpoints of flat stretches, which carry no probability, so $P\{F(Y) \leq u\} = F(q_u) = u$ by continuity. Independence of the U_i follows from independence of the Y_i , each F_i being a fixed function once the covariates are given.

■

Part (b) is the bridge between the two halves of this chapter. A quantile regression fitted at a dense grid of levels gives a predictive quantile function, evaluated by Eq. 45.6.4 with exactly the loss it was fitted with; a GAMLSS gives a predictive distribution function, evaluated by Eq. 45.6.2. The same number, in the units of the response, is available for both.

Remark (Other proper rules). The **logarithmic score** $S(F, y) = -\log f(y)$ is strictly proper and is what likelihood fitting optimizes, but it needs a density and is unbounded: one observation where the predictive density is nearly zero dominates everything, as Example (Watching it happen) showed. The CRPS needs no density, is finite for every observation, and grows only linearly in how far the observation falls from the forecast where the log score diverges — the safer default across methods. For a single level, the **pinball loss** $\rho_\tau(y - \hat{q}_\tau)$ reports how well one quantile is predicted.

45.6.2 Calibration and sharpness

Part (c) gives the standard graphical check. Compute $u_i = \hat{F}_i(y_i)$ for held-out observations and plot their histogram: under a correct model it is flat, and departures have a vocabulary. A **hump** in the middle means predictive distributions that are too wide; a **U shape** too narrow, the common and dangerous failure; a **slope** a biased location; **spikes at 0 and 1** alone, wrong tails with a sound body.

For a discrete response $F_i(Y_i)$ is not uniform, and the histogram must use a randomized version, drawing U_i uniformly on $[F_i(y_i^-), F_i(y_i)]$: the randomized quantile residuals of Dunn and Smyth (1996), exactly normal under a correct model after applying Φ^{-1} .

Warning (In-sample calibration proves nothing). The transforms must be computed out of sample. A fitted model is calibrated on its own training data almost by construction: Proposition 35.4.2 showed that in a logistic regression with an intercept the recalibration slope is exactly one and the intercept exactly zero, whatever the model's merits. A location-scale fit that has just matched $\hat{\sigma}$ to its own residuals gives a flat in-sample histogram whether or not its scale curve is right.

Calibration alone is not enough either: the unconditional distribution of the response is perfectly

calibrated and useless. The principle of Gneiting, Balabdaoui and Raftery (2007) is to maximize **sharpness subject to calibration** — among predictive distributions that pass the check, prefer the most concentrated. A proper scoring rule does both at once, which is why the scores come first.

45.6.3 Three models, one comparison

Example. (Mean model, quantile model and GAMLSS on Engel's budgets)

The 235 households are split into ten folds. On each fold, three predictive distributions are built from the other nine:

- (i) the homoscedastic linear model of Part II, with normal errors and one $\hat{\sigma}$;
- (ii) quantile regressions at 199 levels $\tau = 1/200, \dots, 199/200$, sorted at each covariate value by [Proposition 45.3.3](#)(b) so that the fitted quantiles are ordered;
- (iii) the location-scale GAMLSS of [Example \(Mean and scale together\)](#).

All three are scored the same way, by the discretized form of [Eq. 45.6.4](#) over that grid of levels, so no model is helped by a formula the others do not get.

model	CRPS	pinball 0.1	pinball 0.5	pinball 0.9	below $\hat{q}_{0.1}$	below $\hat{q}_{0.9}$
mean model	59.34	20.41	38.98	21.76	0.030	0.923
quantile model	53.00	17.69	38.05	14.93	0.089	0.902
GAMLSS	53.12	16.26	37.53	16.49	0.140	0.885

Scores are in francs, and each model gets its own best predictive distribution: for the mean model the exact t predictive of [Section 12.3](#). Both distributional models beat it by about 6 francs of CRPS per household: the differences are -6.35 with a paired standard error of 1.75, and -6.23 with standard error 2.12. Against each other they differ by -0.12 with a paired standard error of 1.99, which is no difference at all. The mean model fails where [Proposition 45.1.2](#) predicted, putting only 0.030 of the households below its own tenth percentile.

The Kolmogorov–Smirnov distance of the held-out transforms from uniformity is 0.098 for the mean model, 0.024 for the quantile model and 0.055 for the GAMLSS ([Figure 45.6.1](#)). The mean model's hump is the signature of predictive distributions that are too wide; the GAMLSS histogram is raised at both ends, the signature of a normal shape where the data want heavier tails — an actionable criticism, whose answer is a three-parameter family.

```
import numpy as np
from scipy import stats

LEVELS = np.arange(1, 200) / 200.0          # the tau grid the CRPS integral uses

def check_loss(u, tau):
    """The check function of Section 45.2."""
```

Figure 45.6.1: Held-out probability integral transforms from ten-fold cross-validation; a correct model gives a flat histogram (dashed). The mean model is humped, the quantile model close to flat, the GAMLSS raised at both ends.

```

return u * (tau - (u < 0))

def crps_from_quantiles(q, y):
    """CRPS = 2 * integral of the check loss over tau, on the grid LEVELS.

    q has one row per observation and one column per level of LEVELS.
    """
    return 2 * np.mean(check_loss(y[:, None] - q, LEVELS[None, :]), axis=1)

def pit_from_quantiles(q, y):
    """The probability integral transform read off a set of fitted quantiles."""
    return np.mean(q <= y[:, None], axis=1)

# one household: a normal predictive with mean 600 and scale 120 francs, observed at
# 700
q_one = 600.0 + 120.0 * stats.norm.ppf(LEVELS)[None, :]
y_one = np.array([700.0])
print(f"CRPS {crps_from_quantiles(q_one, y_one)[0]:.2f} francs,"
      f" PIT {pit_from_quantiles(q_one, y_one)[0]:.3f}")

```

45.6.4 Reading a score difference honestly

Three cautions close the comparison, the same three that have followed every model comparison in this book. A difference needs a standard error: 59.34 against 53.00 is three and a half paired standard errors, 53.00 against 53.12 less than a tenth of one, and the formal test, corrected for dependence in time series, is Diebold and Mariano (1995). Selecting on the score inflates it: the GAMLSS smoothing parameters were chosen in [Example \(Mean and scale together\)](#) on these same ten folds, so its score is optimistic in the way [Proposition 29.5.1](#) describes. And a score is not a purpose: the CRPS weights all levels alike, whereas an insurer who cares about the upper tail should compare pinball losses at $\tau = 0.95$ and a nutritionist concerned with the poorest households at $\tau = 0.05$. Decide what the model is for, then choose a scoring function consistent for it.

45.6.5 Exercises

45.6.5.1 A. Check your understanding

Exercise A1.

A forecaster issues $N(0, 4)$ every day while the truth is $N(0, 1)$. Sketch the probability integral transform histogram, and say which of the four shapes listed above appears.

Solution. $U = \Phi(Y/2)$ with $Y \sim N(0, 1)$ concentrates near $1/2$, since $Y/2$ rarely leaves $(-1, 1)$ and Φ maps that to $(0.16, 0.84)$: a hump in the middle, the signature of predictive distributions that are too wide.

45.6.5.2 B. Practice

Exercise B1.

Show that for $F = N(\mu, \sigma^2)$ and $z = (y - \mu)/\sigma$,

$$\text{CRPS}(F, y) = \sigma \left\{ z(2\Phi(z) - 1) + 2\varphi(z) - \frac{1}{\sqrt{\pi}} \right\},$$

using the identity $\text{CRPS}(F, y) = E|X - y| - \frac{1}{2} E|X - X'|$ for independent $X, X' \sim F$.

Solution. For $Z \sim N(0, 1)$ and a constant a , integrating by parts gives $E|Z - a| = 2\varphi(a) + a\{2\Phi(a) - 1\}$. Writing $X = \mu + \sigma Z$, $E|X - y| = \sigma E|Z - z| = \sigma\{2\varphi(z) + z(2\Phi(z) - 1)\}$. Next $X - X' \sim N(0, 2\sigma^2)$, and $E|N(0, v^2)| = v\sqrt{2/\pi}$, so $E|X - X'| = \sigma\sqrt{2} \cdot \sqrt{2/\pi} = 2\sigma/\sqrt{\pi}$. Substituting both into the identity gives the stated formula. By [Proposition 45.6.1\(a\)](#) the expected score is minimized in (μ, σ) at the true values.

Exercise B2.

Prove the identity used in [Exercise \(B1\)](#): $\text{CRPS}(F, y) = E|X - y| - \frac{1}{2} E|X - X'|$ for independent $X, X' \sim F$ with finite mean.

Solution. The key is $|a - b| = \int \{1\{a \leq s\} - 1\{b \leq s\}\}^2 ds$, since the integrand is one exactly on the interval between a and b . Taking $a = X$, $b = y$ and expectations, and using $E\{A - c\}^2 = \text{Var}(A) + (E A - c)^2$ with $A = 1\{X \leq s\}$,

$$E|X - y| = \int \left[\{F(s) - 1\{y \leq s\}\}^2 + F(s)\{1 - F(s)\} \right] ds = \text{CRPS}(F, y) + \int F(1 - F) ds.$$

Applying the same identity to the independent pair, $E\{A - A'\}^2 = 2 \text{Var}(A)$ gives $E|X - X'| = 2 \int F(1 - F) ds$. Subtracting half of the second display from the first gives the identity; finiteness of the mean makes $\int F(1 - F) ds$ finite.

45.6.5.3 C. Going deeper

Exercise C1.

Interpret the two terms of [Eq. 45.6.3](#). Show that the second depends only on the truth G , so it is an irreducible floor, and that the first is an integrated squared error between the forecast and the truth. Relate this to the bias-variance decomposition of prediction error in [Section 29.1](#).

45.7 Summary and Notes

45.7.1 Summary

Idea.

1. A model of the conditional mean constrains the whole conditional distribution: in a location model every quantile curve is the same curve shifted, and in a location-scale model the shape is frozen though the spread moves ([Proposition 45.1.2](#), using [Lemma 45.1.1](#)).
2. The τ -quantile is exactly the set of minimizers of the expected check loss, for any distribution with a finite mean; the sample problem is a linear program, equivariant under scaling, shifts, reparameterization and monotone transformation of the response ([Theorem 45.2.1](#)).
3. A regression quantile interpolates p observations, and the numbers of residual signs satisfy $n_- \leq \tau n \leq n_- + n_0$ ([Proposition 45.2.2](#)).
4. Knight's identity splits the increment of the check loss into a linear term and a controllable remainder ([Lemma 45.3.1](#)); with the convexity lemma it gives asymptotic normality with a sandwich covariance built from the error densities at zero, and in the iid case the sparsity function ([Theorem 45.3.2](#)).
5. That density can be estimated by a difference quotient of the empirical quantile function, or avoided by rank-score tests or the pairs bootstrap; on heteroscedastic data only the last two keep their nominal coverage ([Example \(Which interval keeps its promise\)](#)).
6. Fitted quantile curves are ordered at the average covariate vector but can cross elsewhere; sorting them can only bring them closer to the truth, in every L^p sense ([Proposition 45.3.3](#)).
7. Squared deviation in place of absolute gives expectiles: unique, increasing in τ , equal to the mean at $\tau = 1/2$, affinely equivariant, and at the quantile level $E(\mu - Y)_+ / E|Y - \mu|$, which depends on the distribution ([Proposition 45.4.1](#)).
8. Expectile regression is weighted least squares with weights determined by the signs of the residuals; a step that leaves the weights unchanged has found the exact global minimizer ([Proposition 45.4.2](#)).
9. A GAMLSS gives every parameter of a chosen family its own structured additive predictor ([Definition 45.5.1](#)) and maximizes a penalized log-likelihood by block-wise Fisher scoring, each step a penalized weighted least squares fit; for the normal location-scale model the information is block diagonal ([Theorem 45.5.1](#)).
10. The likelihood of a flexible location-scale model is unbounded, so the smooth-

ing parameters are what make the problem well posed and cannot be chosen by maximizing it ([Example \(Watching it happen\)](#)).

11. Predictive distributions are compared by proper scoring rules. The continuous ranked probability score is strictly proper, splits into a discrepancy and an irreducible floor, and is the check loss averaged over all levels; probability integral transforms are uniform under a correct model ([Proposition 45.6.1](#)).
12. On Engel's budgets the quantile model and the location-scale GAMLSS beat the homoscedastic mean model by about three paired standard errors of the score, and are indistinguishable from each other ([Example \(Mean model, quantile model and GAMLSS on Engel's budgets\)](#)).

45.7.2 Notes and sources

Quantile regression. The subject begins with Koenker and Bassett (1978), which introduced the check loss, the linear programming formulation, the counting properties and the asymptotics under identically distributed errors, and with Koenker and Bassett (1982), which brought Engel's budget data into the literature as a test bed for heteroscedasticity. Koenker (2005) is the standard monograph and the source for everything in [Section 45.3](#) stated here without proof; Koenker and Hallock (2001) is a short introduction. The median regression ancestor is far older, as [Section 5.9](#) records.

The proof in [Theorem 45.3.2](#) follows the convexity route of Pollard (1991), using the exact identity of Knight (1998); the convexity lemma is the one ingredient taken on trust. The sparsity estimate and its bandwidth are Hall and Sheather (1988); rank-score inference Gutenbrunner and Jurečková (1992); bootstrap validity Hahn (1995); computation Koenker and d'Orey (1987) and Portnoy and Koenker (1997). Crossing and its repairs: He (1997), Bondell, Reich and Wang (2010), and the rearrangement of Chernozhukov, Fernández-Val and Galichon (2010), whose L^p -contraction property is [Proposition 45.3.3\(b\)](#). The statistic $R_1(\tau)$ is Koenker and Machado (1999), nonparametric extensions start from Koenker, Ng and Portnoy (1994), and the Bayesian route through the asymmetric Laplace is Yu and Moyeed (2001), made practical by Kozumi and Kobayashi (2011).

Expectiles. Newey and Powell (1987) introduced asymmetric least squares, proved the properties collected in [Proposition 45.4.1](#), and gave the iterated weighted least squares algorithm; Efron (1991) developed the regression percentile view and Jones (1994) the sense in which expectiles are quantiles of a related distribution. The revival came with smoothing: Schnabel and Eilers (2009), Sobotka and Kneib (2012). The risk-measurement interest follows Gneiting (2011) and Ziegel (2016).

GAMLSS. The framework is Rigby and Stasinopoulos (2005), with software in Stasinopoulos and Rigby (2007); the ancestor is the LMS method of Cole and Green (1992). The Bayesian version is Klein, Kneib, Lang and Sohn (2015) and the boosting version Mayr, Fenske, Hofner, Kneib and Schmid (2012); randomized quantile residuals are Dunn and Smyth (1996). The survey chapter of Fahrmeir, Kneib, Lang and Marx (2021) covers all three approaches and supplied this chapter's coverage checklist.

Scoring rules. The continuous ranked probability score dates to Matheson and Winkler (1976); Gneiting and Raftery (2007) is the definitive treatment of propriety, and Gneiting, Balabdaoui and Raftery (2007) formulated sharpness subject to calibration. The probability integral transform goes back to Rosenblatt (1952) and entered forecast assessment through the prequential principle of Dawid (1984). Comparing predictions by a paired test of their score difference is

Diebold and Mariano (1995).

Data. Engel's 1857 budget survey is public domain and distributed with statsmodels. It appeared in chapters 20 to 23 as an example of a difficulty; here it is the subject, and nothing in this chapter is a claim about nineteenth-century Belgium.

45.7.3 What the ladder reached, and what lies beyond it

This book began with a projection onto a subspace and ends with an estimated conditional distribution. Each part changed one thing. Parts I to III built the classical model and its exact theory; Part IV let the design be a set of factors, so that the model matrix is rank deficient by construction; Part V audited every assumption in turn and asked what survives each departure; Part VI gave up unbiasedness; Part VII dropped $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$; Part VIII dropped normality; Part IX dropped the linear predictor; and Part X dropped the decision to model only the mean.

What holds the sequence together is that almost nothing was thrown away at each step. The normal equations became estimating equations; the projection became a smoother matrix and then a weighted smoother matrix; the residual sum of squares became a deviance and then a penalized log-likelihood; the trace of the hat matrix became effective degrees of freedom, and it is still a trace. A reader who has followed the argument to here has not learned forty-five methods but one method, restated.

Three directions are left untouched, and it is more useful to name them than to gesture at them.

Prediction without a model. Random forests, gradient boosting and neural networks predict better than any model in this book on many problems, and they can be made distributional: quantile regression forests (Meinshausen 2006) return a conditional distribution rather than a conditional mean. What they do not return is a coefficient with an interpretation. Conformal prediction (Vovk, Gammerman and Shafer 2005) is the counterweight, wrapping any predictor in a prediction set with finite-sample coverage under exchangeability alone — a stronger guarantee than anything proved here, and a weaker statement, because it says nothing about the mechanism.

Causal inference. [Chapter 25](#) went as far as a regression book can. The modern subject — instrumental variables beyond [Definition 24.4.1](#), difference-in-differences, regression discontinuity, synthetic controls, the semiparametric theory behind doubly robust estimation — is a separate discipline with its own books, linked to this one by the Frisch–Waugh–Lovell theorem ([Theorem 6.6.2](#)), the engine inside double machine learning.

Data that are not vectors, and data that are not complete. Functional data analysis (Ramsay and Silverman 2005) rebuilds the linear model when the response or the covariate is a curve, with the penalized splines of [Chapter 43](#) as its tool and the same trace as its degrees of freedom. Conditional transformation models (Hothorn, Kneib and Bühlmann 2014) learn the map to a reference law, a fourth route alongside the three of [Section 45.1](#). Regression for event times has its own century of theory beginning with Cox (1972); and censored quantile regression (Powell 1986) belongs here too, its point being that quantiles are equivariant under the censoring map $y \mapsto \max(y, c)$ by [Theorem 45.2.1\(d\)](#) while means are not.

None of these is promised in a later chapter, because there is no later chapter. What this book offers is the apparatus with which to read them.
