from scipy import optimize, stats

def r_cdf(c, rho, n, m=4000):
    """Exact P(r <= c) for n iid bivariate normal pairs with correlation rho."""
    if c < 0:
        # law of -r is that for
        -rho
        return 1 - r_cdf(-c, -rho, n, m)
    t = c * np.sqrt(n - 2) / np.sqrt(1 - c ** 2)
    # increasing in c
    if rho == 0:
        return stats.t.cdf(t, n - 2)
    V = stats.chi2.ppf((np.arange(m) + 0.5) / m, n - 1)
    # equal-probability
    nodes
    delta = rho / np.sqrt(1 - rho ** 2)
    return np.mean(stats.nct.cdf(t, n - 2, delta * np.sqrt(V)))
```

When $\rho \neq 0$ the distribution of r is skewed towards zero, because r cannot pass ± 1 . For $\rho = 0.8$ and $n = 15$, 200000 simulated samples give a mean of 0.7886, a median of 0.811, a skewness of -1.40 and a variance of 0.01195 (panel (a) of [Figure 14.4.1](#)). The variance depends strongly on ρ : the standard deviation of r is 0.267 at $\rho = 0$ and 0.032 at $\rho = 0.95$ (panel (c)). An interval $r \pm \text{constant} \times \text{standard error}$ would inherit both problems.

14.4.2 Fisher's transformation

Fisher (1921) proposed to work instead with

$$z = \tanh^{-1} r = \frac{1}{2} \log \frac{1+r}{1-r}, \quad \zeta = \tanh^{-1} \rho. \quad (14.4.2)$$

To see why this helps we need the large-sample behaviour of r , and for that three standard tools from probability theory, used here without proof (see van der Vaart 1998, chapters 2 and 3).

Remark (Three limit theorems).

- (i) *Central limit theorem.* If $\mathbf{W}_1, \mathbf{W}_2, \dots$ are independent copies of a random vector with mean $\boldsymbol{\mu}$ and covariance matrix $\boldsymbol{\Gamma}$, then $\sqrt{n}(\bar{\mathbf{W}}_n - \boldsymbol{\mu}) \rightarrow N(\mathbf{0}, \boldsymbol{\Gamma})$ in distribution.
- (ii) *Slutsky's lemma.* If $\mathbf{U}_n \rightarrow \mathbf{U}$ in distribution and $\mathbf{V}_n \rightarrow \mathbf{c}$ in probability, then $\mathbf{U}_n + \mathbf{V}_n \rightarrow \mathbf{U} + \mathbf{c}$, and $V_n U_n \rightarrow cU$ for scalars. (iii) *Delta method.* If $\sqrt{n}(\mathbf{T}_n - \boldsymbol{\theta}) \rightarrow N(\mathbf{0}, \boldsymbol{\Gamma})$ and g is differentiable at $\boldsymbol{\theta}$ with gradient ∇g , then $\sqrt{n}(g(\mathbf{T}_n) - g(\boldsymbol{\theta})) \rightarrow N(0, \nabla g^\top \boldsymbol{\Gamma} \nabla g)$.

The limiting variance of r needs fourth moments of the bivariate normal distribution.

Lemma 14.4.2 — Fourth moments of a standard bivariate normal pair

Let (X, Y) be bivariate normal with means 0, variances 1 and correlation ρ . Then $E X^4 = 3$, $E X^3 Y = 3\rho$ and $E X^2 Y^2 = 1 + 2\rho^2$. Consequently the covariance matrix of (X^2, Y^2, XY) is

$$\boldsymbol{\Gamma} = \begin{pmatrix} 2 & 2\rho^2 & 2\rho \\ 2\rho^2 & 2 & 2\rho \\ 2\rho & 2\rho & 1 + \rho^2 \end{pmatrix}.$$

Proof. Write $Y = \rho X + \sqrt{1 - \rho^2} U$ with $U \sim N(0, 1)$ independent of X ; the pair has the right means, variances and covariance, and it is normal by [Theorem 3.3.1](#). Using $E X^2 = 1$, $E X^4 = 3$ (the fourth moment of a standard normal) and the vanishing of odd moments, $E X^3 Y = \rho E X^4 = 3\rho$ and $E X^2 Y^2 = \rho^2 E X^4 + (1 - \rho^2) E X^2 E U^2 = 3\rho^2 + 1 - \rho^2 = 1 + 2\rho^2$. The covariances follow by subtracting products of means, $E X^2 = E Y^2 = 1$ and $E XY = \rho$: for instance $\text{Var}(XY) = 1 + 2\rho^2 - \rho^2$ and $\text{Cov}(X^2, XY) = E X^3 Y - \rho = 2\rho$. ■

Theorem 14.4.3 — Fisher's z transformation

As $n \rightarrow \infty$,

$$\sqrt{n}(r - \rho) \rightarrow N(0, (1 - \rho^2)^2) \quad \text{and} \quad \sqrt{n}(z - \zeta) \rightarrow N(0, 1)$$

Figure 14.4.1: The sample correlation of $n = 15$ normal pairs. (a) r for $\rho = 0.8$, with the exact density, obtained by differentiating Eq. 14.4.1. (b) Fisher's z , with the normal approximation. (c) The standard deviations of r and z across ρ ; dashed: $1/\sqrt{n-3}$.

in distribution. The same limits hold with $\sqrt{n-3}$ in place of $\sqrt{n}$. The limiting variance of z does not depend on ρ : $\tanh^{-1}$ is a variance-stabilizing transformation for r .

Proof. The correlation is unchanged by the maps $X \mapsto a + bX$, $Y \mapsto c + dY$ with $b, d > 0$, so we may assume $\mathbb{E}X = \mathbb{E}Y = 0$ and $\text{Var} X = \text{Var} Y = 1$. Let $\bar{\mathbf{W}}_n$ be the average of $\mathbf{W}_i = (X_i^2, Y_i^2, X_i Y_i)$, whose mean is $\boldsymbol{\theta} = (1, 1, \rho)$ and whose covariance is $\mathbf{\Gamma}$ of Lemma 14.4.2. With divisor n , the sample variances and covariance are $\bar{\mathbf{W}}_n - (\bar{X}^2, \bar{Y}^2, \bar{X}\bar{Y})$. Since $\sqrt{n} \bar{X}$ converges in distribution and $\bar{X} \rightarrow 0$ in probability, $\sqrt{n} \bar{X}^2 \rightarrow 0$ in probability, and similarly for the other two products, so by Slutsky's lemma the centring does not affect the limit. The divisor cancels in $r = g(\text{sample moments})$, where $g(a, b, c) = c/\sqrt{ab}$, and $\nabla g(\boldsymbol{\theta}) = (-\rho/2, -\rho/2, 1)$. By the central limit theorem and the delta method, $\sqrt{n}(r - \rho)$ is asymptotically normal with variance

$$\nabla g^\top \mathbf{\Gamma} \nabla g = \frac{\rho^2}{4}(2+2+4\rho^2) - 2 \cdot \frac{\rho}{2}(2\rho+2\rho) + (1+\rho^2) = \rho^2 + \rho^4 - 4\rho^2 + 1 + \rho^2 = (1-\rho^2)^2.$$

The derivative of $\tanh^{-1}$ at ρ is $1/(1-\rho^2)$, so a second application of the delta method gives variance 1 for z . Finally $\sqrt{n-3}/\sqrt{n} \rightarrow 1$, and Slutsky's lemma allows the substitution. ■

The transformation solves $g'(\rho) = 1/(1-\rho^2)$, the condition for a limiting standard deviation of one (Exercise B1). Why the approximation is so good for small n is another matter: Fisher (1921) showed that the mean of z exceeds ζ by about $\rho/(2(n-1))$ and that its variance is close to $1/(n-3)$, and the distribution of z is nearly symmetric even when that of r is strongly skewed. In the simulation with $\rho = 0.8$ and $n = 15$, z has mean 1.1295 against $\zeta = 1.0986$ and $\zeta + \rho/(2(n-1)) = 1.1272$, variance 0.0811 against $1/(n-3) = 0.0833$, and skewness 0.01. Its standard deviation is 0.288 at $\rho = 0$ and 0.283 at $\rho = 0.95$ (panel (c)).

14.4.3 Intervals and tests for a correlation

The approximation $z \approx N(\zeta, 1/(n-3))$ gives the interval

$$\tanh\left(z - \frac{z_{\alpha/2}}{\sqrt{n-3}}\right) \leq \rho \leq \tanh\left(z + \frac{z_{\alpha/2}}{\sqrt{n-3}}\right), \quad (14.4.3)$$

with $z_{\alpha/2}$ the upper $\alpha/2$ point of $N(0, 1)$. It is asymmetric about r , as it should be, and it never leaves $(-1, 1)$. The exact interval inverts [Eq. 14.4.1](#), using part (d) of [Proposition 14.4.1](#) exactly as for ρ^2 : its limits are the values of ρ at which the observed r is the 97.5% and the 2.5% point.

How good is the approximation? For $n = 10$ pairs, the coverage of the 95% interval [Eq. 14.4.3](#) over 200000 samples is 0.949, 0.949 and 0.952 at $\rho = 0, 0.5$ and 0.9 . The interval $r \pm 1.96(1 - r^2)/\sqrt{n}$, which uses the asymptotic standard error of [Theorem 14.4.3](#) directly, covers only 0.839, 0.838 and 0.834.

```
def sample_r(rho, n, reps, rng):
    x = rng.normal(size=(reps, n))
    y = rho * x + np.sqrt(1 - rho ** 2) * rng.normal(size=(reps, n))
    xc = x - x.mean(axis=1, keepdims=True)
    yc = y - y.mean(axis=1, keepdims=True)
    return np.sum(xc * yc, axis=1) / np.sqrt(np.sum(xc ** 2, axis=1) * np.sum(yc **
2, axis=1))

rng = np.random.default_rng(1443)
n_c, reps_c, zq = 10, 200_000, stats.norm.ppf(0.975)
for rho_c in (0.0, 0.5, 0.9):
    r_c = sample_r(rho_c, n_c, reps_c, rng)
    z_c = np.arctanh(r_c)
    fisher = np.abs(z_c - np.arctanh(rho_c)) <= zq / np.sqrt(n_c - 3)
    naive = np.abs(r_c - rho_c) <= zq * (1 - r_c ** 2) / np.sqrt(n_c)
    print(f"rho = {rho_c}: Fisher z covers {fisher.mean():.4f}, naive covers {naive.
mean():.4f}")
```

Because z has an approximately known variance, it also compares correlations. With independent samples of n_1 and n_2 cases, the hypothesis $\rho_1 = \rho_2$ is tested by referring

$$\frac{z_1 - z_2}{\sqrt{1/(n_1 - 3) + 1/(n_2 - 3)}}$$

to the standard normal distribution. The t statistic of [Proposition 14.4.1\(c\)](#) remains the exact test of $\rho = 0$; for any other null value ρ_0 , either $(z - \tanh^{-1} \rho_0)\sqrt{n - 3}$ or the exact law [Eq. 14.4.1](#) is used.

Example. (Poverty and graduation)

Across the 50 states, the correlation between the poverty rate and the high-school graduation rate is $r = -0.7613$. Its t statistic for $\rho = 0$ is -8.13 on 48 degrees of freedom, far out in the tail. The Fisher interval [Eq. 14.4.3](#) is $(-0.858, -0.613)$ and the exact interval is $(-0.855, -0.609)$, almost the same, and both are noticeably asymmetric about r .

```
data = sm.datasets.statcrime.load_pandas().data.drop(index="District of Columbia")
x, y = data["poverty"].to_numpy(), data["hs_grad"].to_numpy()
n_s = len(x)
r_s = np.corrcoef(x, y)[0, 1]
t_s = r_s * np.sqrt(n_s - 2) / np.sqrt(1 - r_s ** 2)
lo_z, hi_z = np.tanh(np.arctanh(r_s) + np.array([-1, 1]) * zq / np.sqrt(n_s - 3))
# exact interval: the rho at which the observed r sits at the 97.5% and 2.5% points
```

```

lo_x = optimize.brentq(lambda rh: r_cdf(r_s, rh, n_s) - 0.975, -0.99, 0.99)
hi_x = optimize.brentq(lambda rh: r_cdf(r_s, rh, n_s) - 0.025, -0.99, 0.99)
print(f"r = {r_s:.4f}, t = {t_s:.2f} on {n_s - 2} df")
print(f"Fisher z interval ({lo_z:.3f}, {hi_z:.3f}); exact interval ({lo_x:.3f}, {
    hi_x:.3f})")

```

Warning. Everything in this section uses bivariate normality, and not only through the conditional linear model. The asymptotic variance $(1 - \rho^2)^2/n$ comes from the fourth moments of Lemma 14.4.2. For other distributions it can be quite different, and then neither z nor the exact interval is reliable (Exercise B2). The t test of $\rho = 0$ is more robust: by Theorem 14.1.2 it needs only that Y given X follow a normal linear model with constant variance, and when X and Y are independent this holds as soon as Y is normal.

14.4.4 Exercises

14.4.4.1 A. Check your understanding

Exercise A1.

A sample of $n = 28$ pairs has $r = 0.62$. Compute the 95% Fisher interval for ρ .

Solution. $z = \tanh^{-1} 0.62 = 0.7250$ and $1.96/\sqrt{25} = 0.392$, so ζ lies in $(0.333, 1.117)$, and ρ in $(\tanh 0.333, \tanh 1.117) = (0.321, 0.806)$. The interval is longer below r than above.

Exercise A2.

Two independent samples give $r_1 = 0.45$ with $n_1 = 60$ and $r_2 = 0.20$ with $n_2 = 80$. Test $\rho_1 = \rho_2$ at level 0.05.

14.4.4.2 B. Practice

Exercise B1.

Suppose $\sqrt{n}(T_n - \theta) \rightarrow N(0, s(\theta)^2)$ for every θ in an interval, with s positive and continuous. Show that if $g'(\theta) = 1/s(\theta)$, then $\sqrt{n}(g(T_n) - g(\theta)) \rightarrow N(0, 1)$. Solve $g'(\rho) = 1/(1 - \rho^2)$ and recover Eq. 14.4.2.

Solution. By the delta method the limiting variance is $g'(\theta)^2 s(\theta)^2 = 1$. With partial fractions, $1/(1 - \rho^2) = \frac{1}{2}[1/(1 + \rho) + 1/(1 - \rho)]$, whose antiderivative vanishing at zero is $\frac{1}{2}[\log(1 + \rho) - \log(1 - \rho)] = \tanh^{-1} \rho$.

Exercise B2.

Let X and U be independent standard normal variables and $Y = XU$. Show that X and Y are uncorrelated but not independent, and that $\sqrt{n}r \rightarrow N(0, 3)$. What happens

to the level of the test that rejects $\rho = 0$ when $|T| > t_{n-2,0.025}$ in large samples? Which assumption of [Theorem 14.1.2](#) fails?

Solution. $E XY = E X^2 E U = 0$, but $E(X^2 Y^2) = E X^4 E U^2 = 3 \neq E X^2 E Y^2 = 1$, so they are dependent. Repeat the proof of [Theorem 14.4.3](#) at $\rho = 0$: the gradient is $(0, 0, 1)$, so the limiting variance of $\sqrt{n}r$ is $\text{Var}(XY)/(\text{Var } X \text{Var } Y) = 3$. Since $T \approx \sqrt{n}r$ for large n , the test rejects with probability tending to $2\{1 - \Phi(1.96/\sqrt{3})\} = 0.258$, not 0.05. Given X, Y is normal with mean zero but variance X^2 : the errors are not homoscedastic, so the conditional model of [Definition 14.1.1](#) fails.

14.4.4.3 C. Going deeper

Exercise C1.

For a general pair (X, Y) with finite fourth moments, standardized to means 0 and variances 1, show that $\sqrt{n}(r - \rho)$ is asymptotically normal with variance $(1 + \frac{\rho^2}{2}) E X^2 Y^2 + \frac{\rho^2}{4} (E X^4 + E Y^4) - \rho(E X^3 Y + E X Y^3)$. Check that it reduces to $(1 - \rho^2)^2$ under normality, and explain why no transformation of r stabilizes the variance across all distributions.

14.5 Partial correlation

A partial correlation measures linear association after the linear effects of conditioning variables have been removed from both variables ([Definition 3.6.1](#), [Proposition 3.6.1](#)). [Section 3.6](#) computed the sample version and [Theorem 9.5.4](#) identified its square with a partial R^2 ; the sampling distribution is still missing. This section shows that a partial correlation from n cases with q conditioning variables behaves exactly like an ordinary correlation from $n - q$ cases, and that its test is the t test of a regression coefficient.

14.5.1 The sample partial correlation

Definition 14.5.1 — Sample partial correlation

Let $\mathbf{y}, \mathbf{x} \in \mathbb{R}^n$, let $\mathbf{Z}$ be an $n \times q$ matrix, and let $\mathbf{D} = [\mathbf{1}, \mathbf{Z}]$ have rank $q + 1 < n$. With $\mathbf{M}_D$ the projection onto $\mathcal{C}(\mathbf{D})$, put $\tilde{\mathbf{y}} = (\mathbf{I} - \mathbf{M}_D)\mathbf{y}$ and $\tilde{\mathbf{x}} = (\mathbf{I} - \mathbf{M}_D)\mathbf{x}$, and suppose both are nonzero. The **sample partial correlation** of $\mathbf{y}$ and $\mathbf{x}$ given $\mathbf{Z}$ is

$$r_{yx \cdot Z} = \frac{\tilde{\mathbf{y}}^\top \tilde{\mathbf{x}}}{\|\tilde{\mathbf{y}}\| \|\tilde{\mathbf{x}}\|}.$$

Both residual vectors have mean zero, because $\mathbf{1} \in \mathcal{C}(\mathbf{D})$, so $r_{yx \cdot Z}$ is the ordinary sample correlation of the two residual vectors. With $q = 0$ it is the ordinary correlation of $\mathbf{y}$ and $\mathbf{x}$.

14.5.2 Its distribution

The key is that residualizing on $q + 1$ columns leaves $n - q - 1$ dimensions, exactly as centring alone leaves $n - 1$.

Theorem 14.5.1 — Distribution of a sample partial correlation

Let $\mathbf{Z}$ be a random $n \times q$ matrix with $\text{rank}[\mathbf{1}, \mathbf{Z}] = q + 1$ with probability one, and $n \geq q + 3$. Suppose that, given $\mathbf{Z}$, the rows (y_i, x_i) are independent bivariate normal vectors with means $\mathbf{a} + \mathbf{B}\mathbf{z}_{(i)}$, affine in the i th row $\mathbf{z}_{(i)}$ of $\mathbf{Z}$, and a common covariance matrix with correlation ρ . Then $r_{yx \cdot \mathbf{Z}}$ has the same distribution as the sample correlation of $n - q$ independent bivariate normal pairs with correlation ρ , and it is independent of $\mathbf{Z}$.

In particular, if the rows $(y_i, x_i, \mathbf{z}_{(i)}^\top)$ are independent draws from a multivariate normal distribution with a nonsingular covariance matrix, the conclusion holds with $\rho = \rho_{yx \cdot \mathbf{Z}}$, the population partial correlation.

Proof. Fix $\mathbf{Z}$ and write $\mathbf{D} = [\mathbf{1}, \mathbf{Z}]$. Let $\mathbf{K}$ be an $(n - q - 1) \times n$ matrix whose rows form an orthonormal basis of $\mathcal{C}(\mathbf{D})^\perp$, so that $\mathbf{KD} = \mathbf{0}$ and $\mathbf{K}^\top \mathbf{K} = \mathbf{I} - \mathbf{M}_D$. Then $\tilde{\mathbf{y}}^\top \tilde{\mathbf{x}} = \mathbf{y}^\top (\mathbf{I} - \mathbf{M}_D) \mathbf{x} = (\mathbf{Ky})^\top (\mathbf{Kx})$, and similarly for the squared lengths, so

$$r_{yx \cdot \mathbf{Z}} = \frac{(\mathbf{Ky})^\top (\mathbf{Kx})}{\|\mathbf{Ky}\| \|\mathbf{Kx}\|}.$$

Stack the pairs as the $n \times 2$ matrix $[\mathbf{y}, \mathbf{x}]$. Given $\mathbf{Z}$, $[\mathbf{y}, \mathbf{x}] = \mathbf{DA} + \mathbf{E}$ for a $(q + 1) \times 2$ matrix of coefficients $\mathbf{A}$, where $\mathbf{E}$ has independent $N_2(\mathbf{0}, \mathbf{C})$ rows. Hence $\mathbf{K}[\mathbf{y}, \mathbf{x}] = \mathbf{KE}$. Writing $\mathbf{E} = \mathbf{E}_0 \mathbf{C}^{1/2}$ with independent standard normal entries in $\mathbf{E}_0$, each column of $\mathbf{KE}_0$ is $N(\mathbf{0}, \mathbf{KK}^\top) = N(\mathbf{0}, \mathbf{I}_{n-q-1})$ (Theorem 3.3.1), so the $n - q - 1$ rows of $\mathbf{KE}$ are independent $N_2(\mathbf{0}, \mathbf{C})$ vectors. Thus, given $\mathbf{Z}$, $r_{yx \cdot \mathbf{Z}}$ is the *uncentred* correlation of $m = n - q - 1$ independent $N_2(\mathbf{0}, \mathbf{C})$ pairs.

The same argument with $q = 0$ and $\mathbf{Z}$ absent shows that the ordinary sample correlation of $m + 1$ bivariate normal pairs is the uncentred correlation of m independent $N_2(\mathbf{0}, \mathbf{C})$ pairs. So the conditional law of $r_{yx \cdot \mathbf{Z}}$ is that of an ordinary correlation from $m + 1 = n - q$ pairs, whatever $\mathbf{Z}$ is, and Lemma 14.1.1 gives the unconditional statement.

For the multivariate normal case, Theorem 3.5.2 says that given the conditioning variables the pair is bivariate normal with mean affine in them and covariance $\Sigma_{11 \cdot 2}$, whose correlation is $\rho_{yx \cdot \mathbf{Z}}$ by Definition 3.6.1. ■

This is the result promised in Section 3.6: each conditioning variable costs one case. Everything in Section 14.4 transfers with n replaced by $n - q$: the exact law Eq. 14.4.1, the t test with $n - q - 2$ degrees of freedom, and Fisher's interval with $\sqrt{n - q - 3}$ (Fisher 1924). The conditioning variables need not be normal.

Example. (Twelve cases, two skewed conditioning variables)

Take $n = 12$, $q = 2$ conditioning variables drawn as squares of exponential variables,

which are very skewed, a pair whose conditional means depend linearly on them, and conditional correlation $\rho = 0.6$. Over 100000 samples, the 10%, 50% and 90% points of the sample partial correlation are 0.257, 0.624 and 0.834. For ordinary correlations from $n - q = 10$ normal pairs they are 0.256, 0.625 and 0.835. A two-sample Kolmogorov–Smirnov test finds no difference between the two sets of simulated values (p -value 0.09).

```
import numpy as np
import statsmodels.api as sm
from scipy import optimize, stats

rng = np.random.default_rng(1451)
n, q, rho, reps = 12, 2, 0.6, 100_000
B = np.array([[1.0, -2.0], [0.5, 3.0]])          # dependence of the pair on Z
C = np.array([[1.0, rho], [rho, 1.0]])          # conditional covariance of the
pair
Lc = np.linalg.cholesky(C)

partial = np.empty(reps)
for s in range(reps):
    Zc = rng.exponential(size=(n, q)) ** 2        # skewed conditioning variables
    pair = Zc @ B.T + rng.normal(size=(n, 2)) @ Lc.T
    D = np.column_stack([np.ones(n), Zc])
    coef, *_ = np.linalg.lstsq(D, pair, rcond=None)
    e = pair - D @ coef                          # residuals of both variables
    partial[s] = e[:, 0] @ e[:, 1] / np.sqrt((e[:, 0] @ e[:, 0]) * (e[:, 1] @ e[:, 1]))

# ordinary correlations from n - q pairs with correlation rho
x = rng.normal(size=(reps, n - q))
y = rho * x + np.sqrt(1 - rho ** 2) * rng.normal(size=(reps, n - q))
ordinary = np.array([np.corrcoef(a, b)[0, 1] for a, b in zip(x, y)])
print("quantiles, partial :", np.quantile(partial, [0.1, 0.5, 0.9]).round(3))
print("quantiles, ordinary:", np.quantile(ordinary, [0.1, 0.5, 0.9]).round(3))
print("two-sample KS p-value:", round(stats.ks_2samp(partial, ordinary).pvalue, 3))
```

14.5.3 The test of a partial correlation is a coefficient test

In the population, a zero partial correlation and a zero regression coefficient are the same thing.

Proposition 14.5.2 — Partial correlation and the regression coefficient

Let $(Y, X, \mathbf{Z})$ have finite second moments, with $\text{Cov}((\mathbf{Z}^\top, X)^\top)$ positive definite, and let β_X be the coefficient of X in the best linear predictor of Y from $(\mathbf{Z}, X)$. Then

$$\beta_X = \frac{\sigma_{yx \cdot Z}}{\sigma_{xx \cdot Z}} = \rho_{yx \cdot Z} \sqrt{\frac{\sigma_{yy \cdot Z}}{\sigma_{xx \cdot Z}}},$$

so $\beta_X = 0$ iff $\rho_{yx \cdot Z} = 0$.

Proof. Let $e_X = X - L(X | \mathbf{Z})$ and $e_Y = Y - L(Y | \mathbf{Z})$ be the prediction errors of [Proposition 3.6.1\(a\)](#), with $\text{Var}(e_X) = \sigma_{xx \cdot Z} > 0$ and $\text{Cov}(e_Y, e_X) = \sigma_{yx \cdot Z}$. The affine span of $(\mathbf{Z}, X)$ is the orthogonal sum, in L^2 , of the affine span of $\mathbf{Z}$ and the line spanned by e_X , which is orthogonal to it. By the population version of [Theorem 6.3.7](#), projecting Y onto the sum projects it onto each piece: $L(Y | \mathbf{Z}, X) = L(Y | \mathbf{Z}) + (\text{Cov}(Y, e_X) / \text{Var}(e_X)) e_X$. Since $L(Y | \mathbf{Z})$ is orthogonal to e_X , $\text{Cov}(Y, e_X) = \text{Cov}(e_Y, e_X) = \sigma_{yx \cdot Z}$. The coefficient of X in this expression comes only from the last term, because $e_X = X -$ (affine function of $\mathbf{Z}$); it is $\sigma_{yx \cdot Z} / \sigma_{xx \cdot Z}$. ■

This is the Frisch–Waugh–Lovell theorem in the population, and the sample version is [Theorem 6.6.2](#) itself. Combining the two with [Theorem 14.5.1](#):

Theorem 14.5.3 — The partial correlation test is the coefficient t test

Regress $\mathbf{y}$ on the $p = q + 2$ columns $[\mathbf{1}, \mathbf{Z}, \mathbf{x}]$, assumed of full rank, and let t be the t statistic of the coefficient of $\mathbf{x}$ for the value zero. Then:

- (a) for every data set, $t = \sqrt{n - p} r_{yx \cdot Z} / \sqrt{1 - r_{yx \cdot Z}^2}$;
- (b) under the assumptions of [Theorem 14.5.1](#) with $\rho = 0$, $t \sim t(n - p)$, whatever the distribution of $\mathbf{Z}$;
- (c) when the rows are multivariate normal, the t test of the coefficient of $\mathbf{x}$ and the test of $\rho_{yx \cdot Z} = 0$ are the same test, and it has exact size.

Proof.

- (a) By [Theorem 9.5.4\(c\)](#) (see also [Exercise \(B3\)](#)), $r_{yx \cdot Z}^2 = t^2 / (t^2 + n - p)$. By [Theorem 6.6.2](#) the coefficient of $\mathbf{x}$ is $\tilde{\mathbf{x}}^\top \tilde{\mathbf{y}} / \|\tilde{\mathbf{x}}\|^2$, which has the sign of $r_{yx \cdot Z}$, so t and $r_{yx \cdot Z}$ have the same sign. Solving for t gives (a).
- (b) By [Theorem 14.5.1](#), $r_{yx \cdot Z}$ has the law of an ordinary correlation from $n - q$ pairs with $\rho = 0$, and by [Proposition 14.4.1\(c\)](#) the statistic in (a) is then $t((n - q) - 2) = t(n - p)$.
- (c) Under multivariate normality the best linear predictor ([Theorem 2.5.2](#)) is the conditional mean ([Proposition 3.5.3](#)), so the regression coefficient of $\mathbf{x}$ in the conditional model is β_X of [Proposition 14.5.2](#), which vanishes iff $\rho_{yx \cdot Z} = 0$. By (a) the two test statistics are monotone functions of each other, and by (b) or by [Theorem 14.1.2](#) the null distribution is exact. ■

So the test of a single coefficient in [Chapter 11](#) ([Theorem 11.6.1](#)) and the test of a partial correlation are one and the same, under either reading of the regressors. What the partial correlation adds is a scale-free measure of effect size, with its own confidence interval, which a coefficient does not provide.

Example. (Violent crime and urbanization)

Across the 50 states, the violent crime rate and the urbanization rate have correlation 0.345. Given the percentage of single-parent households and the poverty rate ($q = 2$), their partial correlation is $r = 0.1863$. In the regression of violent crime on the three variables and an intercept, the coefficient of urbanization is 1.388 with $t = 1.286$ on 46 degrees of freedom (p -value 0.2049), and indeed $\sqrt{46} r / \sqrt{1 - r^2} = 1.286$. With $n - q = 48$, the Fisher interval for $\rho_{yx \cdot Z}$ is $(-0.103, 0.447)$ and the exact interval is $(-0.103, 0.443)$. Much of the marginal association is shared with single parenthood and poverty, and what remains is compatible with none.

```
def r_cdf(c, rho, n, m=4000):
    """Exact P(r <= c) for an ordinary sample correlation of n bivariate normal
    pairs."""
    if c < 0:
        return 1 - r_cdf(-c, -rho, n, m)
    t = c * np.sqrt(n - 2) / np.sqrt(1 - c ** 2)
    if rho == 0:
        return stats.t.cdf(t, n - 2)
    V = stats.chi2.ppf((np.arange(m) + 0.5) / m, n - 1)
    return np.mean(stats.nct.cdf(t, n - 2, rho / np.sqrt(1 - rho ** 2) * np.sqrt(V))
    )

data = sm.datasets.statecrime.load_pandas().data.drop(index="District of Columbia")
y = data["violent"].to_numpy()
x = data["urban"].to_numpy()
Z = np.column_stack([np.ones(len(y)), data["single"], data["poverty"]])
n_s, q_s = len(y), Z.shape[1] - 1          # q = 2 conditioning variables

def resid(v, Z):
    coef, *_ = np.linalg.lstsq(Z, v, rcond=None)
    return v - Z @ coef

ey, ex = resid(y, Z), resid(x, Z)
r_p = ey @ ex / np.sqrt((ey @ ey) * (ex @ ex))          # sample partial correlation
fit = sm.OLS(y, np.column_stack([Z, x])).fit()          # p = 4 columns
t = fit.tvalues[-1]
df = n_s - 4
print(f"partial r = {r_p:.4f}, t = {t:.3f}, sqrt(df) r/sqrt(1-r^2) = "
      f"{np.sqrt(df) * r_p / np.sqrt(1 - r_p**2):.3f}")
zq = stats.norm.ppf(0.975)
lo_z, hi_z = np.tanh(np.arctanh(r_p) + np.array([-1, 1]) * zq / np.sqrt(n_s - q_s -
3))
lo_x = optimize.brentq(lambda rh: r_cdf(r_p, rh, n_s - q_s) - 0.975, -0.99, 0.99)
hi_x = optimize.brentq(lambda rh: r_cdf(r_p, rh, n_s - q_s) - 0.025, -0.99, 0.99)
print(f"Fisher z interval ({lo_z:.3f}, {hi_z:.3f}); exact ({lo_x:.3f}, {hi_x:.3f})")
```

Remark (Which variables to condition on). Conditioning can shrink an association, as in the example, reverse its sign, as in [Example \(Employment and unemployment\)](#) and Simpson's paradox, or create one where none exists, when the conditioning variable is a common effect of the two ([Exercise \(C1\)](#)). The distribution theory is silent on the choice of conditioning set; [Chapter 25](#) takes it up.

14.5.4 Exercises

14.5.4.1 A. Check your understanding

Exercise A1.

From $n = 40$ cases, the partial correlation of y and x given $q = 3$ other variables is -0.30 . Compute the t statistic, its degrees of freedom, and the 95% Fisher interval for the population partial correlation.

Exercise A2.

Explain, in terms of dimensions of subspaces, why the t test of a partial correlation given q variables has $n - q - 2$ degrees of freedom, and why this equals $n - p$ for the corresponding regression.

14.5.4.2 B. Practice

Exercise B1.

Let $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2]$ with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_1)$, $\text{rank } \mathbf{X}_1 = r_1$, $\text{rank } \mathbf{X} = r$ almost surely, and suppose that, given the regressors, $\mathbf{Y}$ follows the normal linear model with mean $\mathbf{X}_1\boldsymbol{\beta}_1$. Show that the partial R^2 of Definition 9.5.1 has the $\text{Beta}(\frac{r-r_1}{2}, \frac{n-r}{2})$ distribution, whatever the distribution of the regressors.

Solution. By Theorem 9.5.4(b), $R_{\mathbf{X}|\mathbf{X}_1}^2 = qF/(qF+n-r)$ with $q = r - r_1$, where F is the F ratio for the added block. Given the regressors, the null hypothesis holds, so $F \sim F(q, n-r)$ for every design (Theorem 14.1.2(b)), and by Lemma 14.1.1 unconditionally. Writing $F = (U/q)/(V/(n-r))$ with independent chi-squared variables, $R_{\mathbf{X}|\mathbf{X}_1}^2 = U/(U+V)$, which is $\text{Beta}(q/2, (n-r)/2)$ by Exercise (B4).

Exercise B2.

The *semipartial* correlation of $\mathbf{y}$ and $\mathbf{x}$ given $\mathbf{Z}$ is the correlation between $\mathbf{y}$ itself and the residual $\tilde{\mathbf{x}} = (\mathbf{I} - \mathbf{M}_D)\mathbf{x}$. Show that its square equals $R_{\text{full}}^2 - R_{\text{reduced}}^2$, the increase in R^2 when $\mathbf{x}$ is added to $[\mathbf{1}, \mathbf{Z}]$. How does it relate to the squared partial correlation?

Solution. By Lemma 9.2.1, the extra sum of squares of $\mathbf{x}$ is $(\tilde{\mathbf{x}}^\top \mathbf{y})^2 / \|\tilde{\mathbf{x}}\|^2$. Dividing by $\text{SST} = \|(\mathbf{I} - \mathbf{P}_1)\mathbf{y}\|^2$ gives $R_{\text{full}}^2 - R_{\text{reduced}}^2$. Since $\tilde{\mathbf{x}}$ has mean zero, $\tilde{\mathbf{x}}^\top \mathbf{y} = \tilde{\mathbf{x}}^\top (\mathbf{I} - \mathbf{P}_1)\mathbf{y}$, so the quotient is the squared correlation of $\mathbf{y}$ and $\tilde{\mathbf{x}}$. The squared partial correlation divides the same extra sum of squares by $\text{SSE}_{\text{reduced}}$ instead of SST, so it equals the squared semipartial correlation divided by $1 - R_{\text{reduced}}^2$, and is never smaller.

14.5.4.3 C. Going deeper

Exercise C1.

Let X and Y be independent $N(0, 1)$ and $C = X + Y + U$ with $U \sim N(0, 1)$ independent of both. Compute $\rho_{XY.C}$. With $n = 200$ cases, what does the t test of the coefficient of X in the regression of Y on C and X tend to conclude? Is the conclusion about the relation between X and Y wrong, or is the question wrong?

14.6 Testing lack of fit with replicates

Every test and interval so far has assumed that the mean function is right, that $E(\mathbf{Y}) \in \mathcal{C}(\mathbf{X})$. When it is wrong, the residual mean square overestimates the error variance: [Example \(Residual sum of squares under a wrong mean\)](#) showed that $E(\text{SSE}) = \sigma^2(n - r) + \|(\mathbf{I} - \mathbf{M})\boldsymbol{\theta}\|^2$ for a mean vector $\boldsymbol{\theta}$ outside the model space. Separating noise from systematic error needs an estimate of σ^2 free of the form of the mean, and repeated rows provide one: observations at identical settings differ only by noise. The idea, and the test built on it, go back to Fisher (1922).

14.6.1 Replicates and the cell-means model

Suppose the model matrix has c distinct rows $\mathbf{x}_1^\top, \dots, \mathbf{x}_c^\top$, the i th occurring $n_i \geq 1$ times, with $n = \sum_i n_i$. Index the observations by the distinct row and the replicate, y_{ij} with $j = 1, \dots, n_i$, so that the model is

$$E(y_{ij}) = \mathbf{x}_i^\top \boldsymbol{\beta}, \quad i = 1, \dots, c, \quad j = 1, \dots, n_i.$$

Let $\mathbf{Z}$ be the $n \times c$ matrix of group indicators, the model matrix of the one-way layout in which each distinct row has its own mean μ_i . Call two matrices with n rows *alike in row structure* as $\mathbf{X}$ if their rows are equal whenever the corresponding rows of $\mathbf{X}$ are equal.

Lemma 14.6.1 — The largest model with the same replicates

- (a) $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$. More generally, every matrix $\mathbf{W}$ with n rows whose rows are constant within the groups satisfies $\mathcal{C}(\mathbf{W}) \subseteq \mathcal{C}(\mathbf{Z})$.
- (b) $\mathbf{M}_{\mathbf{Z}\mathbf{Y}}$ replaces each observation by its group mean $\bar{y}_i$, and $\mathbf{M}\mathbf{y}$ is constant within groups.

Proof.

- (a) Let $\bar{\mathbf{W}}$ be the $c \times s$ matrix whose i th row is the common row of $\mathbf{W}$ in group i . Then $\mathbf{W} = \mathbf{Z}\bar{\mathbf{W}}$, so $\mathcal{C}(\mathbf{W}) \subseteq \mathcal{C}(\mathbf{Z})$. The matrix $\mathbf{X}$ is a special case.
- (b) The first claim is [Example \(The one-way layout\)](#). For the second, $\mathbf{M}\mathbf{y} \in \mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$, and the vectors of $\mathcal{C}(\mathbf{Z})$ are constant within groups. ■

So the cell-means model is the largest linear model that treats identical rows identically. Any mean function of the regressors at all, linear or not, produces a mean vector in $\mathcal{C}(\mathbf{Z})$.

Definition 14.6.1 — Pure error and lack of fit

With $\mathbf{M}_Z$ the projection onto $\mathcal{C}(\mathbf{Z})$, the **pure error** and **lack-of-fit** sums of squares are

$$\begin{aligned} \text{SSPE} &= \|(\mathbf{I} - \mathbf{M}_Z)\mathbf{y}\|^2 = \sum_{i=1}^c \sum_{j=1}^{n_i} (y_{ij} - \bar{y}_i)^2, \\ \text{SSLF} &= \|(\mathbf{M}_Z - \mathbf{M})\mathbf{y}\|^2 = \sum_{i=1}^c n_i (\bar{y}_i - \hat{y}_i)^2, \end{aligned} \quad (14.6.1)$$

with $n - c$ and $c - r$ degrees of freedom, where $\hat{y}_i = \mathbf{x}_i^\top \hat{\boldsymbol{\beta}}$ is the common fitted value of group i and $r = \text{rank}(\mathbf{X})$.

The two expressions for each sum of squares agree by [Lemma 14.6.1\(b\)](#): $(\mathbf{I} - \mathbf{M}_Z)\mathbf{y}$ has entries $y_{ij} - \bar{y}_i$, and $(\mathbf{M}_Z - \mathbf{M})\mathbf{y}$ has entries $\bar{y}_i - \hat{y}_i$, repeated n_i times.

14.6.2 The test**Theorem 14.6.2 — Pure-error lack-of-fit test**

Let $\mathbf{Y} \sim N_n(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ with $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{Z})$, that is, $E(y_{ij}) = \mu_i$ depends only on the row of $\mathbf{X}$; assume $r < c < n$. Then:

- (a) $\text{SSE} = \text{SSLF} + \text{SSPE}$, and SSLF and SSPE are independent;
- (b) $\text{SSPE}/\sigma^2 \sim \chi^2(n - c)$ for every $\mu_1, \dots, \mu_c$;
- (c) $\text{SSLF}/\sigma^2 \sim \chi^2(c - r, \gamma)$ with

$$\gamma = \frac{\|(\mathbf{I} - \mathbf{M})\boldsymbol{\theta}\|^2}{\sigma^2} = \frac{1}{\sigma^2} \sum_{i=1}^c n_i (\mu_i - \tilde{\mu}_i)^2, \quad (14.6.2)$$

where $\tilde{\mu}_i$ is the i th group value of $\mathbf{M}\boldsymbol{\theta}$, the least squares fit to the true means;

- (d) the ratio

$$F = \frac{\text{SSLF}/(c - r)}{\text{SSPE}/(n - c)} \sim F(c - r, n - c, \gamma),$$

and $\gamma = 0$ iff $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{X})$, that is, iff the model is correct. The test that rejects the model when $F > F_\alpha(c - r, n - c)$ has size α , and its power increases strictly with γ .

Proof. By [Lemma 14.6.1](#), $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$, so by [Theorem 6.5.1](#) $\mathbf{M}_Z - \mathbf{M}$ is the projection onto the orthogonal complement of $\mathcal{C}(\mathbf{X})$ in $\mathcal{C}(\mathbf{Z})$, of rank $c - r$, and $\mathbf{I} - \mathbf{M} = (\mathbf{M}_Z - \mathbf{M}) + (\mathbf{I} - \mathbf{M}_Z)$ splits into two orthogonal projections. This gives the identity in (a). By [Theorem 4.4.4](#), SSLF/σ^2 and SSPE/σ^2 are independent noncentral chi-squared variables with $c - r$ and $n - c$ degrees of freedom and noncentralities $\|(\mathbf{M}_Z - \mathbf{M})\boldsymbol{\theta}\|^2/\sigma^2$ and $\|(\mathbf{I} - \mathbf{M}_Z)\boldsymbol{\theta}\|^2/\sigma^2$. The second is zero because $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{Z})$, which proves (b). In the first, $\mathbf{M}_Z\boldsymbol{\theta} = \boldsymbol{\theta}$, so $(\mathbf{M}_Z - \mathbf{M})\boldsymbol{\theta} = (\mathbf{I} - \mathbf{M})\boldsymbol{\theta}$, whose entries are $\mu_i - \tilde{\mu}_i$, repeated n_i times; this is (c). Part (d) follows from [Definition 4.1.2](#), the fact that $(\mathbf{I} - \mathbf{M})\boldsymbol{\theta} = \mathbf{0}$ iff $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{X})$,

and [Theorem 4.1.4](#).

■

The test is the F test of the reduced model $\mathcal{C}(\mathbf{X})$ inside the full model $\mathcal{C}(\mathbf{Z})$ ([Theorem 11.1.1](#), [Theorem 4.4.6](#)). What makes it special is the full model, which is chosen not by the analyst but by the replication in the data, and which contains every mean function of the regressors. The residual sum of squares of the working model is split into two rows of an analysis of variance:

Source	Degrees of freedom	Sum of squares	Mean square
Lack of fit	$c - r$	$\sum_i n_i (\bar{y}_i - \hat{y}_i)^2$	$\text{SSLF}/(c - r)$
Pure error	$n - c$	$\sum_i \sum_j (y_{ij} - \bar{y}_i)^2$	$\text{SSPE}/(n - c)$
Residual	$n - r$	SSE	s^2

The noncentrality [Eq. 14.6.2](#) is the weighted squared distance between the true group means and their best approximation by the model, in units of σ^2 . It grows with the replication, so replicates buy power twice: through γ and through the pure-error degrees of freedom.

Example. (Stack loss and air flow)

Brownlee's stack loss data record $n = 21$ days of operation of a plant that oxidizes ammonia. Air flow, the rate of operation, takes only $c = 7$ distinct values, so a straight-line regression of stack loss on air flow can be tested for lack of fit with 14 degrees of freedom for pure error. The line has intercept -44.13 and slope 1.020 , and $R^2 = 0.846$. Its residual sum of squares 319.12 splits into $\text{SSPE} = 96.53$ and $\text{SSLF} = 222.58$ on 5 degrees of freedom. The mean squares are 44.52 and 6.90 , so $F = 6.46$ with p -value 0.0026 ; the 5% point of $F(5, 14)$ is 2.96 . The residual mean square of the line, 16.80 , is more than twice the pure-error estimate of σ^2 .

[Figure 14.6.1](#) shows why. The group means do not lie on any smooth curve: the single day at air flow 70 has stack loss 15.0, below the mean 20.6 of the five days at air flow 62. A parabola does not help, with $F = 7.22$ on 4 and 14 degrees of freedom (p -value 0.0023). The mean of stack loss is not a function of air flow alone, which points to the other operating variables, taken up in [Example \(Is the three-variable model adequate?\)](#).

```
import numpy as np
import statsmodels.api as sm
from scipy import stats
data = sm.datasets.stackloss.load_pandas().data
y = data["STACKLOSS"].to_numpy()
x = data["AIRFLOW"].to_numpy()
n = len(y)
levels, groups = np.unique(x, return_inverse=True)  # c distinct rows of X
c = len(levels)
Z = np.eye(c)[groups]  # cell-means model matrix

def sse(A):
    coef, *_ = np.linalg.lstsq(A, y, rcond=None)
    return np.sum((y - A @ coef) ** 2)

ss_pe = sse(Z)  # pure error, n - c df
for name, X in [("line", np.column_stack([np.ones(n), x])),
```

Figure 14.6.1: Stack loss against air flow on 21 days (replicates spread sideways), the seven group means (bars), the least squares line and parabola.

```

("parabola", np.column_stack([np.ones(n), x, x ** 2]))]:
r = np.linalg.matrix_rank(X)
ss_lf = sse(X) - ss_pe                                # lack of fit, c - r df
F = (ss_lf / (c - r)) / (ss_pe / (n - c))
print(f"{name:8s}: SSE {sse(X):7.2f} = SSLF {ss_lf:7.2f} ({c - r} df)"
      f" + SSPE {ss_pe:6.2f} ({n - c} df); F = {F:.2f}, p = {stats.f.sf(F, c -
r, n - c):.4f}")

```

14.6.3 When pure error is not pure

The theorem assumes $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{Z})$: the mean depends on the observation only through its row of $\mathbf{X}$. If a variable that is not in the model affects the response and varies within the groups of replicates, as water temperature does among the days with equal air flow in the stack loss data, then observations in a group do not share a mean. By [Theorem 9.6.1\(b\)](#), applied to the cell-means model,

$$E\left(\frac{\text{SSPE}}{n - c}\right) = \sigma^2 + \frac{\|(\mathbf{I} - \mathbf{M}_Z)\boldsymbol{\theta}\|^2}{n - c},$$

so the “pure” error estimate is inflated, and F becomes a ratio of two noncentral chi-squared variables, a *doubly noncentral F*, which rejects less often than it would with a pure estimate of σ^2 . Two further cautions: the pooled estimate assumes a common variance across groups ([Exercise \(C2\)](#)), and a non-significant result with few degrees of freedom is weak evidence that the model is adequate.

Remark (Designing for a lack-of-fit test). The test needs $c > r$ distinct rows and $n > c$ observations. The design that estimates a straight line most precisely puts half the observations at each end of the range; it has $c = r = 2$ and cannot detect any curvature. A few intermediate settings buy a check of the model at a small cost in precision. Replicates also cap what any model of the regressors can achieve: $R^2 \leq 1 - \text{SSPE}/\text{SST}$ ([Exercise \(B2\)](#)).

14.6.4 Exercises

14.6.4.1 A. Check your understanding

Exercise A1.

A straight line is fitted to $n = 24$ observations at $c = 6$ distinct values of x , each replicated four times. The residual sum of squares is 50.0 and the pure-error sum of squares is 36.0. Complete the analysis of variance table for lack of fit and compute F . Is there evidence of lack of fit at level 0.05, given that $F_{0.05}(4, 18) = 2.93$?

14.6.4.2 B. Practice

Exercise B1.

Show that the least squares estimate $\hat{\beta}$ from all n observations is also the weighted least squares estimate from the c group means, with weights n_i , and that SSLF is the weighted residual sum of squares of that fit.

Solution. By [Theorem 6.5.1](#), $\mathbf{M}\mathbf{y} = \mathbf{M}\mathbf{M}_Z\mathbf{y}$: projecting $\mathbf{y}$ onto $\mathcal{C}(\mathbf{X})$ is the same as projecting the vector of group means $\mathbf{M}_Z\mathbf{y}$. For a vector constant within groups, $\|\mathbf{M}_Z\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 = \sum_i n_i (\bar{y}_i - \mathbf{x}_i^\top \mathbf{b})^2$, so minimizing it over $\mathbf{b}$ is weighted least squares on the c means with weights n_i . Its minimum is $\|(\mathbf{M}_Z - \mathbf{M})\mathbf{y}\|^2 = \text{SSLF}$.

Exercise B2.

Suppose $\mathbf{1} \in \mathcal{C}(\mathbf{X})$. Show that every model whose model matrix has the row structure of $\mathbf{X}$ has $R^2 \leq 1 - \text{SSPE}/\text{SST}$, with equality for the cell-means model.

Solution. By [Lemma 14.6.1\(a\)](#) the column space $\mathcal{V}$ of such a model lies in $\mathcal{C}(\mathbf{Z})$, so its residual sum of squares $\|(\mathbf{I} - \mathbf{P}_\mathcal{V})\mathbf{y}\|^2$ is at least $\|(\mathbf{I} - \mathbf{M}_Z)\mathbf{y}\|^2 = \text{SSPE}$ (projection onto a smaller space leaves a longer residual). Hence $R^2 = 1 - \text{SSE}/\text{SST} \leq 1 - \text{SSPE}/\text{SST}$, with equality when $\mathcal{V} = \mathcal{C}(\mathbf{Z})$.

Exercise B3.

Show that rows i and j of $\mathbf{M}$ are equal iff rows i and j of $\mathbf{X}$ are equal. So replicates can be read off the hat matrix.

14.6.4.3 C. Going deeper

Exercise C1.

A straight line is to be tested for lack of fit at the four values $x = 0, 1, 2, 3$, each replicated m times, when the true mean is $\beta_0 + \beta_1 x + \beta_2 x^2$ with $\beta_2/\sigma = 0.5$. Show that $\gamma = m\beta_2^2 \|(\mathbf{I} - \mathbf{M}_4)\mathbf{q}\|^2/\sigma^2$, where $\mathbf{q} = (0, 1, 4, 9)^\top$ and $\mathbf{M}_4$ is the projection for a line on the four points, and find the smallest m for which the test at level 0.05 has power at least 0.8.

Exercise C2.

Suppose the groups have different variances σ_i^2 . Compute $E(SSPE)$ and $E(SSLF)$ under a correct mean model, and show by an example with two large groups of very different sizes and variances that the F test can then reject far more or far less often than α .

14.7 Near replicates and nonparametric lack-of-fit tests

Exact replicates are a luxury of designed experiments. With continuous regressors, rows of the model matrix are rarely identical: stack loss with all three operating variables has 21 rows and a single repeated pair, one degree of freedom for pure error. The pure-error test survives in a more general form: any larger model chosen without looking at the response gives an exact test, and so do regressors built from the fitted values. What is lost is the guarantee that the larger model contains every alternative: each test looks in some directions and is blind in others.

14.7.1 A general recipe

Proposition 14.7.1 — Testing against any larger model

Let $\mathbf{Y} \sim N_n(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$, let $\mathbf{X}$ have rank r , and let $\mathbf{Z}$ be a fixed matrix, chosen without reference to $\mathbf{Y}$, with $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$ and $\text{rank}(\mathbf{Z}) = s$, $r < s < n$. Let $\mathbf{M}$ and $\mathbf{M}_Z$ be the two projections and

$$F = \frac{[\text{SSE}(\mathbf{X}) - \text{SSE}(\mathbf{Z})]/(s - r)}{\text{SSE}(\mathbf{Z})/(n - s)}.$$

- (a) If $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{X})$, then $F \sim F(s - r, n - s)$.
- (b) If $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{Z})$, then $F \sim F(s - r, n - s, \|(\mathbf{I} - \mathbf{M})\boldsymbol{\theta}\|^2/\sigma^2)$.
- (c) In general $F = \frac{U/(s - r)}{V/(n - s)}$ with independent $U \sim \chi^2(s - r, \gamma_1)$ and $V \sim \chi^2(n - s, \gamma_2)$, where $\gamma_1 = \|(\mathbf{M}_Z - \mathbf{M})\boldsymbol{\theta}\|^2/\sigma^2$ and $\gamma_2 = \|(\mathbf{I} - \mathbf{M}_Z)\boldsymbol{\theta}\|^2/\sigma^2$. For every $c > 0$, $\Pr(F > c)$ is strictly increasing in γ_1 and strictly decreasing in γ_2 .

Proof. The decomposition $\mathbf{I} - \mathbf{M} = (\mathbf{M}_Z - \mathbf{M}) + (\mathbf{I} - \mathbf{M}_Z)$ into orthogonal projections of ranks $s - r$ and $n - s$ comes from [Theorem 6.5.1](#), and [Theorem 4.4.4](#) gives (c) apart from the monotonicity. Parts (a) and (b) are the cases $\gamma_1 = \gamma_2 = 0$ and $\gamma_2 = 0$. For the monotonicity, write $\Pr(F > c) = E[\Pr(U > c'V \mid V)]$ with $c' = c(s - r)/(n - s)$. For each value $V > 0$ the inner probability is strictly increasing in γ_1 by [Proposition 4.1.3](#). Similarly $\Pr(F > c) = E[\Pr(V < U/c' \mid U)]$, and $\Pr\{\chi^2(n - s, \gamma_2) < u\}$ is strictly decreasing in γ_2 for $u > 0$. ■

The size is exact however $\mathbf{Z}$ is chosen without using $\mathbf{Y}$; with random regressors, $\mathbf{Z}$ may be any function of $\mathbf{X}$ ([Theorem 14.1.2](#)). The pure-error test is the case $\mathbf{Z} = \text{cell means}$. Part (c)

describes what happens under the alternatives that matter, where the true mean lies in neither model. Departures captured by the larger model raise γ_1 and help; departures outside it raise γ_2 , inflate the denominator and hurt. A departure orthogonal to $\mathcal{C}(\mathbf{Z})$ gives power *below* the level (Exercise (B3)).

14.7.2 Near replicates, partitions and the rainbow test

Without exact replicates, the natural substitute is to group rows that are *nearly* identical. A cluster analysis of the standardized rows of $\mathbf{X}$ forms g clusters of near replicates, with indicator matrix $\mathbf{D}$. Testing $\mathbf{X}$ against $\mathbf{Z} = [\mathbf{X}, \mathbf{D}]$ allows each cluster its own shift from the fitted plane. This is the near-replicate test studied by Christensen (1989); Shillington (1979) proposed a variant based on the cluster averages of the regressors, and Christensen (1991) characterized the kinds of lack of fit each detects. With exact replicates all reduce to the pure-error test.

A second family partitions the cases instead of the regressor space. If the rows are split into two groups, with model matrices $\mathbf{X}_1$ and $\mathbf{X}_2$, the model that fits a separate regression to each group has $\mathbf{Z} = \begin{pmatrix} \mathbf{X}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_2 \end{pmatrix}$, whose column space contains $\mathcal{C}(\mathbf{X})$, and $\text{SSE}(\mathbf{Z})$ is the sum of the two residual sums of squares (Exercise (B1)). A straight line fitted to a curved mean is beaten by two lines, one for each half of the range. Utts (1982) proposed an extreme partition, the **rainbow test**: fit the model to a central subset of m cases, those with the smallest leverages, and give each of the remaining $n - m$ cases a free mean of its own. Then $\text{SSE}(\mathbf{Z})$ is the residual sum of squares of the central fit, and the test asks whether the model fitted to the middle of the design extrapolates to its edges.

All of these are exact by Proposition 14.7.1, and all require a decision made from $\mathbf{X}$ alone: how many clusters, where to split, how large a central subset. Choosing the clusters or the split after looking at the residuals destroys the exactness, because $\mathbf{Z}$ then depends on $\mathbf{Y}$.

14.7.3 Richer mean functions

The most direct alternative is a larger parametric model: add squares and cross-products of the regressors, or a regression spline. For a single regressor, a cubic spline with interior knots $\kappa_1, \dots, \kappa_m$ adds the columns x^2 , x^3 and $(x - \kappa_l)_+^3$, $l = 1, \dots, m$, and can follow any smooth curve if the knots are dense enough. These are reduced-model F tests (Theorem 11.1.1), exact by Proposition 14.7.1(a) provided the larger model is fixed before seeing the data. Their power is concentrated on departures that the added columns can represent. A quadratic term is excellent against smooth curvature and nearly useless against a departure confined to a small part of the range.

14.7.4 Regressors built from the fitted values

A classical alternative looks for departures along the fitted values: if the mean is a nonlinear function of $\mathbf{x}^\top \boldsymbol{\beta}$, then powers of $\hat{y}$ should help predict y . But $\hat{\mathbf{Y}} = \mathbf{M}\mathbf{Y}$ depends on the response, so Proposition 14.7.1 does not apply. Remarkably, the F test is exact anyway.

Theorem 14.7.2 — Regressors that are functions of the fitted values

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$ with $\text{rank}(\mathbf{X}) = r$. Let $\mathbf{W} = w(\mathbf{M}\mathbf{Y})$ be an $n \times q$ matrix computed from the fitted values alone, with $\text{rank}[\mathbf{X}, \mathbf{W}] = r + q < n$ with probability one. Then

$$F = \frac{[\text{SSE}(\mathbf{X}) - \text{SSE}([\mathbf{X}, \mathbf{W}])]/q}{\text{SSE}([\mathbf{X}, \mathbf{W}])/(n - r - q)} \sim F(q, n - r - q).$$

Proof. Let $\tilde{\mathbf{W}} = (\mathbf{I} - \mathbf{M})\mathbf{W}$, which has rank q , and let $\mathbf{P}$ project onto $\mathcal{C}(\tilde{\mathbf{W}})$. As in Lemma 6.6.1, $\mathcal{C}([\mathbf{X}, \mathbf{W}]) = \mathcal{C}(\mathbf{X}) \oplus \mathcal{C}(\tilde{\mathbf{W}})$ with orthogonal summands, so the projection onto $\mathcal{C}([\mathbf{X}, \mathbf{W}])$ is $\mathbf{M} + \mathbf{P}$. With $\hat{\boldsymbol{\epsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{Y}$, and since $\mathbf{P}\mathbf{M} = \mathbf{0}$,

$$\begin{aligned} \text{SSE}(\mathbf{X}) - \text{SSE}([\mathbf{X}, \mathbf{W}]) &= \|\mathbf{P}\mathbf{Y}\|^2 = \|\mathbf{P}\hat{\boldsymbol{\epsilon}}\|^2, \\ \text{SSE}([\mathbf{X}, \mathbf{W}]) &= \|\hat{\boldsymbol{\epsilon}}\|^2 - \|\mathbf{P}\hat{\boldsymbol{\epsilon}}\|^2. \end{aligned}$$

By Theorem 4.4.4, $\mathbf{M}\mathbf{Y}$ and $\hat{\boldsymbol{\epsilon}}$ are independent, and $\hat{\boldsymbol{\epsilon}} \sim N_n(\mathbf{0}, \sigma^2(\mathbf{I} - \mathbf{M}))$. So, given $\mathbf{M}\mathbf{Y}$, the matrix $\mathbf{P}$ is fixed and $\hat{\boldsymbol{\epsilon}}$ keeps its distribution, which is that of $(\mathbf{I} - \mathbf{M})\boldsymbol{\epsilon}^*$ for $\boldsymbol{\epsilon}^* \sim N_n(\mathbf{0}, \sigma^2\mathbf{I})$. Because $\mathcal{C}(\mathbf{P}) \subseteq \mathcal{C}(\mathbf{X})^\perp$, $\mathbf{P}(\mathbf{I} - \mathbf{M}) = \mathbf{P}$, and the two sums of squares become $\|\mathbf{P}\boldsymbol{\epsilon}^*\|^2$ and $\|(\mathbf{I} - \mathbf{M} - \mathbf{P})\boldsymbol{\epsilon}^*\|^2$. These are quadratic forms in orthogonal projections of ranks q and $n - r - q$, independent $\sigma^2\chi^2(q)$ and $\sigma^2\chi^2(n - r - q)$ variables by Theorem 4.4.4. The conditional law of F is therefore $F(q, n - r - q)$ whatever $\mathbf{M}\mathbf{Y}$ is, and by Lemma 14.1.1 it is also the unconditional law. ■

The theorem is due to Milliken and Graybill (1970). Its best-known case is Ramsey's (1969) **RESET**, which adds the squares and cubes of the fitted values, entry by entry. Tukey's (1949) one degree of freedom for nonadditivity, which tests a two-way additive layout against a multiplicative interaction, can be written in the same form with the squared fitted values. With a single regressor the construction brings nothing new: when $\hat{\beta}_1 \neq 0$, the columns $\hat{\mathbf{y}}^2$ and $\hat{\mathbf{y}}^3$ span, together with $\mathbf{1}$ and $\mathbf{x}$, the same space as x^2 and x^3 , so RESET is the cubic polynomial test (Exercise B4). Its value is in many dimensions, where it spends two degrees of freedom on the one direction along which the fit varies.

14.7.5 Smoothing-based tests

Instead of committing to a parametric alternative, one can ask whether the residuals contain any smooth structure. Let $\mathbf{S}$ be a fixed smoother matrix, for instance kernel weights that average each residual with those of its neighbours in the regressor space, and consider

$$T = \frac{\|\mathbf{S}\hat{\boldsymbol{\epsilon}}\|^2}{\|\hat{\boldsymbol{\epsilon}}\|^2}. \quad (14.7.1)$$

If the model is right, the residuals are noise and smoothing them leaves little; if the mean has structure the model misses, the smoothed residuals keep it and T is large.

Proposition 14.7.3 — The smoother statistic is pivotal

If $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$, the distribution of T in Eq. 14.7.1 depends only on $\mathbf{X}$ and $\mathbf{S}$, not on $\boldsymbol{\beta}$ or σ^2 . It equals the distribution of $\|\mathbf{S}(\mathbf{I} - \mathbf{M})\mathbf{u}\|^2 / \|\mathbf{I} - \mathbf{M}\mathbf{u}\|^2$ with $\mathbf{u} \sim N_n(\mathbf{0}, \mathbf{I})$.

Proof. $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{Y} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$, and $\boldsymbol{\varepsilon} = \sigma\mathbf{u}$ with $\mathbf{u} \sim N_n(\mathbf{0}, \mathbf{I})$. The factor σ^2 cancels in the ratio. ■

So the null distribution of T can be simulated as precisely as desired, from the design alone, and the test has exact size apart from Monte Carlo error. Statistics of this kind were proposed by Azzalini and Bowman (1993), who compare the residual sums of squares of the parametric fit and of a nonparametric smoother, and they are developed at length by Hart (1997). The power depends on the amount of smoothing, and a bandwidth chosen after inspecting the data breaks the exact size. With several regressors, neighbourhoods become sparse, so in practice one smooths along a single direction, such as the fitted values. And exactness depends, as for every test in this section, on normal homoscedastic errors.

14.7.6 Stack loss with all three regressors**Example. (Is the three-variable model adequate?)**

Return to the stack loss data with air flow, water temperature and acid concentration, $n = 21$ and $r = 4$. Ward clustering of the standardized rows into 8 clusters and testing $\mathbf{X}$ against $[\mathbf{X}, \mathbf{D}]$ gives $F = 1.43$ on 7 and 10 degrees of freedom (p -value 0.292). Adding the squares of the three regressors gives $F = 1.92$ on 3 and 14 (p -value 0.172). The rainbow test with the 11 cases of smallest leverage as the central subset gives $F = 1.04$ on 10 and 7 (p -value 0.497), and RESET gives $F = 1.17$ on 2 and 15 (p -value 0.336). None of the tests finds lack of fit. The strong lack of fit of the line in air flow alone (Example (Stack loss and air flow)) was the omitted water temperature, which varies within the groups of equal air flow. With 21 cases none of these tests is powerful, and a few unusual days deserve the scrutiny of Chapter 20.

```

14.7.7 Which test?

No lack-of-fit test is best against every alternative: by [Proposition 14.7.1\(c\)](#), a test gains power from departures its larger model can represent and loses power from the others.

Example. (Two departures, five tests)

Take $n = 50$ equally spaced values of x in $(0, 1)$, a straight-line working model, standard normal errors, and five tests at level 0.05: adding x^2 ; RESET with squared and cubed fitted values; a cubic spline with knots at 0.25, 0.5 and 0.75; near replicates formed by 10 clusters of 5 neighbouring values; and the smoother statistic [Eq. 14.7.1](#) with Gaussian kernel weights of bandwidth 0.06, its critical value simulated from 50000 null residual vectors. Over 4000 samples from the straight line, the rejection rates are 0.050, 0.054, 0.054, 0.052 and 0.054: all five tests are exact.

Against smooth curvature, a mean of $1 + 2x + 6(x - 0.5)^2$, the powers are 0.874 for the

Figure 14.7.1: Power of five exact lack-of-fit tests of a straight line ($n = 50$, level 0.05). (a) The two departures. (b) Smooth curvature. (c) A local bump, against which the quadratic test has power below its level.

quadratic term, 0.786 for RESET (which here is the cubic polynomial test), 0.606 for the spline, 0.422 for near replicates and 0.723 for the smoother. Against a narrow bump of height 2.5 near $x = 0.8$, the order is reversed: the smoother has power 0.622, the spline 0.501, near replicates 0.459, RESET 0.227, and the quadratic term 0.029, *below* the level: the bump is nearly orthogonal to x^2 after the line is removed, so it inflates the denominator of that test without feeding its numerator. Figure 14.7.1 shows the power curves.

})

```

The lesson is to decide which inadequacy matters before testing: a low-degree polynomial or RESET for smooth curvature, a flexible alternative or a smoother for local departures. Only the pure-error test of [Theorem 14.6.2](#) has a larger model containing every mean function of the regressors. Residual plots, which look in all directions informally, remain indispensable ([Chapter 20](#)).

14.7.8 Exercises

14.7.8.1 A. Check your understanding

Exercise A1.

A regression with an intercept and two regressors has $n = 30$ cases, whose rows are grouped into 8 clusters of near replicates. Assuming no combination of cluster indicators lies in $\mathcal{C}(\mathbf{X})$ except the constant, give the degrees of freedom of the near-replicate test of $\mathbf{X}$ against $[\mathbf{X}, \mathbf{D}]$.

14.7.8.2 B. Practice

Exercise B1.

Let $\mathbf{X} = \begin{pmatrix} \mathbf{X}_1 \\ \mathbf{X}_2 \end{pmatrix}$ and $\mathbf{Z} = \begin{pmatrix} \mathbf{X}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_2 \end{pmatrix}$. Show that $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$, that the projection onto $\mathcal{C}(\mathbf{Z})$ is $\begin{pmatrix} \mathbf{M}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{M}_2 \end{pmatrix}$, and that $\text{SSE}(\mathbf{Z})$ is the sum of the residual sums of squares of the

two separate regressions.

Solution. $\mathbf{X} = \mathbf{Z} \begin{pmatrix} \mathbf{I} \\ \mathbf{0} \end{pmatrix}$, so $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$. The block-diagonal matrix of the two projections is symmetric and idempotent, and its column space is $\mathcal{C}(\mathbf{X}_1) \times \mathcal{C}(\mathbf{X}_2) = \mathcal{C}(\mathbf{Z})$, so it is the projection onto $\mathcal{C}(\mathbf{Z})$ (Theorem 6.3.3). Applying $\mathbf{I}$ minus it to $\mathbf{y} = (\mathbf{y}_1^\top, \mathbf{y}_2^\top)^\top$ gives the two residual vectors $(\mathbf{I} - \mathbf{M}_1)\mathbf{y}_1$ and $(\mathbf{I} - \mathbf{M}_2)\mathbf{y}_2$, whose squared lengths add.

Exercise B2.

In the rainbow test, order the cases so that the central subset of size m comes first, and let its model matrix $\mathbf{X}_c$ have rank r . Show that $\mathbf{Z} = \begin{pmatrix} \mathbf{X}_c & \mathbf{0} \\ \mathbf{0} & \mathbf{I}_{n-m} \end{pmatrix}$ has $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$, that $\text{SSE}(\mathbf{Z})$ is the residual sum of squares of the central fit, and that the test has $n - m$ and $m - r$ degrees of freedom.

Exercise B3.

In Proposition 14.7.1, suppose $\boldsymbol{\theta} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\delta}$ with $\boldsymbol{\delta} \neq \mathbf{0}$ orthogonal to $\mathcal{C}(\mathbf{Z})$. Show that the power of the test is strictly less than its size.

Solution. Here $(\mathbf{M}_Z - \mathbf{M})\boldsymbol{\theta} = \mathbf{M}_Z\boldsymbol{\delta} - \mathbf{M}\boldsymbol{\delta} = \mathbf{0}$, since $\boldsymbol{\delta} \perp \mathcal{C}(\mathbf{Z}) \supseteq \mathcal{C}(\mathbf{X})$, so $\gamma_1 = 0$, while $\gamma_2 = \|\boldsymbol{\delta}\|^2/\sigma^2 > 0$. By part (c), $\Pr(F > c)$ is strictly smaller than its value at $\gamma_2 = 0$, which is the size by part (a).

Exercise B4.

With a single regressor and an intercept, show that if $\hat{\beta}_1 \neq 0$, then $\mathcal{C}([\mathbf{1}, \mathbf{x}, \hat{\mathbf{y}}^2, \hat{\mathbf{y}}^3]) = \mathcal{C}([\mathbf{1}, \mathbf{x}, \mathbf{x}^2, \mathbf{x}^3])$, powers taken entry by entry. Conclude that RESET is then the F test of the cubic polynomial.

14.7.8.3 C. Going deeper

Exercise C1.

In a two-way layout with one observation per cell and the additive model $E(y_{ij}) = \mu + \alpha_i + \beta_j$, Tukey's statistic tests the added regressor $(\hat{\alpha}_i \hat{\beta}_j)$. Show that, after the additive model is projected out, this regressor spans the same space as the entrywise square of the fitted values, and deduce from Theorem 14.7.2 that Tukey's test has an exact $F(1, (a-1)(b-1)-1)$ null distribution.

14.8 Summary and notes

14.8.1 Summary

Idea.

1. If the errors are normal, homoscedastic and independent of the regressors, every t and F statistic has the same law given every design, so tests and intervals stay exact with random regressors of any distribution. Power depends on the design drawn and is averaged over it (Lemma 14.1.1, Theorem 14.1.2).
2. The estimates themselves change law. With normal regressors the slope of a simple regression is a scaled $t(n-1)$ variable with variance $\sigma^2/(\sigma_X^2(n-3))$, and with k regressors the slopes have covariance $\sigma^2 \Sigma_{XX}^{-1}/(n-k-2)$ (Proposition 14.1.4, Lemma 14.2.4, Corollary 14.2.5).
3. The conditional mean is the only predictor whose errors are uncorrelated with every function of the regressors, and the correlation ratio bounds the correlation any predictor can reach (Proposition 14.2.1).
4. A fitted linear predictor pays for estimation. With normal regressors its expected error on a new case is $\sigma^2(1+1/n)(n-2)/(n-k-2)$, while its in-sample error has mean $\sigma^2(n-k-1)/n$; with a fixed design the gap is $2r\sigma^2/n$ (Proposition 14.2.2, Theorem 14.2.6, Proposition 14.2.7).
5. When the new error is correlated with the data, the best linear unbiased predictor adds to the estimated mean the best linear prediction of that error from the generalized least squares residuals (Theorem 14.2.8).
6. R^2 is the maximum likelihood estimate of $\rho_{Y.X}^2$. Given the design it is a transformed noncentral F variable; with normal regressors its noncentrality is $\lambda\chi^2(n-1)$, $\lambda = \rho^2/(1-\rho^2)$, which gives its exact law, its bias, the power of the overall F test and an exact interval for ρ^2 (Proposition 14.3.1, Theorem 14.3.2).
7. The sample correlation has an exact law expressed through noncentral t probabilities, and it is stochastically increasing in ρ . Fisher's $z = \tanh^{-1} r$ is asymptotically $N(\zeta, 1/n)$ whatever ρ , and in practice $N(\zeta, 1/(n-3))$ (Proposition 14.4.1, Theorem 14.4.3).
8. A sample partial correlation given q variables behaves exactly like an ordinary correlation from $n-q$ cases, and its test is the t test of the corresponding regression coefficient (Theorem 14.5.1, Proposition 14.5.2, Theorem 14.5.3).
9. With replicated rows, the residual sum of squares splits into pure error and lack of fit, and their ratio is an exact F test of the model against every mean function of the regressors (Lemma 14.6.1, Theorem 14.6.2).
10. Without replicates, any larger model chosen from $\mathbf{X}$ alone, any regressors built from the fitted values, and any smoother of the residuals give exact tests. Each has power only against departures its alternative can represent, and some departures reduce its power below the level (Proposition 14.7.1, Theorem 14.7.2, Proposition 14.7.3).

14.8.2 Notes and sources

Source texts. The chapter covers Christensen (2020, sections 6.3 to 6.7) on prediction theory, multiple and partial correlation, best linear unbiased prediction and lack of fit; Rencher and Schaalje (2008, chapter 10) on regression with random regressors; and Agresti (2015, sections 3.3 and 3.4), whose worked example includes partial correlations and model checking. Christensen's near-replicate tests and his view of prediction as the goal of regression shaped Section 14.2

and [Section 14.7](#). Rencher and Schaalje give the normal-theory formulas for R^2 , z and partial correlations. Agresti's intervals of section 3.3 belong to [Chapter 12](#).

Random regressors and prediction. Reporting precision conditionally on an ancillary design is Fisher's conditionality principle; Cox (1958) gave the standard discussion. The Wishart distribution is due to Wishart (1928), and Anderson (2003) treats it and the mean of its inverse through densities; the proof of [Lemma 14.2.4](#) here uses only conditioning and symmetry. Breiman and Freedman (1983) use the prediction error of regression with normal regressors to study how many variables to enter, a question [Chapter 29](#) takes up. Best linear unbiased prediction is due to Goldberger (1962); [Chapter 31](#) and [Chapter 32](#) develop it for general covariance structures and mixed models ([Theorem 32.3.1](#)).

Correlation coefficients. Fisher found the exact distribution of r (1915), introduced z with its approximate mean and variance (1921), showed that partial correlations follow the same law with the sample size reduced by the number of conditioning variables (1924), and derived the distribution of the multiple correlation (1928). Hotelling (1953) refined the moments of r and z . [Lemma 14.4.2](#) is a case of Isserlis's (1918) formula, and the mean of R^2 in [Example \(How biased is R-squared?\)](#) follows from Fisher's (1928) distribution; see Olkin and Pratt (1958), who also give the unbiased estimator of ρ^2 . For the limit theorems of [Section 14.4](#), see van der Vaart (1998).

Lack of fit. The pure-error test is Fisher's (1922). Near-replicate tests were proposed by Shillington (1979) and analysed by Christensen (1989, 1991); the rainbow test is due to Utts (1982). Ramsey (1969) introduced RESET, and Milliken and Graybill (1970) proved [Theorem 14.7.2](#), which also covers Tukey's (1949) one degree of freedom for nonadditivity. Smoothing-based tests were proposed by Azzalini and Bowman (1993) and are the subject of Hart (1997).

Data. The stack loss data are from Brownlee (1965). The RAND Health Insurance Experiment is described by Manning et al. (1987); the extract and the 2009 state data are public-domain data distributed with statsmodels.

What is new here. The conditional derivations of the laws of R^2 , r and partial correlations ([Theorem 14.3.2](#), [Proposition 14.4.1](#), [Theorem 14.5.1](#)), the proof of [Lemma 14.2.4](#), the organization of lack-of-fit tests around [Proposition 14.7.1](#), and the examples and simulations are this book's.

Chapter 15

Analysis of Variance as Subspace Comparison

An experimenter assigns treatments to units at random and measures a response. The simplest such experiment has one factor, and its analysis is the prototype for Part IV. The mean vector lies in the space of vectors constant within groups, that space splits orthogonally into the constants and a treatment space, and every question about the treatments concerns the component of the mean in the treatment space. This chapter turns that geometry into a working analysis. It states the one-way model and what its parameters mean, shows that single contrasts, families of contrasts and the overall F test are projections of the data onto pieces of one subspace, and derives the analysis of variance table and its expected mean squares. It splits the treatment sum of squares into single degrees of freedom along directions chosen for their meaning, including polynomial trends in a quantitative factor. Finally it asks what balance buys: plain orthogonality, the largest guaranteed power, and a test that tolerates unequal variances. When the design is unbalanced and the variances differ, the classical test can go badly wrong, and the chapter describes the heteroscedasticity-robust tests of Welch and of Brown and Forsythe.

What you need. The one-way projection and its generalized inverses from [Chapter 6](#) ([Example \(A rank-deficient layout\)](#), [Example \(The one-way layout\)](#), [Theorem 6.5.1](#)); estimability, side conditions and contrasts from [Chapter 8](#) ([Theorem 8.7.1](#), [Proposition 8.7.2](#), [Theorem 8.4.2](#)); orthogonal decompositions and expected mean squares from [Chapter 9](#) ([Theorem 9.6.1](#), [Theorem 9.4.4](#)); the F test and its power from [Chapter 11](#) ([Theorem 11.1.1](#), [Theorem 11.5.1](#)); the t interval from [Chapter 12](#) ([Theorem 12.1.1](#)); and the simultaneous methods of [Chapter 13](#) ([Theorem 13.2.2](#), [Theorem 13.3.2](#), [Theorem 13.4.1](#)). The pure-error lack-of-fit test of [Chapter 14](#) ([Theorem 14.6.2](#)) reappears as trend analysis.

Figure 15.1.1: The nitrogen trial: yields of thirty plots at five nitrogen rates, six plots per rate (slightly spread horizontally), with the rate means and the grand mean.

15.1 The one-way layout as a linear model

Earlier chapters used the one-way layout as an example of rank deficiency ([Chapter 6](#)), estimability ([Chapter 8](#)), orthogonal decomposition ([Chapter 9](#)) and simultaneous inference ([Chapter 13](#)). Here it is the subject. This section fixes the model, recalls its projection, and settles what its parameters mean and where they come from.

15.1.1 A designed experiment

An agronomist wants to know how the yield of a wheat variety responds to nitrogen fertilizer. Thirty field plots of equal size are available. Five application rates are chosen, 0, 40, 80, 120 and 160 kilograms of nitrogen per hectare, and each rate is assigned to six plots chosen at random from the thirty. At harvest the grain yield of each plot is recorded in tonnes per hectare. This is a **completely randomized design** with one **factor** (nitrogen) at five **levels**, also called **treatments**, with six **replicates** of each. The data used throughout this chapter were simulated from a smooth response curve with plot-to-plot standard deviation 0.5 t/ha, which the analysis does not know about.

Rate (kg N/ha)	Yields (t/ha)	Mean	Standard deviation
0	3.69, 4.10, 3.41, 3.67, 4.54, 4.62	4.005	0.498
40	5.57, 5.21, 4.98, 4.99, 5.77, 4.90	5.237	0.357
80	5.86, 5.80, 6.64, 5.99, 5.72, 6.33	6.057	0.357
120	6.59, 6.85, 6.74, 6.32, 6.39, 6.20	6.515	0.254
160	6.60, 5.14, 7.82, 7.19, 6.61, 6.55	6.652	0.889

[Figure 15.1.1](#) shows the thirty yields. Mean yield rises with the rate, steeply at first and then more slowly, and the plots within a rate scatter by roughly half a tonne. The later sections compare particular treatments ([Section 15.2](#)), ask whether the rates differ at all ([Section 15.3](#)), and describe the shape of the response ([Section 15.4](#)).

15.1.2 The model in two forms

Index the groups by $k = 1, \dots, g$ and the observations within group k by $j = 1, \dots, n_k$. The observations may be listed in any order in the vector $\mathbf{Y}$; what matters is which group each belongs to.

Definition 15.1.1 — The one-way layout

A **one-way layout** has $g \geq 2$ groups with $n_k \geq 1$ observations in group k and $n = \sum_k n_k > g$ observations in all. Its **cell-means form** is

$$Y_{kj} = \mu_k + \varepsilon_{kj}, \quad \text{that is,} \quad \mathbf{Y} = \mathbf{Z}\boldsymbol{\mu} + \boldsymbol{\varepsilon},$$

where $\mathbf{Z}$ is the $n \times g$ matrix whose column k is the indicator $\mathbf{z}_k$ of group k and $\boldsymbol{\mu} = (\mu_1, \dots, \mu_g)^\top$. Its **effects form** is

$$Y_{kj} = \mu + \alpha_k + \varepsilon_{kj}, \quad \text{that is,} \quad \mathbf{Y} = [\mathbf{1}, \mathbf{Z}] \begin{pmatrix} \mu \\ \boldsymbol{\alpha} \end{pmatrix} + \boldsymbol{\varepsilon}.$$

In both, the errors have $E(\boldsymbol{\varepsilon}) = \mathbf{0}$ and $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$. The **normal one-way model** adds $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$. The layout is **balanced** if $n_1 = \dots = n_g = m$, say. The treatment parameters μ_k (or α_k) are **fixed effects**: unknown constants attached to the g treatments actually studied.

The two forms describe the same mean vectors: since $\mathbf{z}_1 + \dots + \mathbf{z}_g = \mathbf{1}$, the column space of $[\mathbf{1}, \mathbf{Z}]$ is $\mathcal{C}(\mathbf{Z})$, the vectors constant within each group (Example (A rank-deficient layout)). The effects matrix has $g + 1$ columns but rank g , so its parameters are not identified. Fitted values, residuals, sums of squares and tests depend only on $\mathcal{C}(\mathbf{Z})$, so the choice of form decides which parameters one talks about, never the results of the analysis.

A word on notation. Group means are written $\bar{y}_k$ (the literature also writes $\bar{y}_{k\cdot}$), the grand mean is $\bar{y} = n^{-1} \sum_{k,j} y_{kj}$, and $\bar{\mu} = n^{-1} \sum_k n_k \mu_k$ is the *weighted* average of the group means, which is $E(\bar{Y})$. The unweighted average $g^{-1} \sum_k \mu_k$ is a different quantity unless the layout is balanced.

15.1.3 The model space and its projection

The orthogonal projection onto $\mathcal{C}(\mathbf{Z})$ was computed in Example (The one-way layout):

$$\mathbf{M} = \sum_{k=1}^g \frac{\mathbf{z}_k \mathbf{z}_k^\top}{n_k}, \quad (\mathbf{M}\mathbf{y})_{kj} = \bar{y}_k, \quad (15.1.1)$$

so the fitted value of every observation is its group mean and the residual is its deviation from that mean. Whatever the parameterization and whatever generalized inverse is used to solve the normal equations, this is the fit (Theorem 6.3.6). In the cell-means form the least squares estimate is unique, $\hat{\boldsymbol{\mu}} = (\bar{y}_1, \dots, \bar{y}_g)^\top$, because $\mathbf{Z}^\top \mathbf{Z} = \text{diag}(n_1, \dots, n_g)$ is invertible.

The residual sum of squares pools the variation inside the groups:

$$\text{SSE} = \|(\mathbf{I} - \mathbf{M})\mathbf{y}\|^2 = \sum_{k=1}^g \sum_{j=1}^{n_k} (y_{kj} - \bar{y}_k)^2 = \sum_{k=1}^g (n_k - 1)s_k^2, \quad (15.1.2)$$

where s_k^2 is the sample variance of group k (taken as zero when $n_k = 1$). The error space $\mathcal{C}(\mathbf{Z})^\perp$ has dimension $n - g$, so the unbiased estimator of σ^2 ([Theorem 5.6.1](#)) is

$$s^2 = \frac{\text{SSE}}{n - g} = \sum_{k=1}^g \frac{n_k - 1}{n - g} s_k^2,$$

a weighted average of the group variances with weights proportional to their degrees of freedom. In the nitrogen trial $s = 0.5211$ t/ha on 25 degrees of freedom, and since the design is balanced s^2 is the plain average of the five group variances.

```
import numpy as np

rates = np.array([0, 40, 80, 120, 160])          # kg N per hectare
g, m = len(rates), 6                             # 5 rates, 6 plots per rate
true_means = 6.8 - 2.7 * np.exp(-0.018 * rates)  # unknown to the analyst
rng = np.random.default_rng(1515)
group = np.repeat(np.arange(g), m)               # plot i received rate group[i]
y = np.round(true_means[group] + rng.normal(0, 0.5, g * m), 2) # yield, t/ha
n = len(y)

Z = (group[:, None] == np.arange(g)).astype(float) # cell-means model matrix
n_k = Z.sum(axis=0)
means = Z.T @ y / n_k                            # least squares: the group means
fitted = Z @ means                                # M y
resid = y - fitted                                # (I - M) y
s2 = resid @ resid / (n - g)                      # pooled within-group variance
print("group means:", means.round(3))
print(f"s = {np.sqrt(s2):.4f} on {n - g} degrees of freedom")
```

15.1.4 What the parameters mean

The group means μ_k are estimable, and so is every linear function of them. The effects form adds one parameter that the data cannot determine. By [Theorem 8.7.1](#), a function $\lambda_0\mu + \sum_k \lambda_k\alpha_k$ is estimable iff $\lambda_0 = \sum_k \lambda_k$; in particular no single α_k and not μ itself is estimable, while every difference $\alpha_k - \alpha_l$ is.

Software nevertheless reports values of μ and α_k , by adding a side condition, one nonestimable linear restriction that picks a single solution of the normal equations ([Theorem 8.4.2](#)). Under the restriction, each parameter becomes a particular estimable function of the group means ([Proposition 8.4.3](#)), and it is worth knowing which:

Side condition	μ becomes	α_k becomes
$\sum_k \alpha_k = 0$	$g^{-1} \sum_l \mu_l$, the unweighted average	$\mu_k - g^{-1} \sum_l \mu_l$
$\sum_k n_k \alpha_k = 0$	$\bar{\mu} = n^{-1} \sum_l n_l \mu_l$, the weighted average	$\mu_k - \bar{\mu}$
$\alpha_1 = 0$	μ_1 , the reference group	$\mu_k - \mu_1$

Each row solves the g equations $\mu + \alpha_k = \mu_k$ together with the side condition, and the estimates put $\bar{y}_k$ for μ_k ([Exercise \(B1\)](#)). The second gives the classical $\hat{\mu} = \bar{y}$, $\hat{\alpha}_k = \bar{y}_k - \bar{y}$. The first two agree in a balanced layout; in an unbalanced one they define different “overall means”, and a reported $\hat{\alpha}_k$ means different things under each ([Example \(Five side conditions, one fit\)](#)). Contrasts are unaffected by the choice.

Warning. A side condition is a convention for printing, not a statement about the treatments. “The effect of treatment 3 is 0.4” means nothing until the side condition is named. Report group means and contrasts.

15.1.5 Where the model comes from

In a randomized experiment much of the one-way model can be derived rather than assumed. Suppose each plot i has a yield u_i it would give without nitrogen, reflecting its soil and position, and suppose rate k adds a fixed amount τ_k , the same on every plot: this is **unit–treatment additivity**. Random assignment then makes the set of plots receiving rate k a simple random sample of the thirty. The observed yields in group k are τ_k plus a sample of the u_i , so each has expectation $\tau_k + \bar{u}$, with $\bar{u}$ the average of all thirty plot values. The expectations therefore have exactly the cell-means structure, with $\mu_k = \tau_k + \bar{u}$, whatever the pattern of fertility in the field. Had the six plots given the highest rate been chosen for convenience, say all at one end of the field, a fertility gradient would be confounded with the rate, and no analysis could separate the two.

The derived errors are not exactly those of [Definition 15.1.1](#): sampling without replacement makes them slightly negatively correlated ([Exercise \(B3\)](#)), and nothing makes them normal. But under the hypothesis that no treatment has any effect, every rearrangement of the yields among the treatments was equally likely, so the **randomization distribution** of the F statistic of [Section 15.3](#) can be computed exactly by permuting the data, and for moderate designs the normal-theory F distribution approximates it closely. [Chapter 23](#) develops permutation tests ([Theorem 23.4.2](#)). Here the normal model is the working model, and randomization is the reason for trusting it.

15.1.6 Fixed and random effects

The five nitrogen rates were chosen deliberately, and the conclusions are about them: the treatment parameters are fixed constants, the setting of this chapter. In other studies the levels are themselves a sample. A laboratory measuring an enzyme activity in batches of reagent from a production line wants to know how much batches vary, not how batch 3 compares with batch 5. The natural model then takes the effects α_k to be random, uncorrelated with mean zero and variance σ_a^2 , and independent of the errors. The mean vector is $\mu\mathbf{1}$ and the covariance matrix is $\sigma^2\mathbf{I} + \sigma_a^2\mathbf{Z}\mathbf{Z}^\top$, so the model is no longer a linear model with covariance $\sigma^2\mathbf{I}$.

The projections and sums of squares are the same in both models, but their expectations differ ([Section 15.3](#)), and so does the target: contrasts among the treatments studied, or the variance components σ_a^2 and σ^2 ([Exercise \(B1\)](#)). [Chapter 32](#) develops random and mixed effects ([Proposition 32.1.1](#)).

15.1.7 Exercises

15.1.7.1 A. Check your understanding

Exercise A1.

For a one-way layout with group sizes 2, 1, 3, write down $\mathbf{Z}$, $\mathbf{M}$ and $\mathbf{I} - \mathbf{M}$ with the observations listed group by group. What is the residual of the observation in group 2, and why? How many degrees of freedom does the error space have, and which groups contribute to them?

Exercise A2.

Show that $\mu_1 = \cdots = \mu_g$ iff $\sum_k c_k \mu_k = 0$ for every contrast $\mathbf{c}$ ($\sum_k c_k = 0$), and iff $\mu_k - \mu_g = 0$ for $k = 1, \dots, g-1$.

Solution. If all means are equal to μ , then $\sum_k c_k \mu_k = \mu \sum_k c_k = 0$. Conversely, the differences $\mu_k - \mu_g$ are contrasts, and if they vanish the means are equal. So the three conditions are equivalent. The differences $\mu_k - \mu_g$ span the space of contrasts, which has dimension $g-1$.

15.1.7.2 B. Practice

Exercise B1.

Derive the three rows of the table in “What the parameters mean”. Then show that under $\sum_k n_k \alpha_k = 0$ the least squares estimates are $\hat{\mu} = \bar{y}$ and $\hat{\alpha}_k = \bar{y}_k - \bar{y}$, and that $\sum_k n_k \hat{\alpha}_k^2 = \sum_k n_k (\bar{y}_k - \bar{y})^2$.

Solution. A solution of the normal equations ([Theorem 6.4.2](#)) reproduces the fitted values, so $\hat{\mu} + \hat{\alpha}_k = \bar{y}_k$ for every k . With $\sum_k \alpha_k = 0$, summing over k gives $g\hat{\mu} = \sum_k \bar{y}_k$. With $\sum_k n_k \alpha_k = 0$, multiplying by n_k and summing gives $n\hat{\mu} = \sum_k n_k \bar{y}_k = n\bar{y}$. With $\alpha_1 = 0$, the first equation gives $\hat{\mu} = \bar{y}_1$. In each case $\hat{\alpha}_k = \bar{y}_k - \hat{\mu}$. The same algebra with μ_k in place of $\bar{y}_k$ gives the parameter column. The last identity is immediate from $\hat{\alpha}_k = \bar{y}_k - \bar{y}$.

Exercise B2.

For $g = 2$, show that the pooled variance of the one-way model is the pooled variance of the two-sample t test, and that the t statistic for $\mu_1 - \mu_2$ is $(\bar{y}_1 - \bar{y}_2)/(s\sqrt{1/n_1 + 1/n_2})$. ([Section 15.3](#) shows that its square is the one-way F statistic.)

Exercise B3.

In the setting of “Where the model comes from”, suppose N units with values $u_1, \dots, u_N$ are divided at random into groups of fixed sizes $n_1, \dots, n_g$, and unit i in group k yields $u_i + \tau_k$. Show that $E(\bar{Y}_k) = \tau_k + \bar{u}$ and that $\text{Cov}(Y_{kj}, Y_{k'j'}) = -S_u^2/N$ for two different units, where $S_u^2 = \sum_i (u_i - \bar{u})^2/(N-1)$. *Hint:* the sum of the N deviations $u_i - \bar{u}$ is

zero.

Solution. Under random assignment the unit placed in position (k, j) is equally likely to be any of the N , so $E(Y_{kj}) = \tau_k + \bar{u}$, and so is the average $E(\bar{Y}_k)$. For two different positions, the pair of units is equally likely to be any ordered pair of distinct units, so $\text{Cov}(Y_{kj}, Y_{k'j'}) = E\{(u_I - \bar{u})(u_J - \bar{u})\}$ with (I, J) a random ordered pair of distinct indices. Since $\sum_i (u_i - \bar{u}) = 0$,

$$\sum_{i \neq l} (u_i - \bar{u})(u_l - \bar{u}) = \left(\sum_i (u_i - \bar{u}) \right)^2 - \sum_i (u_i - \bar{u})^2 = -(N-1)S_u^2,$$

and dividing by the $N(N-1)$ ordered pairs gives $-S_u^2/N$. The variance of a single observation is $(N-1)S_u^2/N$, so the correlation between two observations is $-1/(N-1)$, small when N is large.

15.1.7.3 C. Going deeper

Exercise C1.

Let $\mathcal{G}$ be the set of $n \times n$ permutation matrices that permute observations only within groups. Show that

$$\mathbf{M} = \frac{1}{|\mathcal{G}|} \sum_{\mathbf{\Pi} \in \mathcal{G}} \mathbf{\Pi},$$

so the one-way projection is the average over the symmetries of the design. Deduce that $\mathcal{C}(\mathbf{Z})$ is exactly the set of vectors fixed by every $\mathbf{\Pi} \in \mathcal{G}$.

Solution. Take observations a and b . If they are in different groups, no $\mathbf{\Pi} \in \mathcal{G}$ sends b to a , so entry (a, b) of the average is $0 = m_{ab}$. If both are in group k , the permutations of group k that send b to a are a fraction $1/n_k$ of all permutations of group k , and the other groups are permuted freely, so entry (a, b) is $1/n_k = m_{ab}$. A vector fixed by every $\mathbf{\Pi}$ is constant within groups, because a transposition of two members of a group exchanges their entries. Conversely, a vector constant within groups is fixed by each $\mathbf{\Pi}$, hence by their average $\mathbf{M}$, so it lies in $\mathcal{C}(\mathbf{M}) = \mathcal{C}(\mathbf{Z})$.

Exercise C2.

In the random-effects model of “Fixed and random effects”, show that $\text{Var}(\bar{Y}) = \sigma^2/n + \sigma_a^2 \sum_k n_k/n^2$. For fixed n and g , which group sizes make the grand mean most precise? Contrast this with the fixed-effects model, where $\text{Var}(\bar{Y}) = \sigma^2/n$ whatever the group sizes.

15.2 Estimable contrasts

Most questions about the treatments of a one-way experiment are contrasts. Does fertilizer help at all? Is the highest rate worth its cost? Which pairs of treatments differ? Earlier chapters supplied the theory: estimability (Chapter 8), the t test and interval (Chapter 11, Chapter 12) and simultaneous methods (Chapter 13). This section collects them for the one-way analysis,

adds a geometric fact about power, and applies them to the nitrogen trial.

15.2.1 Contrasts are the treatment space

Recall that a contrast is a linear function $\psi = \sum_k c_k \mu_k$ with $\sum_k c_k = 0$ and $\mathbf{c} \neq \mathbf{0}$ (Definition 8.7.1). In the effects form it equals $\sum_k c_k \alpha_k$, and the contrasts are exactly the estimable functions of the effects alone (Theorem 8.7.1). Their estimates are $\hat{\psi} = \sum_k c_k \bar{y}_k$, whatever side condition or coding was used to fit the model.

Behind this lies a simple geometry. Let

$$\mathcal{T} = \mathcal{C}(\mathbf{Z}) \cap \mathbf{1}^\perp$$

be the **treatment space**: the vectors that are constant within groups and sum to zero. Its dimension is $g - 1$ (Theorem 6.5.1). A vector $\mathbf{u} \in \mathcal{T}$ takes some value v_k on every observation of group k , with $\sum_k n_k v_k = 0$. Put $c_k = n_k v_k$. Then $\mathbf{c}$ is a contrast and $\mathbf{u}$ is the vector $\mathbf{u}_{\mathbf{c}} = \mathbf{Z}\mathbf{D}^{-1}\mathbf{c}$ of Eq. 8.7.2, with $\mathbf{D} = \text{diag}(n_1, \dots, n_g)$. Conversely every $\mathbf{u}_{\mathbf{c}}$ lies in $\mathcal{T}$ (Proposition 8.7.2). So contrasts and nonzero vectors of the treatment space correspond one to one, and $\hat{\psi} = \mathbf{u}_{\mathbf{c}}^\top \mathbf{y}$. A contrast is a direction in the treatment space, and its estimate is the component of the data along that direction.

Equal treatment means say that the mean vector $\boldsymbol{\theta} = \mathbf{E}(\mathbf{Y})$ has no component in $\mathcal{T}$, that is, that every contrast vanishes (Exercise A2). The overall test of Section 15.3 looks at all of $\mathcal{T}$; a single contrast looks along one line of it.

15.2.2 The test and interval for one contrast

For a contrast $\mathbf{c}$ write

$$v_{\mathbf{c}} = \sum_{k=1}^g \frac{c_k^2}{n_k},$$

so that $\text{Var}(\hat{\psi}) = \sigma^2 v_{\mathbf{c}}$ (Eq. 8.7.1).

Proposition 15.2.1 — Sum of squares and test for a contrast

In the normal one-way model, let $\psi = \sum_k c_k \mu_k$ be a contrast, $\hat{\psi} = \sum_k c_k \bar{Y}_k$, and $\psi_0 \in \mathbb{R}$. Then:

- (a) $\hat{\psi} \sim N(\psi, \sigma^2 v_{\mathbf{c}})$, and $\hat{\psi}$ is independent of s^2 ;
- (b) the statistic

$$T = \frac{\hat{\psi} - \psi_0}{s\sqrt{v_{\mathbf{c}}}} \sim t(n - g, \delta), \quad \delta = \frac{\psi - \psi_0}{\sigma\sqrt{v_{\mathbf{c}}}},$$

so the test of $\psi = \psi_0$ rejects when $|T| > t_{n-g, \alpha/2}$, and $\hat{\psi} \pm t_{n-g, \alpha/2} s\sqrt{v_{\mathbf{c}}}$ is an exact $1 - \alpha$ confidence interval for ψ ;

- (c) the **sum of squares of the contrast**

$$\text{SS}(\mathbf{c}) = \frac{\hat{\psi}^2}{v_{\mathbf{c}}} = \|\mathbf{P}_{\mathbf{c}} \mathbf{Y}\|^2,$$

where $\mathbf{P}_{\mathbf{c}}$ projects onto the line spanned by $\mathbf{u}_{\mathbf{c}}$, has one degree of freedom, and $SS(\mathbf{c})/s^2 = T^2$ for $\psi_0 = 0$ has the $F(1, n - g, \delta^2)$ distribution. Replacing $\mathbf{c}$ by $a\mathbf{c}$ with $a \neq 0$ changes neither $SS(\mathbf{c})$ nor the test;

(d) $SS(\mathbf{c}) \leq \sum_k n_k (\bar{Y}_k - \bar{Y})^2$, with equality when $c_k = n_k(\bar{Y}_k - \bar{Y})$ for every k .

Proof. Use the cell-means form, with model matrix $\mathbf{Z}$ of full rank g , so that $(\mathbf{Z}^\top \mathbf{Z})^{-1} = \mathbf{D}^{-1}$ and $\mathbf{c}^\top \mathbf{D}^{-1} \mathbf{c} = v_{\mathbf{c}}$. The function $\mathbf{c}^\top \boldsymbol{\mu}$ is estimable with estimate $\mathbf{c}^\top \hat{\boldsymbol{\mu}} = \hat{\psi}$. (a) and (b) are [Theorem 11.6.1\(a\)](#) and [Corollary 7.5.2](#) with $\boldsymbol{\lambda} = \mathbf{c}$, $r = g$, and the interval is [Theorem 12.1.1](#). The independence of $\hat{\psi}$ and s^2 is part of [Theorem 7.5.1](#). (c) The identity $\hat{\psi}^2/v_{\mathbf{c}} = \|\mathbf{P}_{\mathbf{c}} \mathbf{Y}\|^2$ is [Proposition 8.7.2\(b\)](#), and T^2 is the F statistic of the hypothesis $\psi = 0$ by [Theorem 11.6.1\(b\)](#), with noncentrality δ^2 . Scaling $\mathbf{c}$ by a multiplies $\hat{\psi}^2$ and $v_{\mathbf{c}}$ by a^2 , and leaves the line spanned by $\mathbf{u}_{\mathbf{c}}$ unchanged. (d) is [Exercise \(B1\)](#). ■

By part (c) a contrast's sum of squares is a projection onto a line of $\mathcal{T}$, and by part (d) no line captures more than the whole space. The line that captures all of it is chosen by the data, which is why its t statistic needs Scheffé's multiplier ([Theorem 13.2.2](#)).

15.2.3 Planned contrasts in the nitrogen trial

Before the trial the agronomist wrote down two questions. First, does nitrogen raise yield at all? The natural contrast compares the average of the four fertilized rates with the control, $\psi_1 = \frac{1}{4}(\mu_2 + \mu_3 + \mu_4 + \mu_5) - \mu_1$. Second, is the highest rate better than the moderate one? That is $\psi_2 = \mu_5 - \mu_3$, the difference between 160 and 80 kg N/ha.

Example. (Two planned contrasts)

The pooled standard deviation is $s = 0.5211$ on 25 degrees of freedom. For ψ_1 , $v_{\mathbf{c}} = \frac{1}{6}(1 + 4 \cdot \frac{1}{16})$, the estimate is 2.110 t/ha with standard error 0.238, so $t = 8.87$ and the 95% interval is [1.620, 2.600]. Fertilizer raises yield by roughly two tonnes per hectare. Its sum of squares is 21.370.

For ψ_2 the estimate is 0.595 t/ha with standard error 0.301, $t = 1.98$, two-sided $p = 0.059$, and the interval [−0.025, 1.215]. The data are consistent with anything from no gain to a gain of more than a tonne: with six plots per rate, half a tonne is only about 1.7 standard errors of a pairwise difference.

```
import numpy as np
from scipy import stats

rates = np.array([0, 40, 80, 120, 160])           # kg N per hectare
g, m = len(rates), 6                             # 5 rates, 6 plots per rate
true_means = 6.8 - 2.7 * np.exp(-0.018 * rates)  # unknown to the analyst
rng = np.random.default_rng(1515)
group = np.repeat(np.arange(g), m)                # plot i received rate group[i]
y = np.round(true_means[group] + rng.normal(0, 0.5, g * m), 2) # yield, t/ha
n = len(y)

n_k = np.bincount(group).astype(float)
```

```

means = np.bincount(group, weights=y) / n_k
nu = n - g
s = np.sqrt(np.sum((y - means[group]) ** 2) / nu)

def contrast(c, psi0=0.0, mult=None):
    """Estimate, standard error, t statistic, SS and interval for sum_k c_k mu_k."""
    est = c @ means
    v = np.sum(c ** 2 / n_k) # Var(estimate) / sigma^2
    se = s * np.sqrt(v)
    mult = stats.t.ppf(0.975, nu) if mult is None else mult
    return est, se, (est - psi0) / se, est ** 2 / v, (est - mult * se, est + mult * se)

c_fert = np.array([-1, 0.25, 0.25, 0.25, 0.25]) # fertilized (average) minus control
c_top = np.array([0, 0, -1, 0, 1]) # 160 against 80 kg N/ha
for name, c in (("fertilized - control", c_fert), ("160 - 80", c_top)):
    est, se, t, ss, (lo, hi) = contrast(c)
    print(f"{name:21s} {est:6.3f} se {se:.3f} t = {t:5.2f} SS = {ss:6.3f}"
          f" 95% interval [{lo:.3f}, {hi:.3f}]")

```

Each was a single planned question, so each gets an unadjusted t interval; joint coverage for the pair would use Bonferroni's $t_{25,0.0125}$. Writing the questions down in advance fixes a small family (Section 13.6).

15.2.4 Families of comparisons

Three families come up in almost every one-way analysis, and Chapter 13 supplies a method for each. The multipliers below multiply the standard error of a difference of two means, $s\sqrt{2/m} = 0.3009$ here.

Comparisons with a control. The four differences $\mu_k - \mu_1$, $k = 2, \dots, 5$, form a planned family of size four. Bonferroni's method (Theorem 13.4.1) uses the multiplier $t_{25,0.05/8} = 2.692$ in place of the unadjusted 2.060:

Rate against control	Difference	Bonferroni 95% interval
40	1.232	[0.422, 2.041]
80	2.052	[1.242, 2.861]
120	2.510	[1.700, 3.320]
160	2.647	[1.837, 3.456]

Every fertilized rate beats the control. The four estimates share $\bar{y}_1$, so they are positively correlated, with correlation $\frac{1}{2}$ in a balanced design (Exercise (B4)). Dunnett (1955) computed the exact joint distribution of the four t statistics under this correlation; his multiplier here is 2.606 (Exercise (B2) characterizes it), a few percent shorter than Bonferroni's. We do not derive its tables.

All pairs. Tukey's method (Theorem 13.3.2) covers all ten differences $\mu_k - \mu_l$ with exact joint coverage in a balanced design. With $q_{0.05}(5, 25) = 4.153$ the half-width is $q s / \sqrt{m} = 0.884$, and six of the ten pairs are declared different. The four that are not are 40 and 80, 80 and 120, 80 and 160, and 120 and 160. The conclusions are not transitive: 40 is not distinguished from

80, nor 80 from 160, yet 40 and 160 are declared different, since $6.652 - 5.237 = 1.415$ exceeds 0.884. “Not declared different” means “not enough evidence of a difference”, which is not an equivalence relation, so displays that sort treatments into groups of “equal” means should be read with care, especially in unbalanced designs.

Contrasts suggested by the data. Looking at Figure 15.1.1, one might ask whether the response has levelled off, by comparing the average of the two highest rates with 80 kg N/ha, $\frac{1}{2}(\mu_4 + \mu_5) - \mu_3$. The estimate is 0.527 with standard error 0.261. The unadjusted interval $[-0.010, 1.063]$ is not legitimate, because the contrast was chosen after seeing the means. Scheffé’s interval (Eq. 13.2.4), with multiplier $\sqrt{4F_{0.05}(4, 25)} = 3.322$, is $[-0.339, 1.392]$. It is valid however the contrast was found, and it says the question is open.

```
import itertools

k_ctrl = g - 1                                # four comparisons with the
control
bonf = stats.t.ppf(1 - 0.05 / (2 * k_ctrl), nu) # Bonferroni multiplier
se_pair = s * np.sqrt(2 / m)
for k in range(1, g):
    d = means[k] - means[0]
    print(f"{rates[k]:3d} - 0: {d:6.3f} Bonferroni interval"
          f" [{d - bonf * se_pair:.3f}, {d + bonf * se_pair:.3f}]")

q = stats.studentized_range.ppf(0.95, g, nu)    # q_{0.05}(g, nu)
hsd = q * s / np.sqrt(m)                       # Tukey half-width, all pairs
pairs = list(itertools.combinations(range(g), 2))
different = [(int(rates[k]), int(rates[l])) for k, l in pairs if abs(means[k] -
    means[l]) > hsd]
print(f"Tukey half-width {hsd:.3f}; pairs declared different: {len(different)} of {
    len(pairs)}")
print("not declared different:",
      [(int(rates[k]), int(rates[l])) for k, l in pairs if abs(means[k] - means[l])
    <= hsd])
```

15.2.5 Why planned contrasts are powerful

A single contrast is tested with one numerator degree of freedom, the overall test with $g - 1$. When the scientific question is sharp, the contrast is the better test, and the reason is geometric. Write $\mathbf{P}_{\mathcal{T}}$ for the projection onto the treatment space and

$$\gamma_{\mathcal{T}} = \frac{\|\mathbf{P}_{\mathcal{T}}\boldsymbol{\theta}\|^2}{\sigma^2} = \frac{1}{\sigma^2} \sum_{k=1}^g n_k (\mu_k - \bar{\mu})^2,$$

the squared length of the treatment component of the mean in units of σ^2 . (Section 15.3 shows that it is the noncentrality of the overall F test.)

Proposition 15.2.2 — The noncentrality of a contrast

Let $\mathbf{c}$ be a contrast with vector $\mathbf{u}_{\mathbf{c}} \in \mathcal{T}$, and suppose $\mathbf{P}_{\mathcal{T}}\boldsymbol{\theta} \neq \mathbf{0}$. The noncentrality of the test of $\psi = 0$ in Proposition 15.2.1 is

$$\delta^2 = \frac{\psi^2}{\sigma^2 v_{\mathbf{c}}} = \gamma_{\mathcal{T}} \cos^2 \varphi,$$

where φ is the angle between $\mathbf{u}_c$ and $\mathbf{P}_T\boldsymbol{\theta}$. In particular $\delta^2 \leq \gamma_T$, with equality iff $\mathbf{u}_c$ is parallel to $\mathbf{P}_T\boldsymbol{\theta}$, that is, iff $c_k \propto n_k(\mu_k - \bar{\mu})$.

Proof. By Proposition 8.7.2(a) applied to the mean vector, $\psi = \mathbf{u}_c^\top \boldsymbol{\theta}$, and $v_c = \|\mathbf{u}_c\|^2$ by the computation in the proof of that result. Since $\mathbf{u}_c \in \mathcal{T}$, $\mathbf{u}_c^\top \boldsymbol{\theta} = \mathbf{u}_c^\top \mathbf{P}_T \boldsymbol{\theta}$. So

$$\delta^2 = \frac{(\mathbf{u}_c^\top \mathbf{P}_T \boldsymbol{\theta})^2}{\sigma^2 \|\mathbf{u}_c\|^2} = \frac{\|\mathbf{P}_T \boldsymbol{\theta}\|^2}{\sigma^2} \cdot \frac{(\mathbf{u}_c^\top \mathbf{P}_T \boldsymbol{\theta})^2}{\|\mathbf{u}_c\|^2 \|\mathbf{P}_T \boldsymbol{\theta}\|^2} = \gamma_T \cos^2 \varphi$$

by Eq. 6.2.2. Equality in $\cos^2 \varphi \leq 1$ holds iff the two vectors are parallel. The vector $\mathbf{P}_T \boldsymbol{\theta}$ has entry $\mu_k - \bar{\mu}$ in group k (Theorem 6.5.1), so it is $\mathbf{u}_c$ for $c_k = n_k(\mu_k - \bar{\mu})$. ■

If the departure from equal means lies along the planned contrast, the contrast test gets all of the noncentrality on one degree of freedom, while the overall test spreads the same noncentrality over $g - 1$. For the nitrogen design, with 25 error degrees of freedom, the powers at level 0.05 are:

γ_T , all along the contrast	4	8	12
contrast test, $F(1, 25)$	0.485	0.776	0.914
overall test, $F(4, 25)$	0.269	0.516	0.714

The price is paid when the question is wrong: a contrast orthogonal to $\mathbf{P}_T \boldsymbol{\theta}$ has power α however large the treatment differences, and a direction chosen at random captures on average only $1/(g - 1)$ of γ_T (Exercise (C1)).

```
def power_f(gamma, q, nu, alpha=0.05):
    return stats.ncf.sf(stats.f.ppf(1 - alpha, q, nu), q, nu, gamma)

for gamma in (4.0, 8.0, 12.0):
    # all of it along the planned contrast
    print(f"gamma = {gamma:4.1f}: contrast test {power_f(gamma, 1, nu):.3f},"
          f" omnibus F test {power_f(gamma, g - 1, nu):.3f}")
```

15.2.6 Exercises

15.2.6.1 A. Check your understanding

Exercise A1.

In the nitrogen trial, compute by hand the estimate and standard error of $\frac{1}{2}(\mu_4 + \mu_5) - \frac{1}{2}(\mu_1 + \mu_2)$, the average of the two highest rates minus the average of the two lowest, from the rate means of Section 15.1 and $s = 0.5211$.

Solution. The estimate is $\frac{1}{2}(6.515 + 6.652) - \frac{1}{2}(4.005 + 5.237) = 6.5835 - 4.621 = 1.9625$. With $m = 6$, $v_{\mathbf{c}} = 4 \cdot \frac{1}{4}/6 = 1/6$, so the standard error is $0.5211/\sqrt{6} \approx 0.213$.

Exercise A2.

Show directly that the t statistic of Proposition 15.2.1(b) with $\psi_0 = 0$ is unchanged when $\mathbf{c}$ is multiplied by $a > 0$ and changes sign when $a < 0$. What happens to the confidence interval?

15.2.6.2 B. Practice

Exercise B1.

In a balanced layout with m observations per group, show that the noncentrality of the test of a contrast is $\delta^2 = m\psi^2/(\sigma^2 \sum_k c_k^2)$. How many observations per group are needed for the test of $\mu_5 - \mu_3$ in the nitrogen trial to have power 0.8 at level 0.05 when the true difference is 0.5 t/ha and $\sigma = 0.5$? (Use software for the noncentral F , or the normal approximation.)

Solution. Here $v_{\mathbf{c}} = \sum_k c_k^2/m$, so $\delta^2 = \psi^2/(\sigma^2 v_{\mathbf{c}}) = m\psi^2/(\sigma^2 \sum_k c_k^2)$. For $\mu_5 - \mu_3$, $\sum_k c_k^2 = 2$, $\psi/\sigma = 1$, and $\delta^2 = m/2$. The normal approximation asks for $\delta \approx z_{0.025} + z_{0.2} = 1.96 + 0.84 = 2.80$, so $m \approx 2 \cdot 2.80^2 \approx 15.7$. The exact noncentral F with $5(m-1)$ error degrees of freedom gives $m = 17$, since the t quantile exceeds the normal one. The trial's $m = 6$ is far short.

Exercise B2.

A single contrast $\mathbf{c}$ matters above all. For a fixed total n , show that $v_{\mathbf{c}} = \sum_k c_k^2/n_k$ is minimized, over positive real n_k with $\sum_k n_k = n$, by $n_k \propto |c_k|$, with minimum $(\sum_k |c_k|)^2/n$. What does this say about how to allocate plots between two treatments, and between a control and the average of four treatments?

Solution. By the Cauchy–Schwarz inequality, $(\sum_k |c_k|)^2 = (\sum_k (|c_k|/\sqrt{n_k})\sqrt{n_k})^2 \leq \sum_k (c_k^2/n_k) \sum_k n_k = nv_{\mathbf{c}}$, with equality iff $|c_k|/\sqrt{n_k} \propto \sqrt{n_k}$, that is, $n_k \propto |c_k|$. Groups with $c_k = 0$ get no observations. For $\mu_1 - \mu_2$, equal allocation is best. For $\mu_1 - \frac{1}{4}(\mu_2 + \dots + \mu_5)$, the control should get as many plots as the four treatments together, $n_1 = n/2$ and $n_k = n/8$ for the others.

Exercise B3.

In a comparison of $g - 1$ treatments with a control, suppose the control gets n_0 observations and each treatment gets n_t , with $n_0 + (g - 1)n_t = n$ fixed. Show that $\sum_k \text{Var}(\bar{Y}_k - \bar{Y}_0)$ is minimized when $n_0 = \sqrt{g-1}n_t$. For $g = 5$ and $n = 30$, what allocation does this suggest?

Solution. The sum is $\sigma^2(g-1)(1/n_0 + 1/n_t)$. Minimizing $1/n_0 + 1/n_t$ subject to $n_0 + (g-1)n_t = n$ with a Lagrange multiplier gives $1/n_0^2 = \lambda$ and $1/n_t^2 = (g-1)\lambda$, so $n_0/n_t = \sqrt{g-1}$. For $g = 5$ the control should get twice as many observations as each

treatment: $n_0 = 10$ and $n_t = 5$. Contrast [Exercise \(B2\)](#): for the average of the four comparisons the optimal control share is $n/2$, that is $n_0 = 4n_t$. The best allocation depends on whether the four comparisons or their average is the target.

Exercise B4.

With n_0 observations on the control and n_t on each treatment, show that the estimates $\bar{Y}_k - \bar{Y}_0$ and $\bar{Y}_l - \bar{Y}_0$ of two treatment-versus-control differences have correlation $n_t/(n_t + n_0)$. In a balanced design it is $\frac{1}{2}$.

Solution. The covariance is $\text{Var}(\bar{Y}_0) = \sigma^2/n_0$, since the treatment means are independent of each other and of $\bar{Y}_0$. Each variance is $\sigma^2(1/n_t + 1/n_0)$. The ratio is $(1/n_0)/(1/n_t + 1/n_0) = n_t/(n_t + n_0)$.

15.2.6.3 C. Going deeper

Exercise C1.

Let $q = g - 1 \geq 2$ and let $\mathbf{u}$ be uniformly distributed on the unit sphere of the q -dimensional space $\mathcal{T}$ (for example $\mathbf{u} = \mathbf{w}/\|\mathbf{w}\|$ with $\mathbf{w} \sim N$ on $\mathcal{T}$ with covariance $\mathbf{P}_{\mathcal{T}}$). Show that $E \cos^2 \varphi = 1/q$, where φ is the angle between $\mathbf{u}$ and a fixed nonzero $\mathbf{v} \in \mathcal{T}$. Interpret this with [Proposition 15.2.2](#).

Solution. Choose an orthonormal basis of $\mathcal{T}$ whose first vector is $\mathbf{v}/\|\mathbf{v}\|$. In these coordinates $\cos^2 \varphi = u_1^2$. By symmetry the u_i^2 have a common mean, and they sum to 1, so $E u_1^2 = 1/q$. By [Proposition 15.2.2](#), a contrast whose direction is unrelated to the truth captures on average a fraction $1/q$ of $\gamma_{\mathcal{T}}$ on its one degree of freedom, the same average share per degree of freedom as the overall test. Knowledge, not the count of degrees of freedom, is what makes a planned contrast more powerful.

Exercise C2.

The Scheffé multiplier for a family of contrasts depends on the dimension of the space the family spans ([Theorem 13.2.2](#)). Show that the $g - 1$ comparisons with a control span $\mathcal{T}$, and that the family of the four “successive differences” $\mu_{k+1} - \mu_k$ does too. Why, then, are Bonferroni or Dunnett intervals shorter than Scheffé’s for these families?

15.3 The analysis of variance table from projections

Whether the treatments differ at all is answered by the F test, with the analysis of variance table as its bookkeeping. Both come from one orthogonal decomposition of the observation space into the constants, the treatment space and the error space, and every entry of the table is a property of one piece.

15.3.1 Three subspaces

Write $\mathbf{P}_0 = n^{-1}\mathbf{1}\mathbf{1}^\top$ for the projection onto the constants and $\mathbf{M}$ for the projection onto $\mathcal{C}(\mathbf{Z})$ (Eq. 15.1.1). Since $\mathbf{1} \in \mathcal{C}(\mathbf{Z})$, Theorem 6.5.1 applies to the pair $\text{span}(\mathbf{1}) \subseteq \mathcal{C}(\mathbf{Z})$ and gives the orthogonal decomposition

$$\mathbb{R}^n = \underbrace{\text{span}(\mathbf{1})}_{\dim 1} \oplus \underbrace{\mathcal{T}}_{\dim g-1} \oplus \underbrace{\mathcal{C}(\mathbf{Z})^\perp}_{\dim n-g}, \quad \mathbf{I} = \mathbf{P}_0 + (\mathbf{M} - \mathbf{P}_0) + (\mathbf{I} - \mathbf{M}), \quad (15.3.1)$$

with the treatment space $\mathcal{T} = \mathcal{C}(\mathbf{Z}) \cap \mathbf{1}^\perp$ of Section 15.2 and $\mathbf{P}_{\mathcal{T}} = \mathbf{M} - \mathbf{P}_0$. The three projections act on the data in the familiar way:

$$(\mathbf{P}_0 \mathbf{y})_{kj} = \bar{y}, \quad (\mathbf{P}_{\mathcal{T}} \mathbf{y})_{kj} = \bar{y}_k - \bar{y}, \quad ((\mathbf{I} - \mathbf{M}) \mathbf{y})_{kj} = y_{kj} - \bar{y}_k.$$

So every observation is split as $y_{kj} = \bar{y} + (\bar{y}_k - \bar{y}) + (y_{kj} - \bar{y}_k)$, grand mean plus treatment deviation plus residual, and the three vectors so formed are mutually orthogonal. Pythagoras gives

$$\sum_{k,j} y_{kj}^2 = n\bar{y}^2 + \sum_k n_k(\bar{y}_k - \bar{y})^2 + \sum_{k,j} (y_{kj} - \bar{y}_k)^2. \quad (15.3.2)$$

The middle term is the **between-groups sum of squares** $\text{SSB} = \|\mathbf{P}_{\mathcal{T}} \mathbf{y}\|^2$, and the last is the **within-groups** or residual sum of squares $\text{SSE} = \|(\mathbf{I} - \mathbf{M}) \mathbf{y}\|^2$ of Eq. 15.1.2. Their sum $\sum_{k,j} (y_{kj} - \bar{y})^2$ is the corrected total sum of squares. The same decomposition, with the distributions attached, was the first application of Cochran's theorem (Example (The one-way layout)).

15.3.2 The F test

Theorem 15.3.1 — The one-way F test

In the normal one-way model of Definition 15.1.1, with mean vector $\boldsymbol{\theta} = \mathbf{Z}\boldsymbol{\mu}$, put

$$\text{MSB} = \frac{\text{SSB}}{g-1}, \quad s^2 = \text{MSE} = \frac{\text{SSE}}{n-g}, \quad F = \frac{\text{MSB}}{\text{MSE}}.$$

- (a) $\bar{Y}$, $\text{SSB} = \sum_k n_k(\bar{Y}_k - \bar{Y})^2$ and $\text{SSE} = \sum_{k,j} (Y_{kj} - \bar{Y}_k)^2$ are mutually independent.
- (b) $\text{SSE}/\sigma^2 \sim \chi^2(n-g)$, and $\text{SSB}/\sigma^2 \sim \chi^2(g-1, \gamma)$ with

$$\gamma = \frac{\|\mathbf{P}_{\mathcal{T}} \boldsymbol{\theta}\|^2}{\sigma^2} = \frac{1}{\sigma^2} \sum_{k=1}^g n_k(\mu_k - \bar{\mu})^2, \quad \bar{\mu} = \frac{1}{n} \sum_{k=1}^g n_k \mu_k. \quad (15.3.3)$$

- (c) $F \sim F(g-1, n-g, \gamma)$, and $\gamma = 0$ iff $\mu_1 = \dots = \mu_g$. In particular, when the means are equal, $F \sim F(g-1, n-g)$ whatever their common value and σ^2 .
- (d) F is the statistic of the F test of the reduced model $\mathbf{E}(\mathbf{Y}) \in \text{span}(\mathbf{1})$ against $\mathcal{C}(\mathbf{Z})$, and of the testable hypothesis $\alpha_1 = \dots = \alpha_g$ in the effects form. The test that rejects when $F > F_\alpha(g-1, n-g)$ is the likelihood ratio test of equal means. Its

power is a continuous, strictly increasing function of γ , equal to α at $\gamma = 0$.

Proof. By Eq. 15.3.1 the matrices $\mathbf{P}_0$, $\mathbf{P}_{\mathcal{T}}$ and $\mathbf{I} - \mathbf{M}$ are symmetric, idempotent and mutually orthogonal, with ranks 1, $g - 1$ and $n - g$. Theorem 4.4.4 gives (a), since $\bar{Y}$ is a function of $\mathbf{P}_0 \mathbf{Y}$, and it gives the chi-squared laws of (b) with noncentralities $\|\mathbf{P}_{\mathcal{T}} \boldsymbol{\theta}\|^2 / \sigma^2$ and $\|(\mathbf{I} - \mathbf{M}) \boldsymbol{\theta}\|^2 / \sigma^2$. The second is zero because $\boldsymbol{\theta} \in \mathcal{C}(\mathbf{Z})$. The vector $\boldsymbol{\theta}$ has entry μ_k in group k , so $\mathbf{M} \boldsymbol{\theta} = \boldsymbol{\theta}$ and $\mathbf{P}_0 \boldsymbol{\theta} = \bar{\mu} \mathbf{1}$, and $\mathbf{P}_{\mathcal{T}} \boldsymbol{\theta}$ has entry $\mu_k - \bar{\mu}$ in group k . Its squared length is $\sum_k n_k (\mu_k - \bar{\mu})^2$, which proves Eq. 15.3.3.

For (c): by (a) and (b), F is a ratio of independent chi-squared variables divided by their degrees of freedom, the numerator noncentral, which is the noncentral F law (Definition 4.1.2). Since every $n_k \geq 1$, $\gamma = 0$ iff $\mu_k = \bar{\mu}$ for every k .

For (d), take $\mathbf{X}_0 = \mathbf{1}$ inside $\mathbf{X} = \mathbf{Z}$. Then $\text{SSE}_0 - \text{SSE} = \|(\mathbf{M} - \mathbf{P}_0) \mathbf{Y}\|^2 = \text{SSB}$ by Eq. 6.5.2, with $r - r_0 = g - 1$, so F is the statistic of Theorem 11.1.1. In the effects form the hypothesis is $\alpha_k - \alpha_g = 0$, $k < g$: $g - 1$ estimable, linearly independent contrasts, so it is testable (Definition 11.3.1). The mean vectors it allows are the constant vectors, so by Theorem 11.3.2(c) its F statistic is the same one. The likelihood ratio property is Theorem 11.4.1, and the power statement is Theorem 11.5.1(a). ■

The noncentrality Eq. 15.3.3 is a weighted sum of squared deviations of the group means from their *weighted* mean. The weights are the group sizes, because a group of n_k observations carries n_k copies of its mean in $\boldsymbol{\theta}$. In a balanced layout $\gamma = m \sum_k (\mu_k - \bar{\mu})^2 / \sigma^2$, the case studied for planning in Proposition 11.5.2 and Example (How many observations per group?). The dependence on the group sizes in unbalanced layouts is taken up in Section 15.5.

15.3.3 Expected mean squares

The distributions in Theorem 15.3.1 need normality. The expectations of the mean squares do not, and they explain why the ratio of two mean squares is the right statistic.

Theorem 15.3.2 — Expected mean squares in the one-way layout

In the one-way model of Definition 15.1.1 (uncorrelated errors with common variance σ^2 , not necessarily normal):

- (a) $E(\text{MSE}) = \sigma^2$;
- (b) $E(\text{MSB}) = \sigma^2 + \frac{1}{g-1} \sum_{k=1}^g n_k (\mu_k - \bar{\mu})^2$;
- (c) in the effects form, $\sum_k n_k (\mu_k - \bar{\mu})^2 = \sum_k n_k (\alpha_k - \bar{\alpha})^2$ with $\bar{\alpha} = n^{-1} \sum_k n_k \alpha_k$, which is $\sum_k n_k \alpha_k^2$ under the side condition $\sum_k n_k \alpha_k = 0$. In a balanced layout it is $m \sum_k (\mu_k - \bar{\mu})^2$ with $\bar{\mu} = g^{-1} \sum_k \mu_k$, which is $m \sum_k \alpha_k^2$ under $\sum_k \alpha_k = 0$;
- (d) $E(\text{MSB}) \geq E(\text{MSE})$, with equality iff $\mu_1 = \dots = \mu_g$.

Proof. The spaces of Eq. 15.3.1 form an analysis of variance decomposition of $\mathcal{C}(\mathbf{Z})$ in the sense of Theorem 9.6.1, which gives $E(\text{SSE}) = \sigma^2(n - g) + \|(\mathbf{I} - \mathbf{M}) \boldsymbol{\theta}\|^2 = \sigma^2(n - g)$

and $E(\text{SSB}) = \sigma^2(g-1) + \|\mathbf{P}_{\mathcal{T}}\boldsymbol{\theta}\|^2$. The squared length was computed in the proof of [Theorem 15.3.1](#). Dividing by the degrees of freedom gives (a) and (b). For (c), $\mu_k = \mu + \alpha_k$ and $\bar{\mu} = \mu + \bar{\alpha}$, so $\mu_k - \bar{\mu} = \alpha_k - \bar{\alpha}$. In a balanced layout $\bar{\mu} = \tilde{\mu}$ and $\bar{\alpha} = g^{-1} \sum_k \alpha_k$. (d) follows from (a) and (b). Part (b) is also [Exercise \(A2\)](#), which computes it directly from the group means. ■

Both mean squares estimate σ^2 when the treatments do not differ; otherwise MSB estimates σ^2 plus the treatment variation per degree of freedom. Every F ratio in an analysis of variance follows this logic: the denominator's expectation equals the numerator's exactly when the hypothesis holds ([Section 9.6](#)).

The same projections serve the random-effects model of [Section 15.1](#), but the expectations change. With $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I} + \sigma_a^2 \mathbf{Z}\mathbf{Z}^\top$ and a constant mean, $E(\text{MSE}) = \sigma^2$ still, while $E(\text{MSB}) = \sigma^2 + n_0 \sigma_a^2$ with $n_0 = (n - \sum_k n_k^2/n)/(g-1)$, which is m in a balanced layout ([Exercise \(C1\)](#)). The ratio F then tests $\sigma_a^2 = 0$, and the difference of the two mean squares divided by n_0 estimates σ_a^2 . [Chapter 32](#) develops this ([Proposition 32.1.1](#)).

15.3.4 The table, derived

Collecting the pieces gives the one-way analysis of variance table. Each row is a subspace, its degrees of freedom are the dimension, its sum of squares is the squared length of the projection of $\mathbf{y}$, and its expected mean square is σ^2 plus the squared length of the projection of $\boldsymbol{\theta}$ per dimension.

Source	Subspace	df	Sum of squares	Mean square	F	Expected mean square
treatments	$\mathcal{T}$	$g-1$	$\sum_k n_k (\bar{y}_k - \bar{y})^2$	MSB	MSB/MSE	$\sigma^2 + \frac{\sum_k n_k (\mu_k - \bar{\mu})^2}{g-1}$
error	$\mathcal{C}(\mathbf{Z})^\perp$	$n-g$	$\sum_{k,j} (y_{kj} - \bar{y}_k)^2$	MSE		σ^2
corrected total	$\mathbf{1}^\perp$	$n-1$	$\sum_{k,j} (y_{kj} - \bar{y})^2$			

Some tables add a row for the mean, with 1 degree of freedom and sum of squares $n\bar{y}^2 = \|\mathbf{P}_0 \mathbf{y}\|^2$, and an uncorrected total $\sum y_{kj}^2$; its F ratio would test $\bar{\mu} = 0$, rarely of interest.

Hand computation used the group totals T_k and grand total T : $\|\mathbf{M}\mathbf{y}\|^2 = \sum_k T_k^2/n_k$ and $\|\mathbf{P}_0 \mathbf{y}\|^2 = T^2/n$, the “correction factor”, so $\text{SSB} = \sum_k T_k^2/n_k - T^2/n$. Such differences of nearly equal numbers lose accuracy in floating point ([Chapter 10](#)); computing deviations first, as the projections do, avoids this.

Example. (The analysis of variance for the nitrogen trial)

For the thirty yields of [Section 15.1](#), with grand mean $\bar{y} = 5.6930$ t/ha:

Source	df	Sum of squares	Mean square	F
nitrogen	4	28.7074	7.1768	26.43
rates				
plots within	25	6.7887	0.2715	
rates				
corrected	29	35.4960		
total				

The mean row would add $n\bar{y}^2 = 972.307$ on one degree of freedom. The critical value is $F_{0.05}(4, 25) = 2.759$, and the p -value is 1.2×10^{-8} . The table says only that the treatment component of the mean is not zero; the contrasts of [Section 15.2](#) and [Section 15.4](#) say what it is. Since the data were simulated, the true noncentrality is known: $\gamma = 103.4$, far more than needed for power near one.

```
import numpy as np
from scipy import stats

rates = np.array([0, 40, 80, 120, 160])          # kg N per hectare
g, m = len(rates), 6                             # 5 rates, 6 plots per rate
true_means = 6.8 - 2.7 * np.exp(-0.018 * rates)  # unknown to the analyst
rng = np.random.default_rng(1515)
group = np.repeat(np.arange(g), m)               # plot i received rate group[i]
y = np.round(true_means[group] + rng.normal(0, 0.5, g * m), 2) # yield, t/ha
n = len(y)
Z = (group[:, None] == np.arange(g)).astype(float) # cell-means model matrix
n_k = Z.sum(axis=0)

M = Z @ np.diag(1 / n_k) @ Z.T
P0 = np.full((n, n), 1 / n)                     # projection onto span(1)
ss_mean = y @ P0 @ y                            # n * ybar^2
ss_between = y @ (M - P0) @ y                   # sum_k n_k (ybar_k - ybar)^2
ss_within = y @ (np.eye(n) - M) @ y             # sum_kj (y_kj - ybar_k)^2
df_between, df_within = g - 1, n - g
F = (ss_between / df_between) / (ss_within / df_within)
p_value = stats.f.sf(F, df_between, df_within)
print(f"{'source':10s} {'df':>3s} {'SS':>9s} {'MS':>8s}")
print(f"{'rates':10s} {'df_between':3d} {'ss_between':9.4f} {'ss_between / df_between':8.4f}")
print(f"{'plots':10s} {'df_within':3d} {'ss_within':9.4f} {'ss_within / df_within':8.4f}")
print(f"{'corrected':10s} {'n - 1':3d} {'ss_between + ss_within':9.4f}")
print(f"F = {F:.2f} on ({df_between}, {df_within}) df, p = {p_value:.2g}")
```

15.3.5 Three ways to read F

As a proportion of variation. Let $\eta^2 = \text{SSB}/(\text{SSB} + \text{SSE})$, the fraction of the corrected total sum of squares that lies in the treatment space. It is the R^2 of the regression of $\mathbf{y}$ on the group indicators, and the sample version of the correlation ratio of [Eq. 14.2.1](#). By [Theorem 9.5.2](#),

$$F = \frac{\eta^2/(g-1)}{(1-\eta^2)/(n-g)},$$

and in the normal model, under equal means, η^2 has the Beta law of that theorem, with $E(\eta^2) = (g-1)/(n-1)$, not small with many groups and few observations. In the nitrogen trial $\eta^2 = 0.809$: four fifths of the variation among plots is variation among rates.

As the largest contrast. By Proposition 15.2.1(d), every contrast has $SS(c) \leq SSB$, with equality for $c_k \propto n_k(\bar{y}_k - \bar{y})$. Dividing by s^2 , the largest squared t statistic over all contrasts is $(g-1)F$. Hence the F test rejects iff some contrast, perhaps not an interesting one, is declared nonzero by Scheffé's method (Corollary 13.2.3).

As a two-sample test, for $g = 2$. Then $\mathcal{T}$ is a line, the only contrast is $\mu_1 - \mu_2$ up to scale, and $F = T^2$ for the pooled two-sample t statistic of Exercise (B2), whose sensitivity to unequal variances the one-way test inherits (Section 15.5).

15.3.6 Exercises

15.3.6.1 A. Check your understanding

Exercise A1.

A one-way experiment with four treatments and six observations per treatment gives a treatment mean square of 12.0 and a corrected total sum of squares of 96.0. Complete the analysis of variance table, compute F and η^2 , and state the reference distribution of F under equal means.

Solution. The degrees of freedom are 3, 20 and 23. The treatment sum of squares is $3 \times 12 = 36$, so the error sum of squares is $96 - 36 = 60$ and $MSE = 3$. Then $F = 12/3 = 4$, $\eta^2 = 36/96 = 0.375$, and under equal means $F \sim F(3, 20)$.

Exercise A2.

Show from Eq. 15.3.2 that $SSB = \sum_k T_k^2/n_k - T^2/n$ and $SSE = \sum_{k,j} y_{kj}^2 - \sum_k T_k^2/n_k$.

15.3.6.2 B. Practice

Exercise B1.

For $g = 2$ with $n_1 + n_2 = n$ fixed, show that $\gamma = (\mu_1 - \mu_2)^2 n_1 n_2 / (n\sigma^2)$, and that it is largest for $n_1 = n_2$. By how much does the noncentrality fall for the split $n_1 = n/4$, $n_2 = 3n/4$?

Solution. With $\bar{\mu} = (n_1\mu_1 + n_2\mu_2)/n$, $\mu_1 - \bar{\mu} = n_2(\mu_1 - \mu_2)/n$ and $\mu_2 - \bar{\mu} = -n_1(\mu_1 - \mu_2)/n$. So $\sigma^2\gamma = (\mu_1 - \mu_2)^2 (n_1 n_2^2 + n_2 n_1^2) / n^2 = (\mu_1 - \mu_2)^2 n_1 n_2 / n$. The product $n_1 n_2$ with fixed sum is largest at $n_1 = n_2 = n/2$, where it is $n^2/4$. For the split $(n/4, 3n/4)$ it is $3n^2/16$, so the noncentrality falls by a quarter.

Exercise B2.

In the normal model with equal means $E(\eta^2) = (g-1)/(n-1)$, which is not zero, so η^2

overstates the treatment variation in small experiments. Show that the numerator of

$$\hat{\omega}^2 = \frac{\text{SSB} - (g-1)\text{MSE}}{\text{SSB} + \text{SSE}}$$

has expectation $\sum_k n_k(\mu_k - \bar{\mu})^2$, whatever the means, so that it removes the bias from the numerator. When is $\hat{\omega}^2$ negative?

Solution. By [Theorem 15.3.2](#), $E(\text{SSB}) = (g-1)\sigma^2 + \sum_k n_k(\mu_k - \bar{\mu})^2$ and $E\{(g-1)\text{MSE}\} = (g-1)\sigma^2$, so the difference has the stated expectation. The numerator is negative iff $\text{MSB} < \text{MSE}$, that is, iff $F < 1$, which often has null probability above one half: 0.57 for the nitrogen design's $F(4, 25)$ in the normal model. The ratio itself is not unbiased, since its denominator is random.

Exercise B3.

In the nitrogen trial, compute the Scheffé-maximal contrast $c_k = n_k(\bar{y}_k - \bar{y})$ from the rate means, and verify that its squared t statistic is $4F$. Describe in words what it compares.

15.3.6.3 C. Going deeper

Exercise C1.

In the random-effects model $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I} + \sigma_a^2\mathbf{Z}\mathbf{Z}^\top$, $E(\mathbf{Y}) = \mu\mathbf{1}$, use [Theorem 2.3.1](#) to show that $E(\text{SSB}) = (g-1)\sigma^2 + (n - \sum_k n_k^2/n)\sigma_a^2$ and $E(\text{SSE}) = (n-g)\sigma^2$. Show that $n_0 = (n - \sum_k n_k^2/n)/(g-1) \leq n/g$, with equality iff the layout is balanced.

Solution. By [Theorem 2.3.1](#), $E(\mathbf{Y}^\top\mathbf{A}\mathbf{Y}) = \text{tr}(\mathbf{A}\Sigma) + \boldsymbol{\theta}^\top\mathbf{A}\boldsymbol{\theta}$, and $\boldsymbol{\theta} = \mu\mathbf{1}$ is annihilated by both $\mathbf{P}_\mathcal{T}$ and $\mathbf{I} - \mathbf{M}$. Now $\text{tr}(\mathbf{P}_\mathcal{T}) = g-1$ and $\text{tr}(\mathbf{P}_\mathcal{T}\mathbf{Z}\mathbf{Z}^\top) = \text{tr}(\mathbf{Z}^\top\mathbf{M}\mathbf{Z}) - \text{tr}(\mathbf{Z}^\top\mathbf{P}_0\mathbf{Z})$. Since $\mathbf{M}\mathbf{Z} = \mathbf{Z}$, the first term is $\text{tr}(\mathbf{Z}^\top\mathbf{Z}) = n$. The second is $n^{-1}\|\mathbf{Z}^\top\mathbf{1}\|^2 = \sum_k n_k^2/n$. For the error, $(\mathbf{I} - \mathbf{M})\mathbf{Z} = \mathbf{0}$, so only $\sigma^2\text{tr}(\mathbf{I} - \mathbf{M}) = (n-g)\sigma^2$ remains. Finally $\sum_k n_k^2 \geq n^2/g$ by the Cauchy-Schwarz inequality, with equality iff all $n_k = n/g$, so $(g-1)n_0 \leq n - n/g = (g-1)n/g$.

Exercise C2.

Show that F is unchanged when $\mathbf{y}$ is replaced by $a\mathbf{y} + b\mathbf{1}$ with $a \neq 0$, and when the observations are permuted within groups. Show that it changes when a constant is added to the observations of one group only, and explain why it should.

15.4 Orthogonal contrasts

Once the F test of [Section 15.3](#) says that the treatment component of the mean is not zero, the next step is to split that component into interpretable pieces. A complete set of orthogonal contrasts chooses an orthogonal basis of the treatment space, one direction per question, and splits the between-groups sum of squares along it. [Chapter 8](#) proved the arithmetic ([Propo-](#)

sition 8.7.2) and Chapter 9 placed it in the theory of single-degree-of-freedom decompositions (Theorem 9.4.4). This section adds the distribution theory, builds orthogonal sets, and analyses the shape of the nitrogen response.

15.4.1 The decomposition

Contrasts $\mathbf{c}$ and $\mathbf{d}$ are orthogonal for the design if $\sum_k c_k d_k / n_k = 0$ (Definition 8.7.1), which says exactly that $\mathbf{u}_c \perp \mathbf{u}_d$ (Proposition 8.7.2(c)). Since $\dim \mathcal{T} = g - 1$, a set of $g - 1$ pairwise orthogonal contrasts is as large as possible; we call it **complete**.

Theorem 15.4.1 — Orthogonal contrasts decompose the treatment sum of squares

In the one-way model, let $\mathbf{c}_1, \dots, \mathbf{c}_{g-1}$ be contrasts that are pairwise orthogonal for the design,

$$\sum_{k=1}^g \frac{c_{ik} c_{lk}}{n_k} = 0 \quad (i \neq l), \quad (15.4.1)$$

and write $\psi_i = \sum_k c_{ik} \mu_k$ and $F_i = \text{SS}(\mathbf{c}_i) / s^2$.

- (a) The vectors $\mathbf{u}_{\mathbf{c}_1}, \dots, \mathbf{u}_{\mathbf{c}_{g-1}}$ form an orthogonal basis of the treatment space $\mathcal{T}$, and

$$\text{SSB} = \sum_{i=1}^{g-1} \text{SS}(\mathbf{c}_i).$$

- (b) In the normal one-way model, $\text{SS}(\mathbf{c}_1), \dots, \text{SS}(\mathbf{c}_{g-1})$ and SSE are mutually independent, and $\text{SS}(\mathbf{c}_i) / \sigma^2 \sim \chi^2(1, \gamma_i)$ with $\gamma_i = \psi_i^2 / (\sigma^2 v_{\mathbf{c}_i})$. The noncentralities add up to that of the F test: $\sum_i \gamma_i = \gamma$ of Eq. 15.3.3.
- (c) The F statistic is the average of the single-degree-of-freedom statistics: $F = (g - 1)^{-1} \sum_i F_i$.
- (d) In a balanced layout, Eq. 15.4.1 reduces to $\sum_k c_{ik} c_{lk} = 0$.
- (e) Conversely, every orthogonal basis $\mathbf{u}_1, \dots, \mathbf{u}_{g-1}$ of $\mathcal{T}$ arises in this way: if $\mathbf{u}_i$ takes the value v_{ik} on group k , then $c_{ik} = n_k v_{ik}$ defines a complete set of orthogonal contrasts with $\mathbf{u}_{\mathbf{c}_i} = \mathbf{u}_i$.

Proof. Part (a) is Proposition 8.7.2(d), whose proof shows that the $\mathbf{u}_{\mathbf{c}_i}$ are nonzero, pairwise orthogonal vectors of $\mathcal{T}$, hence a basis, and that the projections $\mathbf{P}_i$ onto the lines they span sum to $\mathbf{P}_{\mathcal{T}}$. (b) The $\mathbf{P}_i$ are mutually orthogonal projections of rank one, and each is orthogonal to $\mathbf{I} - \mathbf{M}$ because its range lies in $\mathcal{C}(\mathbf{Z})$. By Theorem 4.4.4 the sums of squares $\|\mathbf{P}_i \mathbf{Y}\|^2 = \text{SS}(\mathbf{c}_i)$ (Proposition 15.2.1(c)) and SSE are independent, with noncentralities $\|\mathbf{P}_i \boldsymbol{\theta}\|^2 / \sigma^2$. By the computation in the proof of Proposition 15.2.2, $\|\mathbf{P}_i \boldsymbol{\theta}\|^2 = (\mathbf{u}_{\mathbf{c}_i}^\top \boldsymbol{\theta})^2 / \|\mathbf{u}_{\mathbf{c}_i}\|^2 = \psi_i^2 / v_{\mathbf{c}_i}$. Since $\sum_i \mathbf{P}_i = \mathbf{P}_{\mathcal{T}}$ and the $\mathbf{P}_i \boldsymbol{\theta}$ are orthogonal, $\sum_i \|\mathbf{P}_i \boldsymbol{\theta}\|^2 = \|\mathbf{P}_{\mathcal{T}} \boldsymbol{\theta}\|^2$, which is $\sigma^2 \gamma$ by Theorem 15.3.1. (c) Divide (a) by $(g - 1)s^2$. (d) Put $n_k = m$. (e) In Section 15.2 we saw that each $\mathbf{u} \in \mathcal{T}$ equals $\mathbf{u}_c$ for the contrast

$c_k = n_k v_k$, and by Proposition 8.7.2(c), $\sum_k c_{ik} c_{lk} / n_k = \mathbf{u}_{\mathbf{c}_i}^\top \mathbf{u}_{\mathbf{c}_l}$, which is zero for $i \neq l$. ■

By part (e) there are infinitely many complete orthogonal sets, one for each orthogonal basis of $\mathcal{T}$, and by part (a) all of them split the same total. The individual pieces depend on the basis (Exercise (C1)): choosing the basis is choosing the questions, and the design of the study, not the mathematics, should make that choice.

Warning. Orthogonality is a convenience, not a requirement. Planned contrasts that are not orthogonal are valid, each with the test and interval of Proposition 15.2.1. What is lost is additivity: their sums of squares need not total SSB, and their estimates are correlated. No contrast should be replaced by a less relevant one merely to achieve orthogonality.

15.4.2 Building orthogonal sets

Three constructions cover most designed experiments.

Splitting the treatments in stages. Many questions form a hierarchy: control against treatments, then old treatments against new, then one new formulation against another. Each splits a set of levels into two parts, and the comparisons are orthogonal for any group sizes provided each part is summarized by the mean of all its observations.

Proposition 15.4.2 — Contrasts from successive splits

For a set S of levels split into disjoint nonempty parts A and B , let $N_A = \sum_{k \in A} n_k$ and $N_B = \sum_{k \in B} n_k$, and define the contrast

$$c_k^{(S)} = \begin{cases} n_k/N_A, & k \in A, \\ -n_k/N_B, & k \in B, \\ 0, & k \notin S. \end{cases}$$

Its estimate is $\bar{y}_A - \bar{y}_B$, the difference between the means of all observations in A and in B , and

$$\text{SS}(\mathbf{c}^{(S)}) = \frac{N_A N_B}{N_A + N_B} (\bar{y}_A - \bar{y}_B)^2.$$

- (a) Every contrast $\mathbf{d}$ that is zero outside A (or outside B) is orthogonal to $\mathbf{c}^{(S)}$ for the design.
- (b) Split the set of all g levels into two parts, split each part with more than one level into two, and continue until every part is a single level. The $g - 1$ contrasts of the splits form a complete set of orthogonal contrasts, whatever the group sizes.

Proof. The estimate is $\sum_{k \in A} n_k \bar{y}_k / N_A - \sum_{k \in B} n_k \bar{y}_k / N_B = \bar{y}_A - \bar{y}_B$, and $v_{\mathbf{c}} = \sum_{k \in A} n_k / N_A^2 + \sum_{k \in B} n_k / N_B^2 = 1/N_A + 1/N_B$, which gives the sum of squares. (a) If $\mathbf{d}$ is zero outside A , then $\sum_k c_k^{(S)} d_k / n_k = \sum_{k \in A} (n_k / N_A) d_k / n_k = N_A^{-1} \sum_{k \in A} d_k = 0$, since $\mathbf{d}$ is a contrast; the case of B is the same. (b) A sequence of splits ending in single levels is a binary tree with g leaves, so it has $g - 1$ internal nodes, one split each. Take two different splits,

of sets S and S' . By construction either S and S' are disjoint, in which case the two contrasts have disjoint supports and are orthogonal, or one of them, say S' , lies inside one part of the split of S , in which case (a) applies. So the $g - 1$ contrasts are pairwise orthogonal, and they form a complete set. ■

The weighting matters: comparing plain averages of the levels in A and B gives orthogonal contrasts, in general, only in a balanced layout, as [Example \(Splitting the education sum of squares\)](#) showed numerically. The Helmert contrasts of [Exercise \(B3\)](#), which compare each level with the average of those before it, are the special case of the proposition that splits off one level at a time; with the weights n_k/N_A they stay orthogonal for unequal group sizes.

Factorial treatments. Four treatments may be the combinations of two fertilizers, each present or absent: none, P only, K only, and both. The contrasts

$$\begin{aligned} \text{effect of } P : & (-1, 1, -1, 1), & \text{effect of } K : & (-1, -1, 1, 1), \\ \text{interaction :} & (1, -1, -1, 1) \end{aligned}$$

are orthogonal in a balanced layout. The third asks whether the effect of P depends on K . A one-way analysis with these contrasts is a two-factor analysis in disguise; [Chapter 16](#) treats such layouts directly and defines interaction in general ([Definition 16.2.1](#)).

Polynomial trends. When the levels are values of a quantitative variable, such as a dose or a fertilizer rate, the orthogonal polynomial contrasts describe the shape of the response one degree at a time. For equally spaced levels and equal group sizes they are the integer vectors obtained from Gram–Schmidt applied to $1, s, s^2, \dots$ in the level scores ([Section 8.7](#), [Section 9.4](#)). For five levels they are

$$\begin{aligned} \text{linear } & (-2, -1, 0, 1, 2), & \text{quadratic } & (2, -1, -2, -1, 2), \\ \text{cubic } & (-1, 2, 0, -2, 1), & \text{quartic } & (1, -4, 6, -4, 1). \end{aligned}$$

The degree- d contrast is orthogonal to every polynomial of lower degree in the score, so it vanishes whenever the means lie on a polynomial of degree less than d . With unequal spacing the Gram–Schmidt step uses the actual level values ([Exercise \(B2\)](#)), and with unequal group sizes it uses the weighted inner product $\sum_k n_k p_k q_k$ and the contrasts $c_k = n_k p_k$ ([Example \(Trend in ideology across party identification\)](#)).

15.4.3 Trend analysis of the nitrogen trial

Example. (The shape of the nitrogen response)

The five rates are equally spaced and the design is balanced, so the integer contrasts above apply. The four single-degree-of-freedom sums of squares, each tested against $s^2 = 0.2715$ on 25 degrees of freedom, are:

Component	Sum of squares	F	p	Share of SSB
linear	25.9121	95.42	5.1×10^{-10}	90.3%
quadratic	2.7904	10.28	0.0037	9.7%
cubic	0.0049	0.02	0.89	0.0%
quartic	8.6×10^{-6}	3.2×10^{-5}	0.996	0.0%
rates (total)	28.7074	26.43		

Figure 15.4.1: Trend analysis of the nitrogen trial. (a) Rate means with bars of two standard errors, and the least squares linear and quadratic curves in the rate fitted to all thirty plots. (b) The four orthogonal polynomial sums of squares (logarithmic scale); the dotted line is the value a single degree of freedom needs to be significant at level 0.05, $s^2 F_{0.05}(1, 25)$.

The pieces add to the between-rates sum of squares of [Example \(The analysis of variance for the nitrogen trial\)](#), and F is the average of the four single-degree-of-freedom F values. Yield rises with the rate and the rise flattens: the quadratic component is clearly significant. The cubic and quartic components together test whether a quadratic in the rate describes the five means; their sum of squares 0.0049 on two degrees of freedom gives $F = 0.009$ and $p = 0.99$ ([Figure 15.4.1](#)).

```
import numpy as np
from scipy import stats

rates = np.array([0, 40, 80, 120, 160])           # kg N per hectare
g, m = len(rates), 6                             # 5 rates, 6 plots per rate
true_means = 6.8 - 2.7 * np.exp(-0.018 * rates)   # unknown to the analyst
rng = np.random.default_rng(1515)
group = np.repeat(np.arange(g), m)                # plot i received rate group[i]
y = np.round(true_means[group] + rng.normal(0, 0.5, g * m), 2) # yield, t/ha
n = len(y)

means = np.array([y[group == k].mean() for k in range(g)])
nu = n - g
s2 = np.sum((y - means[group]) ** 2) / nu
ss_between = m * np.sum((means - means.mean()) ** 2)

C_poly = np.array([[-2, -1, 0, 1, 2],             # linear
                   [2, -1, -2, -1, 2],           # quadratic
                   [-1, 2, 0, -2, 1],             # cubic
                   [1, -4, 6, -4, 1]], float)      # quartic

def contrast_ss(c):
    return (c @ means) ** 2 / (c @ c / m)          # balanced: sum c_k^2 / n_k = c'
    c / m

ss_poly = np.array([contrast_ss(c) for c in C_poly])
F_poly = ss_poly / s2
```

```
p_poly = stats.f.sf(F_poly, 1, nu)
for name, ss, F, p in zip(["linear", "quadratic", "cubic", "quartic"], ss_poly,
    F_poly, p_poly):
    print(f"{name:9s} SS = {ss:8.4f} F = {F:7.2f} p = {p:.2g}")
print(f"sum = {ss_poly.sum():.4f}    between rates = {ss_between:.4f}")
```

The test of the cubic and quartic components is not a new test. Every model in which the mean depends on the rate alone has its mean space inside $\mathcal{C}(\mathbf{Z})$ (Lemma 14.6.1), so the one-way residual sum of squares is the pure-error sum of squares of Section 14.6. The quadratic regression on the rate misses exactly the cubic and quartic directions of $\mathcal{C}(\mathbf{Z})$, so their sum of squares is its lack-of-fit sum of squares, and the trend test is the pure-error test of Theorem 14.6.2 (Exercise (C2)). The listing checks the identity: the quadratic regression has residual sum of squares 6.7935, the lack of fit plus the within-rates sum of squares.

```
ss_lof = ss_poly[2] + ss_poly[3]                                # cubic + quartic, 2 df
F_lof = (ss_lof / 2) / s2
X2 = np.column_stack([np.ones(n), rates[group], rates[group] ** 2])
coef, *_ = np.linalg.lstsq(X2, y, rcond=None)                  # quadratic regression on the
    rate
sse_quad = np.sum((y - X2 @ coef) ** 2)
print(f"lack of fit of the quadratic: SS = {ss_lof:.4f}, F = {F_lof:.3f},"
    f" p = {stats.f.sf(F_lof, 2, nu):.2f}")
print(f"quadratic regression SSE = {sse_quad:.4f} = lack of fit + within = {ss_lof +
    s2 * nu:.4f}")
```

The fitted quadratic is $4.014 + 0.03466 N - 0.0001139 N^2$ t/ha at N kg N/ha. It has a maximum at $N = 0.03466 / (2 \times 0.0001139) \approx 152$, inside the range of rates, and it declines after that. That decline is a property of the parabola, not of the crop: the data were generated from a response that rises at every rate, and five noisy means cannot distinguish a parabola that turns over from a curve that levels off. A trend analysis describes the means at the rates used and should not be extrapolated.

15.4.4 One data set, two decompositions

A different set of questions gives a different complete set. Suppose the agronomist had planned to ask first whether fertilizer helps at all, and then how the response behaves among the fertilized rates. The contrast of the control against the four fertilized rates is a split of the kind in Proposition 15.4.2, with coefficients proportional to $(-4, 1, 1, 1, 1)$. The linear, quadratic and cubic polynomial contrasts among the four fertilized rates, $(0, -3, -1, 1, 3)$, $(0, 1, -1, -1, 1)$ and $(0, -1, 3, -3, 1)$, are zero at the control, so they are orthogonal to it by part (a) of that proposition and to each other by balance. Their sums of squares are 21.3701 ($F = 78.70$), 6.6364 ($F = 24.44$), 0.7004 ($F = 2.58$, $p = 0.12$) and 0.0005, and they add to the same 28.7074.

```
C_ctrl = np.array([[-4, 1, 1, 1, 1],                          # control against the four
    fertilized
                    [0, -3, -1, 1, 3],                          # linear among 40, ..., 160
                    [0, 1, -1, -1, 1],                          # quadratic among them
                    [0, -1, 3, -3, 1]], float)                  # cubic among them
ss_ctrl = np.array([contrast_ss(c) for c in C_ctrl])
print("second set:", ss_ctrl.round(4), " sum =", round(ss_ctrl.sum(), 4))
```

The two decompositions tell different but compatible stories. In the first, curvature is significant;

in the second, the curvature among the fertilized rates is not, because most of the bend is the jump from no nitrogen to 40 kg, which the second set assigns to the control contrast. Computing several decompositions and reporting the one whose pieces look best is the data snooping of [Section 13.6](#).

15.4.5 Exercises

15.4.5.1 A. Check your understanding

Exercise A1.

Check that the four polynomial contrasts for five levels are pairwise orthogonal. Show that the quadratic contrast vanishes when $\mu_k = a + bk$, and the cubic contrast vanishes when $\mu_k = a + bk + ck^2$.

Exercise A2.

For the four fertilizer combinations of “Factorial treatments”, verify that the three contrasts are orthogonal when every group has the same size, and that the P and K contrasts are not orthogonal for group sizes 3, 3, 3, 5 (in the order none, P , K , both). What does the lack of orthogonality mean for the estimates?

Solution. With equal sizes, orthogonality is the plain inner product: $(-1, 1, -1, 1) \cdot (-1, -1, 1, 1) = 1 - 1 - 1 + 1 = 0$, and similarly for the other two pairs. With sizes 3, 3, 3, 5, $\sum_k c_k d_k / n_k = \frac{1}{3} - \frac{1}{3} - \frac{1}{3} + \frac{1}{5} = -\frac{2}{15} \neq 0$. By [Proposition 8.7.2\(c\)](#) the two estimates are then correlated, with covariance $-\frac{2}{15}\sigma^2$, and their sums of squares do not add to the part of SSB that the two contrasts span.

15.4.5.2 B. Practice

Exercise B1.

Show that the two planned contrasts of [Example \(Two planned contrasts\)](#), $(-1, \frac{1}{4}, \frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ and $(0, 0, -1, 0, 1)$, are orthogonal. Find two further contrasts that complete them to a complete orthogonal set, and say what they compare.

Solution. The design is balanced, and $-1 \cdot 0 + \frac{1}{4}(0 - 1 + 0 + 1) = 0$. A contrast $\mathbf{e}$ orthogonal to the first satisfies $-e_1 + \frac{1}{4}(e_2 + e_3 + e_4 + e_5) = 0$, and since $e_2 + e_3 + e_4 + e_5 = -e_1$ this forces $e_1 = 0$. Orthogonality to the second forces $e_3 = e_5$. So $\mathbf{e} = (0, a, b, c, b)$ with $a + 2b + c = 0$. Two orthogonal choices are $(0, 1, 0, -1, 0)$, comparing 40 with 120, and $(0, 1, -1, 1, -1)$, comparing 40 and 120 together with 80 and 160 together. Their inner product is $1 - 1 = 0$. The completion is valid but not very natural: completing a planned set is optional.

Exercise B2.

Five plots at each of four rates 0, 1, 2 and 4 (in units of 50 kg N/ha) are to be analysed for trend. Show that the linear and quadratic orthogonal polynomial contrasts are

proportional to $(-7, -3, 1, 9)$ and $(7, -4, -8, 5)$. Check that the quadratic contrast vanishes when the means are linear in the rate.

Solution. The rates have mean $7/4$, so the linear contrast is proportional to $4(s_k - 7/4) = (-7, -3, 1, 9)$. For the quadratic, centre $s_k^2 = (0, 1, 4, 16)$ at its mean $21/4$ and multiply by four: $(-21, -17, -5, 43)$. Its inner product with $(-7, -3, 1, 9)$ is 580, and the linear vector has squared length 140, so subtract $\frac{580}{140}(-7, -3, 1, 9)$ to get $(8, -\frac{32}{7}, -\frac{64}{7}, \frac{40}{7})$, which is proportional to $(7, -4, -8, 5)$. Its entries sum to zero and its inner product with the linear contrast is $-49 + 12 - 8 + 45 = 0$. For means $a + bs_k$ the quadratic contrast gives $b(0 - 4 - 16 + 20) = 0$.

Exercise B3.

Four equally spaced levels have group sizes 2, 4, 4, 2. Show that the classical linear contrast $(-3, -1, 1, 3)$ is orthogonal for this design to the quadratic $(1, -1, -1, 1)$ but not to the cubic $(-1, 3, -3, 1)$. Explain the first fact by symmetry.

Solution. For linear and quadratic, $\sum_k c_k d_k / n_k = -\frac{3}{2} + \frac{1}{4} - \frac{1}{4} + \frac{3}{2} = 0$. For linear and cubic, it is $\frac{3}{2} - \frac{3}{4} - \frac{3}{4} + \frac{3}{2} = \frac{3}{2} \neq 0$. The sizes are symmetric about the middle of the scale. The linear contrast is odd under the reflection $k \mapsto 5 - k$, the quadratic is even, and the weights $1/n_k$ are even, so the weighted inner product of an odd and an even vector vanishes. Linear and cubic are both odd, and nothing forces their weighted inner product to vanish.

Exercise B4.

Use the formula of [Proposition 15.4.2](#) to recompute the sum of squares of the control against the fertilized rates in the nitrogen trial from the rate means, and compare it with the value 21.3701 in the text.

Solution. Here $N_A = 24$, $N_B = 6$, $\bar{y}_A = \frac{1}{4}(5.237 + 6.057 + 6.515 + 6.652) = 6.11525$ and $\bar{y}_B = 4.005$. The sum of squares is $\frac{24 \cdot 6}{30}(6.11525 - 4.005)^2 = 4.8 \times 2.11025^2 \approx 21.375$. The small difference from 21.3701 comes from using the rounded rate means.

15.4.5.3 C. Going deeper

Exercise C1.

Let $\mathbf{U} = [\mathbf{u}_1, \dots, \mathbf{u}_{g-1}]$ and $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_{g-1}]$ be two orthonormal bases of the treatment space. Show that $\mathbf{V} = \mathbf{U}\mathbf{Q}$ for an orthogonal $(g-1) \times (g-1)$ matrix $\mathbf{Q}$, that the vectors of squared coordinates of $\mathbf{y}$ in the two bases have the same sum SSB, and that the individual squared coordinates generally differ. More generally, show that for any symmetric idempotent $\mathbf{A}$ of rank q and $\mathbf{Y} \sim N_n(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$, $\mathbf{Y}^\top \mathbf{A} \mathbf{Y}$ splits into q independent scaled noncentral $\chi^2(1)$ variables, one for each vector of an orthonormal basis of $\mathcal{C}(\mathbf{A})$.

Solution. Both $\mathbf{U}\mathbf{U}^\top$ and $\mathbf{V}\mathbf{V}^\top$ equal $\mathbf{P}_{\mathcal{T}}$, the unique projection onto $\mathcal{T}$. Put $\mathbf{Q} = \mathbf{U}^\top \mathbf{V}$. Then $\mathbf{U}\mathbf{Q} = \mathbf{P}_{\mathcal{T}} \mathbf{V} = \mathbf{V}$ and $\mathbf{Q}^\top \mathbf{Q} = \mathbf{V}^\top \mathbf{P}_{\mathcal{T}} \mathbf{V} = \mathbf{V}^\top \mathbf{V} = \mathbf{I}$. The coordinate vectors satisfy $\mathbf{V}^\top \mathbf{y} = \mathbf{Q}^\top \mathbf{U}^\top \mathbf{y}$, and an orthogonal matrix preserves length, so both

have squared length $\mathbf{y}^\top \mathbf{P}_\tau \mathbf{y} = \text{SSB}$. The individual coordinates are mixed by $\mathbf{Q}$ and generally change. For the general statement, write $\mathbf{A} = \sum_{i=1}^q \mathbf{w}_i \mathbf{w}_i^\top$ with $\mathbf{w}_1, \dots, \mathbf{w}_q$ an orthonormal basis of $\mathcal{C}(\mathbf{A})$ (Proposition 6.3.2). The rank-one projections $\mathbf{w}_i \mathbf{w}_i^\top$ are mutually orthogonal, so by Theorem 4.4.4 the terms $(\mathbf{w}_i^\top \mathbf{Y})^2$ are independent, and $(\mathbf{w}_i^\top \mathbf{Y})^2 / \sigma^2 \sim \chi^2(1, (\mathbf{w}_i^\top \boldsymbol{\theta})^2 / \sigma^2)$. Eigenvectors of $\mathbf{A}$ for the eigenvalue one are one such basis.

Exercise C2.

For g equally spaced levels with equal group sizes, show that the sum of the sums of squares of the polynomial contrasts of degrees $d+1, \dots, g-1$ is the lack-of-fit sum of squares of the polynomial regression of degree $d < g-1$ on the level score, and that the sum for degrees $1, \dots, d$ is that regression's sum of squares after the mean.

Solution. Let $\mathcal{P}_d \subseteq \mathcal{C}(\mathbf{Z})$ be the mean space of the degree- d regression, spanned by the vectors whose entry in group k is s_k^i , $i = 0, \dots, d$ (Lemma 14.6.1). The contrast vector of the degree- i orthogonal polynomial p_i has entry $p_i(s_k)/m$ in group k , and in a balanced layout orthogonality of these vectors is orthogonality of the p_i in the plain inner product. By construction $p_0, \dots, p_d$ span the polynomials of degree at most d on the scores, so the vectors of degrees $1, \dots, d$ span $\mathcal{P}_d \cap \mathbf{1}^\perp$, and those of degrees $d+1, \dots, g-1$ span $\mathcal{C}(\mathbf{Z}) \cap \mathcal{P}_d^\perp$. The projection onto the first space gives the regression sum of squares after the mean (Theorem 6.5.1), and the projection onto the second gives $\|(\mathbf{M} - \mathbf{P}_{\mathcal{P}_d})\mathbf{y}\|^2$, the lack-of-fit sum of squares of Theorem 14.6.2. Each projection is the sum of the projections onto the lines, by Theorem 6.3.7.

15.5 Balanced and unbalanced one-way layouts

Every result so far holds for any group sizes, yet experimenters aim for balance. This section says what it buys: plain orthogonality, the largest guaranteed power for a fixed number of observations, and a test of equal means that tolerates unequal variances. The third matters most in practice, because unbalanced data with unequal variances are common and the classical F test can then go badly wrong.

15.5.1 Orthogonality and simplicity

In a balanced layout, orthogonality of contrasts is plain orthogonality $\sum_k c_k d_k = 0$ (Theorem 15.4.1(d)), so tabulated sets such as the integer polynomial contrasts can be used as they stand. The side conditions $\sum_k \alpha_k = 0$ and $\sum_k n_k \alpha_k = 0$ define the same parameters, the pooled variance is the plain average of the group variances, and every pairwise difference has the standard error $s\sqrt{2/m}$. Tukey's intervals have exact simultaneous coverage (Theorem 13.3.2), whereas with unequal sizes the Tukey–Kramer intervals (Eq. 13.3.3) are conservative by an unknown amount.

15.5.2 Balance maximizes guaranteed power

The noncentrality [Eq. 15.3.3](#) depends on the group sizes as well as the means. No allocation of a fixed total is best for every configuration of means, and the planner does not know the means, so the relevant criterion is the power *guaranteed* against every configuration whose means span at least a range Δ , as in [Proposition 11.5.2](#). For unequal group sizes, [Exercise \(B1\)](#) already identifies the least favourable configuration; what is new here is the comparison of allocations.

Proposition 15.5.1 — Balance maximizes the guaranteed noncentrality

In a one-way layout with group sizes $n_1, \dots, n_g$, $g \geq 2$, let

$$h = \min_{k \neq l} \frac{n_k n_l}{n_k + n_l} = \min_{k \neq l} \left(\frac{1}{n_k} + \frac{1}{n_l} \right)^{-1}.$$

- (a) For all means with $\max_k \mu_k - \min_k \mu_k \geq \Delta > 0$, the noncentrality of the F test satisfies $\gamma \geq h\Delta^2/\sigma^2$, and there is a configuration with range exactly Δ at which equality holds.
- (b) For fixed $n = \sum_k n_k$, $h \leq n/(2g)$, with equality iff the layout is balanced.

Proof. Part (a) is [Exercise \(B1\)](#), rewritten with h : its bound is $\Delta^2/(\sigma^2(1/n_{(1)} + 1/n_{(2)})) = h\Delta^2/\sigma^2$, since $1/n_k + 1/n_l$ is largest for the two smallest groups. Equality holds when those two groups carry means Δ apart and every other mean equals their weighted average.

For (b): as just noted, $1/n_k + 1/n_l$ is largest for the two smallest groups. Call their sizes $a \leq b$. The other $g-2$ groups have at least b observations each, so $n \geq a + (g-1)b$, and

$$\left(\frac{1}{a} + \frac{1}{b} \right) n \geq \left(\frac{1}{a} + \frac{1}{b} \right) (a + (g-1)b) = g + (g-1)t + \frac{1}{t},$$

where $t = b/a \geq 1$. Now $(g-1)t + 1/t - g = ((g-1)t - 1)(t-1)/t \geq 0$, because both factors are nonnegative when $t \geq 1$ and $g \geq 2$. Hence $1/a + 1/b \geq 2g/n$, that is, $h \leq n/(2g)$. Equality requires $t = 1$ and $n = a + (g-1)b$, so all groups have the same size. Conversely, a balanced layout has $h = n/2 = n/(2g)$. ■

A departure is hardest to detect when it sits in the least informative pair of groups. The balanced value $h = n/2$ is the bound of [Proposition 11.5.2](#).

Example. (Forty observations in four groups)

With $n = 40$ and $g = 4$, the guaranteed noncentrality per unit of $(\Delta/\sigma)^2$ is 5.000 for the balanced allocation 10, 10, 10, 10, 3.938 for the mildly unbalanced 7, 9, 11, 13, and 2.400 for 4, 6, 10, 20. At $\Delta = \sigma$ the guaranteed powers of the level-0.05 test are 0.399, 0.320 and 0.205. To guarantee power 0.8, the range of the means must be at least 1.56σ , 1.76σ and 2.25σ respectively ([Figure 15.5.1](#)). The mild imbalance gives the same

Figure 15.5.1: Guaranteed power of the level-0.05 F test with 40 observations in four groups, against the range of the group means in units of σ , for three allocations. The curves are the power at the least favourable configuration of Proposition 15.5.1; dots mark where each reaches 0.8.

guarantee as a balanced design with $8 \times 3.938 \approx 31.5$ observations, so it wastes a fifth of the experiment.

```
import itertools

import numpy as np
from scipy import stats

def guaranteed_gamma(sizes, delta_over_sigma):
    """Smallest noncentrality over all mean configurations with range at least Delta
    """
    h = min(a * b / (a + b) for a, b in itertools.combinations(sizes, 2))
    return delta_over_sigma ** 2 * h

def power_f(gamma, q, nu, alpha=0.05):
    return stats.ncf.sf(stats.f.ppf(1 - alpha, q, nu), q, nu, gamma)

allocations = {"balanced": [10, 10, 10, 10], "mild": [7, 9, 11, 13], "strong": [4,
    6, 10, 20]}
for name, sizes in allocations.items():
    gam = guaranteed_gamma(sizes, 1.0)
    print(f"{name:9s} {sizes}: guaranteed gamma = {gam:.3f},"
        f" guaranteed power at Delta = sigma: {power_f(gam, 3, 36):.3f}")
```

Balance is optimal for the overall test and for the family of all pairwise comparisons. It is not optimal for every purpose. A single planned contrast is estimated most precisely with $n_k \propto |c_k|$ (Exercise (B2)), and comparisons with a control favour a larger control group (Exercise (B3)). The allocation should follow the questions.

15.5.3 Unequal variances

The one-way model assumes a common variance. Suppose instead that the observations in group k have variance σ_k^2 , with everything else as before. What do the two mean squares then

estimate?

Theorem 15.5.2 — Expected mean squares under unequal variances

Let the Y_{kj} be uncorrelated with $E(Y_{kj}) = \mu_k$ and $\text{Var}(Y_{kj}) = \sigma_k^2$, and write $\bar{n} = n/g$. Then:

- (a) $E(\text{SSE}) = \sum_k (n_k - 1)\sigma_k^2$, so $E(\text{MSE})$ is the average of the σ_k^2 weighted by $n_k - 1$;
- (b) $E(\text{SSB}) = \sum_k (1 - n_k/n)\sigma_k^2 + \sum_k n_k(\mu_k - \bar{\mu})^2$;
- (c) when the means are equal,

$$E(\text{MSB}) - E(\text{MSE}) = \frac{g(n-1)}{n(g-1)(n-g)} \sum_{k=1}^g (\bar{n} - n_k) \sigma_k^2. \quad (15.5.1)$$

In a balanced layout this is zero, and both mean squares estimate $g^{-1} \sum_k \sigma_k^2$. In an unbalanced layout it is positive when the larger variances belong to the smaller groups and negative when they belong to the larger groups.

Proof. The argument of Theorem 9.6.1 applies with a diagonal covariance. Now $\text{Cov}(\mathbf{Y}) = \mathbf{\Sigma}$, diagonal with σ_k^2 on the observations of group k , and $E(\mathbf{Y}) = \boldsymbol{\theta}$. By Theorem 2.3.1, $E(\mathbf{Y}^\top \mathbf{A} \mathbf{Y}) = \text{tr}(\mathbf{A} \mathbf{\Sigma}) + \boldsymbol{\theta}^\top \mathbf{A} \boldsymbol{\theta}$. (a) With $\mathbf{A} = \mathbf{I} - \mathbf{M}$, whose diagonal entries in group k are $1 - 1/n_k$, $\text{tr}(\mathbf{A} \mathbf{\Sigma}) = \sum_k n_k(1 - 1/n_k)\sigma_k^2$, and $\mathbf{A} \boldsymbol{\theta} = \mathbf{0}$. (b) With $\mathbf{A} = \mathbf{M} - \mathbf{P}_0$, the diagonal entries in group k are $1/n_k - 1/n$, so $\text{tr}(\mathbf{A} \mathbf{\Sigma}) = \sum_k (1 - n_k/n)\sigma_k^2$, and $\boldsymbol{\theta}^\top \mathbf{A} \boldsymbol{\theta} = \sum_k n_k(\mu_k - \bar{\mu})^2$ as in Theorem 15.3.1. (c) With equal means, multiply the difference of the two expectations by $(g-1)(n-g)$:

$$\begin{aligned} & (n-g) \sum_k (1 - n_k/n) \sigma_k^2 - (g-1) \sum_k (n_k - 1) \sigma_k^2 \\ &= \sum_k (n-1 - g(n-1)n_k/n) \sigma_k^2 = \frac{g(n-1)}{n} \sum_k (\bar{n} - n_k) \sigma_k^2, \end{aligned}$$

where the middle step collects the coefficient of σ_k^2 : $(n-g) - (n-g)n_k/n - (g-1)n_k + (g-1) = n-1 - gn_k + gn_k/n$. Since $\sum_k (\bar{n} - n_k) = 0$, the sum equals $-\sum_k (n_k - \bar{n})(\sigma_k^2 - \bar{\sigma}^2)$ for any constant $\bar{\sigma}^2$, which is negative when n_k and σ_k^2 move together and positive when they move in opposite directions. In a balanced layout every $\bar{n} - n_k$ is zero, and then $E(\text{MSE}) = \sum_k (m-1)\sigma_k^2/(g(m-1)) = g^{-1} \sum_k \sigma_k^2$. ■

The theorem predicts the behaviour of the F test. In a balanced layout both mean squares estimate the same average variance under the hypothesis, and although the ratio is no longer exactly F -distributed, Box (1954) showed that the effect on the level is modest. In an unbalanced layout MSE leans towards the variances of the large groups and MSB towards those of the small groups. When the small groups are the variable ones the test rejects too often; when the large groups are, it rejects too rarely and loses power.

Example. (How far the level moves)

Four normal groups have equal means and standard deviations increasing geometrically

Figure 15.5.2: Rejection rates under equal means of three tests at nominal level 0.05 (dotted), for four normal groups whose standard deviations increase from 1 to the ratio on the horizontal axis. Each point is based on 40000 simulated data sets.

from 1 to R . Three designs of 40 observations are compared: balanced (10 per group), *positive pairing* (sizes 4, 6, 10, 20, the largest group most variable) and *negative pairing* (sizes 20, 10, 6, 4, the smallest group most variable). For each design and each R , 40000 data sets were simulated and three level-0.05 tests applied: the classical F test and the tests of Welch and of Brown and Forsythe described below (Figure 15.5.2).

At $R = 3$, Eq. 15.5.1 gives expected mean square ratios $E(\text{MSB})/E(\text{MSE})$ of 1.000, 0.559 and 1.923 for the three designs. The simulated levels of the classical test follow: 0.071 when balanced, 0.011 with positive pairing, and 0.241 with negative pairing, almost five times the nominal level. At $R = 4$ the negative pairing gives 0.288. Welch's test stays between 0.048 and 0.068 throughout, and the Brown–Forsythe test between 0.048 and 0.065.

The simulation supports the common rule of thumb that a ratio of about two between the largest and smallest standard deviations does little harm, but only with balance: at $R = 2$ the balanced level is 0.059, while the two unbalanced designs give 0.015 and 0.160.

15.5.4 Tests that allow unequal variances

If the variances σ_k^2 were known, weighted least squares (Section 6.9) would compare the group means with their precision-weighted average $\tilde{\mu} = \sum_k w_k \bar{Y}_k / \sum_k w_k$, $w_k = n_k / \sigma_k^2$, and $\sum_k w_k (\bar{Y}_k - \tilde{\mu})^2$ would have an exact $\chi^2(g-1)$ law under equal means. In practice the σ_k^2 are replaced by the s_k^2 and the reference distribution is approximated. We describe the two approximations in common use without deriving them; Chapter 21 treats heteroscedasticity in general.

Welch's test. Welch (1951) replaced σ_k^2 by s_k^2 in the weights, $w_k = n_k / s_k^2$, and divided the weighted mean square by a correction factor:

$$F_W = \frac{\sum_k w_k (\bar{y}_k - \tilde{\mu})^2 / (g-1)}{1 + \frac{2(g-2)}{g^2-1} \sum_k h_k}, \quad h_k = \frac{(1 - w_k / \sum_l w_l)^2}{n_k - 1},$$

referred to $F(g-1, \nu_W)$ with $\nu_W = (g^2-1) / (3 \sum_k h_k)$. The correction and the degrees of freedom come from an approximation to the statistic's null distribution that is accurate to first

order in the quantities $1/(n_k - 1)$. For two groups F_W is the square of Welch's two-sample t statistic with Satterthwaite's degrees of freedom ([Exercise \(B1\)](#)).

The Brown–Forsythe test. Brown and Forsythe (1974a) kept the unweighted numerator and changed the denominator. By [Theorem 15.5.2\(b\)](#), under equal means SSB has expectation $\sum_k (1 - n_k/n) \sigma_k^2$, whatever the variances. Replacing σ_k^2 by s_k^2 gives an unbiased estimate of that expectation, and the statistic

$$F_{BF} = \frac{\text{SSB}}{\sum_k (1 - n_k/n) s_k^2}$$

compares SSB with an estimate of what it should be under the hypothesis. It is referred to $F(g - 1, f)$, where $1/f = \sum_k c_k^2 / (n_k - 1)$ with $c_k = (1 - n_k/n) s_k^2 / \sum_l (1 - n_l/n) s_l^2$, Satterthwaite's approximation to the degrees of freedom of a linear combination of independent variance estimates. In a balanced layout the denominator is $(g - 1) s^2$, so $F_{BF} = F$ and only the degrees of freedom change.

Individual contrasts need the same care, since $s\sqrt{v_c}$ estimates the wrong variance when the σ_k^2 differ, even in a balanced layout ([Exercise \(C2\)](#)). The **Welch–Satterthwaite** interval uses

$$\widehat{\text{Var}}(\hat{\psi}) = \sum_k \frac{c_k^2 s_k^2}{n_k}, \quad \nu = \frac{(\sum_k c_k^2 s_k^2 / n_k)^2}{\sum_k (c_k^2 s_k^2 / n_k)^2 / (n_k - 1)},$$

and the multiplier $t_{\nu, \alpha/2}$ ([Exercise \(B3\)](#)), adjusted as in [Chapter 13](#) for simultaneous inference.

Example. (An unbalanced trial with unequal variances)

A repair mortar was made with four admixture formulations, and its setting time was measured in minutes. The standard formulation A was tested most often, and the newer formulations least (simulated data, rounded to 0.1 minute):

Formulation	n_k	Setting times (min)	Mean	s_k
A	12	18.9, 20.2, 20.6, 21.2, 20.3, 19.0, 20.2, 19.0, 20.5, 20.6, 20.1, 20.3	20.075	0.73
B	9	22.6, 21.3, 22.2, 22.8, 19.3, 20.7, 21.5, 20.8, 18.8	21.111	1.38
C	6	20.7, 18.2, 18.6, 23.6, 21.3, 22.6	20.833	2.14
D	4	20.1, 22.6, 28.3, 25.3	24.075	3.53

The standard deviations grow as the group sizes shrink, the negative pairing of [Example \(How far the level moves\)](#). The classical analysis gives $F = 5.34$ on $(3, 27)$ degrees of freedom and $p = 0.0051$, apparently strong evidence, driven by the high mean of D. But $\text{MSE} = 3.015$ gives the variance of D weight $3/27$, while the null expectation of MSB in [Theorem 15.5.2\(b\)](#) gives it weight $(1 - 4/31)/3 \approx 0.29$; estimated with the s_k^2 , that expectation is 5.407, far above MSE. Welch's test gives $F_W = 2.64$ on $(3, 8.3)$ degrees of freedom and $p = 0.119$, and the Brown–Forsythe test gives $F_{BF} = 2.98$ on $(3, 6.2)$ degrees of freedom and $p = 0.115$. The difference between D and A is 4.00 minutes. With the pooled standard error 1.003 its 95% interval is $[1.94, 6.06]$; with the Welch–Satterthwaite standard error 1.776 on 3.1 degrees of freedom it is $[-1.56, 9.56]$. Four observations with a standard deviation of 3.5 minutes cannot establish a difference of four minutes.

The weighted and unweighted averages of the group means are 21.039 and 21.524, so the side conditions $\sum_k n_k \alpha_k = 0$ and $\sum_k \alpha_k = 0$ of [Section 15.1](#) ([Theorem 8.4.2](#)) define overall means that differ by half a minute here.

```
import numpy as np
from scipy import stats
from statsmodels.stats.oneway import anova_oneway

labels = ["A", "B", "C", "D"]
n_k = np.array([12, 9, 6, 4])
rng = np.random.default_rng(1520)
samples = [np.round(rng.normal(mu, sd, k), 1)
            for mu, sd, k in zip([20.0, 20.6, 21.0, 22.2], [0.8, 1.2, 2.0, 3.0], n_k)
          ]

g, n = len(samples), n_k.sum()
means = np.array([x.mean() for x in samples])
s2_k = np.array([x.var(ddof=1) for x in samples])      # group variances
s2 = np.sum((n_k - 1) * s2_k) / (n - g)              # pooled within-group
variance
grand = means @ n_k / n
ss_b = np.sum(n_k * (means - grand) ** 2)
F = ss_b / (g - 1) / s2
print("means:", means.round(3), " sds:", np.sqrt(s2_k).round(2))
print(f"classical F = {F:.2f}, p = {stats.f.sf(F, g - 1, n - g):.4f}")
# null expectation of MS_between if the variances really are s2_k (the theorem of
  this section)
print(f"MS_within = {s2:.3f}; estimated null E(MS_between) = "
      f"{np.sum((1 - n_k / n) * s2_k) / (g - 1):.3f}")

welch = anova_oneway(samples, use_var="unequal")
bf = anova_oneway(samples, use_var="bf")
print(f"Welch: F = {welch.statistic:.2f} on ({g - 1}, {welch.df_denom:.1f}) df, p = "
      f"{welch.pvalue:.3f}")
print(f"Brown-Forsythe: F = {bf.statistic:.2f} on ({g - 1}, {bf.df2[1]:.1f}) df, p = "
      f"{bf.pvalue2:.3f}")
lev = stats.levene(*samples, center="median")        # dispersion test on |y -
median/
print(f"variance test on absolute deviations from medians: p = {lev.pvalue:.4f}")
```

(By default `statsmodels` refines the numerator degrees of freedom of the Brown–Forsythe test; `pvalue2` is the original version.)

The simulation of [Example \(How far the level moves\)](#) used the same formulas, applied to group means and variances drawn directly from their sampling distributions:

```
import numpy as np
from scipy import stats

def three_tests(ybar, s2, n_k):
    """p-values of the classical F, Welch and Brown-Forsythe tests; arrays of shape
    (reps, g)."""
    g, n = n_k.size, n_k.sum()
    grand = ybar @ n_k / n
    ss_b = ((ybar - grand[:, None]) ** 2) @ n_k
    ss_w = s2 @ (n_k - 1)
    p_f = stats.f.sf(ss_b / (g - 1) / (ss_w / (n - g)), g - 1, n - g)
    # Welch (1951): weights n_k / s_k^2 and a Satterthwaite-type denominator df
    w = n_k / s2
    mu_w = np.sum(w * ybar, axis=1) / w.sum(axis=1)
    h = (1 - w / w.sum(axis=1)[:, None]) ** 2 / (n_k - 1)
    a = np.sum(w * (ybar - mu_w[:, None]) ** 2, axis=1) / (g - 1)
    b = 1 + 2 * (g - 2) / (g ** 2 - 1) * h.sum(axis=1)
    p_w = stats.f.sf(a / b, g - 1, (g ** 2 - 1) / (3 * h.sum(axis=1)))
    # Brown-Forsythe (1974): SS_between over its null expectation under unequal
    variances
    d = (1 - n_k / n) * s2
    c = d / d.sum(axis=1)[:, None]
    p_bf = stats.f.sf(ss_b / d.sum(axis=1), g - 1, 1 / np.sum(c ** 2 / (n_k - 1),
axis=1))
    return p_f, p_w, p_bf

def size(n_k, sds, reps=40000, seed=0, alpha=0.05):
    """Rejection rates under equal means, from group means and variances drawn
    exactly."""
    rng = np.random.default_rng(seed)
    n_k, sds = np.asarray(n_k, float), np.asarray(sds, float)
    ybar = rng.normal(0, sds / np.sqrt(n_k), (reps, n_k.size))
    s2 = sds ** 2 * rng.chisquare(n_k - 1, (reps, n_k.size)) / (n_k - 1)
    return [np.mean(p < alpha) for p in three_tests(ybar, s2, n_k)]

designs = {"balanced": [10, 10, 10, 10],
          "positive pairing": [4, 6, 10, 20],          # big groups get the big
          variances
          "negative pairing": [20, 10, 6, 4]}          # small groups get the big
          variances
ratios = [1, 1.5, 2, 3, 4]
res = {}
for name, sizes in designs.items():                  # sds grow geometrically from 1
    to R
    res[name] = np.array([size(sizes, R ** (np.arange(4) / 3), seed=int(10 * R)) for
    R in ratios])
for R, row in zip(ratios, res[name]):
    print(f"{name:17s} R = {R:3.1f}: F, Welch, BF sizes = {np.round(row, 3)}")
```

Robustness has a small price. With equal variances and a group of only four observations, Welch's test rejects slightly too often, 0.061 and 0.062 in the two unbalanced designs. The practical advice is simple: with unequal group sizes, use a heteroscedasticity-robust test unless there is good reason to believe the variances are equal; with equal sizes the classical test is acceptable, although individual contrasts still need care.

Figure 15.5.3: Residual plots for the mortar trial. (a) Residuals against fitted values: the spread grows from formulation A to formulation D. (b) Normal quantile plot of the studentized residuals: the curvature at both ends reflects the mixture of groups with different variances, not a heavy-tailed error distribution.

15.5.5 Checking the assumptions

Independence is secured by the design, above all by randomization, and cannot be checked well from the data. Correlation within groups, which arises when the observations in a group share a batch, an operator or a day, inflates the F statistic badly ([Exercise \(C1\)](#)). A common variance and normality are checked with the residuals $e_{kj} = y_{kj} - \bar{y}_k$.

The leverage of an observation in group k is $1/n_k$ ([Proposition 6.8.1](#)), so $\text{Var}(e_{kj}) = \sigma^2(1 - 1/n_k)$. Residuals from small groups are shrunk towards zero, so they are compared on the common scale $r_{kj} = e_{kj}/(s\sqrt{1 - 1/n_k})$. A plot of residuals against the group means shows whether the spread differs between groups, and a spread growing with the mean suggests a transformation ([Chapter 22](#)). A normal quantile plot of the studentized residuals shows skewness and heavy tails. [Chapter 20](#) develops residual diagnostics in general.

[Figure 15.5.3](#) shows the two plots for the mortar trial. The fan shape in panel (a) is unmistakable. The classical tests of equal variances, which compare the logarithms of the s_k^2 , are so sensitive to nonnormality that a rejection says as much about the tails as about the variances. Levene (1960) proposed instead to apply the one-way F test to the absolute deviations $|y_{kj} - \bar{y}_k|$, which are larger on average in a more variable group; Brown and Forsythe (1974b) used deviations from the group *medians*, which behave better for skewed data. For the mortar trial that version gives $p = 0.0019$. Using such a test as a gate for the classical F test is not recommended, since it has little power in small groups, exactly where unequal variances do the most harm. The analysis should be chosen in advance, from the design and from what is known about the response.

Nonnormality is usually the least serious problem for tests about means: the level of the F test is fairly robust to it, more so in balanced designs ([Proposition 19.3.5](#)), though heavy tails cost power by inflating MSE. Transformations ([Chapter 22](#)) and resampling ([Chapter 23](#)), for example the Kruskal–Wallis permutation test on ranks, are the usual remedies.

15.5.6 Exercises

15.5.6.1 A. Check your understanding

Exercise A1.

For the balanced design with $m = 10$ and variances 1, 2, 4, 8, compute $E(\text{MSB})$ under equal means and $E(\text{MSE})$ from [Theorem 15.5.2](#). Repeat for the sizes 4, 6, 10, 20 and for 20, 10, 6, 4.

Solution. Balanced: both equal $(1 + 2 + 4 + 8)/4 = 3.75$. Sizes 4, 6, 10, 20 ($n = 40$): $E(\text{SSB}) = 0.9 + 0.85 \cdot 2 + 0.75 \cdot 4 + 0.5 \cdot 8 = 9.6$, so $E(\text{MSB}) = 3.2$; $E(\text{SSE}) = 3 + 10 + 36 + 152 = 201$, so $E(\text{MSE}) = 201/36 \approx 5.58$. The test is conservative. Sizes 20, 10, 6, 4: $E(\text{SSB}) = 0.5 + 0.75 \cdot 2 + 0.85 \cdot 4 + 0.9 \cdot 8 = 12.6$, so $E(\text{MSB}) = 4.2$; $E(\text{SSE}) = 19 + 18 + 20 + 24 = 81$, so $E(\text{MSE}) = 2.25$. The test is liberal.

Exercise A2.

Show that the hat matrix of the one-way model has diagonal entries $1/n_k$ and that $\text{Var}(e_{kj}) = \sigma^2(1 - 1/n_k)$. What is the residual of an observation that is alone in its group, and why is it useless for checking the model?

Solution. The hat matrix is $\mathbf{M}$ of [Eq. 15.1.1](#), whose diagonal entry for an observation of group k is $1/n_k$. By [Proposition 5.5.3](#), $\text{Cov}(\hat{\boldsymbol{\epsilon}}) = \sigma^2(\mathbf{I} - \mathbf{M})$, so $\text{Var}(e_{kj}) = \sigma^2(1 - 1/n_k)$. An observation alone in its group has leverage one, its fitted value is itself, and its residual is identically zero: it carries no information about the variance or about the model.

15.5.6.2 B. Practice

Exercise B1.

Show that for $g = 2$ the Welch statistic F_W equals t_W^2 , where $t_W = (\bar{y}_1 - \bar{y}_2)/\sqrt{s_1^2/n_1 + s_2^2/n_2}$, and that ν_W is Satterthwaite's $(s_1^2/n_1 + s_2^2/n_2)^2 / [(s_1^2/n_1)^2/(n_1 - 1) + (s_2^2/n_2)^2/(n_2 - 1)]$.

Solution. With $g = 2$ the correction factor is 1. Write $v_k = s_k^2/n_k = 1/w_k$ and $W = w_1 + w_2$. The weighted sum of squares of two numbers about their weighted mean is $w_1 w_2 (\bar{y}_1 - \bar{y}_2)^2 / W = (\bar{y}_1 - \bar{y}_2)^2 / (v_1 + v_2)$, which is t_W^2 . Next $1 - w_1/W = w_2/W = v_1/(v_1 + v_2)$, so $h_1 = v_1^2 / \{(v_1 + v_2)^2(n_1 - 1)\}$ and similarly for h_2 . Then $\nu_W = 3 / (3 \sum_k h_k) = (v_1 + v_2)^2 / \{v_1^2/(n_1 - 1) + v_2^2/(n_2 - 1)\}$.

Exercise B2.

Show that for $g = 2$ the Brown–Forsythe statistic also equals t_W^2 , and that its degrees of freedom f equal ν_W . So the two robust tests coincide for two groups and differ only for three or more.

Solution. With two groups, $SSB = n_1 n_2 (\bar{y}_1 - \bar{y}_2)^2 / n$, and the denominator is $(n_2 s_1^2 + n_1 s_2^2) / n$. Their ratio is $(\bar{y}_1 - \bar{y}_2)^2 / (s_1^2 / n_1 + s_2^2 / n_2) = t_W^2$. The weights are $c_1 = (n_2 s_1^2 / n) / \{(n_2 s_1^2 + n_1 s_2^2) / n\} = v_1 / (v_1 + v_2)$ and $c_2 = v_2 / (v_1 + v_2)$, so $1/f = \sum_k c_k^2 / (n_k - 1) = 1/\nu_W$ by the previous exercise.

Exercise B3.

Let $\hat{V} = \sum_k c_k^2 s_k^2 / n_k$ with independent $s_k^2 \sim \sigma_k^2 \chi^2(n_k - 1) / (n_k - 1)$ under normality. Show that $E \hat{V} = V = \text{Var}(\hat{\psi})$ and $\text{Var} \hat{V} = 2 \sum_k (c_k^2 \sigma_k^2 / n_k)^2 / (n_k - 1)$. Choose ν so that $\nu \hat{V} / V$ has the mean and variance of a $\chi^2(\nu)$ variable, and show that replacing σ_k^2 by s_k^2 in the answer gives the degrees of freedom of the Welch–Satterthwaite interval.

Solution. Since $E s_k^2 = \sigma_k^2$, $E \hat{V} = \sum_k c_k^2 \sigma_k^2 / n_k = V$, which is $\text{Var}(\hat{\psi})$ because the group means are independent with variances σ_k^2 / n_k . $\text{Var}(s_k^2) = 2\sigma_k^4 / (n_k - 1)$, and the terms are independent, which gives $\text{Var} \hat{V}$. A $\chi^2(\nu)$ variable has mean ν and variance 2ν . The mean of $\nu \hat{V} / V$ is ν for every ν , and its variance is $\nu^2 \text{Var}(\hat{V}) / V^2$. Setting this equal to 2ν gives $\nu = 2V^2 / \text{Var} \hat{V} = V^2 / \sum_k (c_k^2 \sigma_k^2 / n_k)^2 / (n_k - 1)$. With s_k^2 for σ_k^2 this is the formula in the text.

Exercise B4.

For $n = 30$ observations in five groups, compare the quantity h of [Proposition 15.5.1](#) for the balanced allocation and for the allocation 10, 5, 5, 5, 5 suggested by [Exercise \(B3\)](#) for comparisons with a control. What does each allocation optimize?

Solution. Balanced: $h = 6/2 = 3$. For 10, 5, 5, 5, 5, the least informative pair is two treatments of size 5, with $h = 25/10 = 2.5$. The guaranteed noncentrality of the overall test is $3(\Delta/\sigma)^2$ against $2.5(\Delta/\sigma)^2$. But each comparison with the control has variance $\sigma^2(1/10 + 1/5) = 0.3\sigma^2$ instead of $\sigma^2/3$. Balance protects the overall test and the comparisons among treatments; the unbalanced allocation sharpens the comparisons with the control.

15.5.6.3 C. Going deeper

Exercise C1.

In a balanced layout, suppose that under equal means the errors within a group are equicorrelated, $\text{Cov}(\varepsilon_{kj}, \varepsilon_{kj'}) = \rho\sigma^2$ for $j \neq j'$ with $\rho \geq 0$, and independent between groups. Show that $E(\text{MSE}) = \sigma^2(1 - \rho)$ and $E(\text{MSB}) = \sigma^2(1 - \rho + m\rho)$. What happens to the level of the F test with $m = 10$ and $\rho = 0.1$?

Solution. The covariance matrix is $\sigma^2\{(1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top\}$, the random-effects form with $\sigma_a^2 = \rho\sigma^2$ and error variance $(1 - \rho)\sigma^2$. By [Exercise \(C1\)](#) with $n_0 = m$, $E(\text{MSE}) = (1 - \rho)\sigma^2$ and $E(\text{MSB}) = (1 - \rho)\sigma^2 + m\rho\sigma^2$. Under normality $\text{MSB}/E(\text{MSB})$ and $\text{MSE}/E(\text{MSE})$ are independent scaled chi-squared variables, so F is $1 + m\rho/(1 - \rho)$ times an $F(g - 1, n - g)$ variable. With $m = 10$ and $\rho = 0.1$ the factor is $1 + 1/0.9 \approx 2.1$, and a nominal 5% test rejects far more often: with $g = 4$ groups its level is 0.271. A small intraclass correlation does great damage when groups are large.

Exercise C2.

In a balanced layout with variances σ_k^2 , show that the pooled variance estimate of the pairwise difference $\bar{Y}_k - \bar{Y}_l$, $2s^2/m$, has expectation $2\bar{\sigma}^2/m$ with $\bar{\sigma}^2 = g^{-1} \sum_i \sigma_i^2$, while the true variance is $(\sigma_k^2 + \sigma_l^2)/m$. Conclude that balance protects the overall test but not individual comparisons, and find the ratio of true to estimated variance for the two most variable groups when the variances are 1, 2, 4, 8.

Solution. By [Theorem 15.5.2\(c\)](#), in a balanced layout $E(s^2) = \bar{\sigma}^2$, so $E(2s^2/m) = 2\bar{\sigma}^2/m$, and the true variance is $\sigma_k^2/m + \sigma_l^2/m$ because the means are independent. For the groups with variances 4 and 8, the true variance is $12/m$ and the pooled estimate targets $2 \cdot 3.75/m = 7.5/m$, a ratio of 1.6. Intervals for that difference built from s^2 are too short by a factor of about $\sqrt{1.6} \approx 1.26$, and intervals for the difference of the two least variable groups are too long.

15.6 Summary and Notes

15.6.1 Summary

Idea.

1. The one-way layout has mean space $\mathcal{C}(\mathbf{Z})$, the vectors constant within groups, in both its forms ([Definition 15.1.1](#)). The fit is the group means, and s^2 pools the group variances. Different side conditions define different “overall means” when the layout is unbalanced ([Section 15.1](#)).
2. Contrasts are the directions of the treatment space $\mathcal{T} = \mathcal{C}(\mathbf{Z}) \cap \mathbf{1}^\perp$, and a contrast’s test, interval and sum of squares come from the projection onto its line ([Proposition 15.2.1](#)). Families use Bonferroni or Dunnett for comparisons with a control, Tukey for all pairs and Scheffé for contrasts suggested by the data ([Section 15.2](#)).
3. A contrast test captures the fraction $\cos^2 \varphi$ of the overall noncentrality, φ being its angle with the true treatment component ([Proposition 15.2.2](#)): a well-chosen planned contrast beats the overall test, a badly chosen one has no power.
4. The decomposition $\mathbf{I} = \mathbf{P}_0 + (\mathbf{M} - \mathbf{P}_0) + (\mathbf{I} - \mathbf{M})$ gives the analysis of variance table. The F statistic has the $F(g-1, n-g, \gamma)$ law with $\gamma = \sum_k n_k (\mu_k - \bar{\mu})^2 / \sigma^2$, and it is the likelihood ratio test of equal means ([Theorem 15.3.1](#)). Without normality, $E(\text{MSE}) = \sigma^2$ and $E(\text{MSB}) = \sigma^2 + \sum_k n_k (\mu_k - \bar{\mu})^2 / (g-1)$ ([Theorem 15.3.2](#)). The quantity $(g-1)F$ is the largest squared contrast t statistic.
5. A complete set of orthogonal contrasts, orthogonal in the sense $\sum_k c_k d_k / n_k = 0$, splits SSB into $g-1$ independent single-degree-of-freedom pieces whose noncentralities add up to γ , and F is the average of their F statistics ([Theorem 15.4.1](#)). Successive splits of the treatments give such sets for any group sizes ([Proposition 15.4.2](#)), and polynomial contrasts give a trend analysis, whose higher-degree pieces are the pure-error lack-of-fit test of a low-degree curve ([Example \(The shape of the nitrogen response\)](#)).
6. Balance makes design orthogonality plain orthogonality and maximizes the noncentrality guaranteed against every configuration of means with a given range

([Proposition 15.5.1](#)).

7. With unequal variances, MSB and MSE estimate the same average variance under equal means if the layout is balanced, but not otherwise. The classical test is liberal when the small groups are the variable ones and conservative when the large groups are ([Theorem 15.5.2](#)). The tests of Welch and of Brown and Forsythe hold their level approximately, and Welch–Satterthwaite intervals do the same for contrasts ([Section 15.5](#)).
8. Residuals have variance $\sigma^2(1 - 1/n_k)$; plotted against the group means and on a normal quantile plot after studentizing, they check the variances and normality. Within-group correlation, which the data cannot reveal, is the most damaging failure.

15.6.2 Notes and sources

Origins. The analysis of variance is Fisher’s. It appears in *Statistical Methods for Research Workers* (Fisher 1925), developed for the field experiments at Rothamsted, and *The Design of Experiments* (Fisher 1935) made randomization the logical basis of the analysis. The derivation of the one-way model from unit–treatment additivity and random assignment, sketched in [Section 15.1](#), is developed in detail by Kempthorne (1952). Scheffé (1959) remains the classic treatment of the fixed-effects theory, including the effects of departures from the assumptions.

The textbook treatments. Christensen (2020, chapter 4) derives the one-way analysis entirely from the projections $\mathbf{M}$ and $\mathbf{M} - \mathbf{P}_0$, including the characterization of contrasts through the space onto which $\mathbf{M} - \mathbf{P}_0$ projects; this chapter follows his geometric approach, with the treatment space as the organizing object. Rencher and Schaalje (2008, chapter 13) give the balanced case through full-and-reduced models and through the general linear hypothesis, derive the expected mean squares both ways, and treat orthogonal and orthogonal polynomial contrasts, including the result that the overall F statistic averages the single-degree-of-freedom statistics of a complete orthogonal set. Their section 12.7 covers the testable hypotheses of non-full-rank models used in [Theorem 15.3.1](#). Seber and Lee (2003, section 8.2) discuss simultaneous intervals and the assumptions, including unequal variances. Note that Rencher and Schaalje and Christensen define noncentrality as half of our γ .

Contrasts and multiple comparisons. Tables of orthogonal polynomials for equally spaced levels go back at least to Fisher and Yates (1938). The exact method for comparisons with a control is due to Dunnett (1955), and the conservativeness of the Tukey–Kramer intervals for unequal group sizes was proved by Hayter (1984); [Chapter 13 \(Exercise \(B2\)\)](#) characterizes the many-to-one multiplier and gives further references. [Proposition 15.2.2](#) and [Proposition 15.4.2](#) are elementary consequences of the projection picture. Part (a) of [Proposition 15.5.1](#) is [Exercise \(B1\)](#) of [Chapter 11](#); part (b), the optimality of balance, is a short calculation.

Unequal variances. Box (1954) computed the effect of unequal variances on the one-way F test, showing that it is small when the groups are of equal size and can be large otherwise, in the directions described by [Theorem 15.5.2](#). The test of Welch (1951) weights the groups by their estimated precisions; the test of Brown and Forsythe (1974a) keeps the unweighted numerator and estimates its null expectation. Welch obtained his correction factor and degrees of freedom from a series expansion of the statistic’s distribution to first order in $1/(n_k - 1)$; the Brown–Forsythe degrees of freedom, like those of the contrast intervals, are Satterthwaite’s (1946) moment match. The robust test of equal variances by analysis of variance of absolute deviations is due to Levene (1960), and the version based on deviations from medians to Brown

and Forsythe (1974b). The simulation of [Example \(How far the level moves\)](#) is ours. [Chapter 21](#) returns to heteroscedasticity with weighted least squares and heteroscedasticity-consistent standard errors, and [Chapter 32](#) to random effects.

Chapter 16

Multi-Way Layouts and Interaction

An experiment with several factors asks more than one question. It asks whether each factor matters, and also whether the effect of one factor depends on the level of another. In a balanced layout, where every combination of levels is observed equally often, these questions correspond to mutually orthogonal subspaces of observation space. Each subspace has a projection that is a Kronecker product of averaging and centring matrices, and the analysis of variance is Pythagoras applied to that decomposition. This chapter builds the decomposition for two factors, with and without replication, for any number of crossed factors, and for factors nested inside other factors. The algebra is the easy part. The harder part is interpretation: what an interaction is, when a transformation removes it, what a main effect means when interaction is present, and when it is safe to pool one term into another.

What you need. Kronecker products ([Section 1.10](#)); independence of projections of a normal vector and the noncentral F distribution ([Chapter 4](#)); nested projections and the two-factor projection identity of [Example \(Additive two-factor model, one observation per cell\)](#) ([Section 6.5](#)); estimability with two factors ([Section 8.6](#)); analysis of variance decompositions, orthogonal designs and expected mean squares ([Chapter 9](#)); F tests of reduced models ([Chapter 11](#)); simultaneous inference ([Chapter 13](#)); the lack-of-fit test and regressors built from fitted values ([Sections 14.6 and 14.7](#)); and the one-way analysis of variance ([Chapter 15](#)).

16.0.1 Roadmap

- [Two-way additive models](#)
- [Interaction and its interpretation](#)
- [Balanced two-way layouts via orthogonal projections](#)
- [Higher-way layouts](#)
- [Nested factors](#)
- [Summary and notes](#)

16.1 Two-way additive models

Two factors are observed together. Factor A has levels $i = 1, \dots, a$ and factor B has levels $j = 1, \dots, b$, with $a, b \geq 2$. Every one of the ab combinations, or **cells**, is observed the same

number $m \geq 1$ of times. We write y_{ijk} for the k th observation in cell (i, j) , so that $n = abm$. [Example \(Additive two-factor model, one observation per cell\)](#) found the projections of the additive model for $m = 1$ by a direct argument. This section redoes it with the tools used throughout the chapter, and adds replication, estimable functions, tests, and a test of additivity with one observation per cell.

16.1.1 Averaging and centring matrices

Stack the observations with the replicate index k running fastest, then j , then i :

$$\mathbf{y} = (y_{111}, \dots, y_{11m}, y_{121}, \dots, y_{12m}, \dots, y_{ab1}, \dots, y_{abm})^\top.$$

With this order a matrix of the form $\mathbf{E}_a \otimes \mathbf{E}_b \otimes \mathbf{E}_m$ acts on each index separately, as in [Example \(The balanced two-way layout\)](#). For $k \geq 1$ write

$$\bar{\mathbf{J}}_k = \frac{1}{k} \mathbf{1}_k \mathbf{1}_k^\top, \quad \mathbf{C}_k = \mathbf{I}_k - \bar{\mathbf{J}}_k.$$

The **averaging matrix** $\bar{\mathbf{J}}_k$ replaces each entry of a k -vector by the mean of the entries. The **centring matrix** $\mathbf{C}_k$ subtracts that mean. With the usual dot notation for means, the following products replace y_{ijk} by

$$\begin{aligned} (\mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m) \mathbf{y} &: \bar{y}_{ij\cdot}, & (\mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m) \mathbf{y} &: \bar{y}_{i\cdot\cdot}, \\ (\bar{\mathbf{J}}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m) \mathbf{y} &: \bar{y}_{\cdot j\cdot}, & (\bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m) \mathbf{y} &: \bar{y}_{\cdot\cdot\cdot}, \end{aligned}$$

the cell, row, column and grand means. Each operator averages over the indices where it has a $\bar{\mathbf{J}}$ and leaves the others alone. Every projection in this chapter is a Kronecker product of factors $\mathbf{I}$, $\bar{\mathbf{J}}$ and $\mathbf{C}$, and the following lemma is all the algebra they need.

Lemma 16.1.1 — Kronecker products of averaging and centring matrices

Let $l_1, \dots, l_t \geq 1$.

- (a) $\bar{\mathbf{J}}_k$ and $\mathbf{C}_k$ are symmetric and idempotent, with ranks 1 and $k - 1$, and $\bar{\mathbf{J}}_k \mathbf{C}_k = \mathbf{0}$, $\bar{\mathbf{J}}_k + \mathbf{C}_k = \mathbf{I}_k$.
- (b) If each $\mathbf{E}_s$ is one of $\mathbf{I}_{l_s}$, $\bar{\mathbf{J}}_{l_s}$, $\mathbf{C}_{l_s}$, then $\mathbf{E}_1 \otimes \dots \otimes \mathbf{E}_t$ is an orthogonal projection whose rank is the product of the ranks of the $\mathbf{E}_s$.
- (c) If each $\mathbf{E}_s$ and each $\mathbf{F}_s$ is one of $\bar{\mathbf{J}}_{l_s}$, $\mathbf{C}_{l_s}$, and $\mathbf{E}_s \neq \mathbf{F}_s$ for at least one s , then $(\mathbf{E}_1 \otimes \dots \otimes \mathbf{E}_t)(\mathbf{F}_1 \otimes \dots \otimes \mathbf{F}_t) = \mathbf{0}$.
- (d) The 2^t products $\mathbf{E}_1 \otimes \dots \otimes \mathbf{E}_t$ with each $\mathbf{E}_s \in \{\bar{\mathbf{J}}_{l_s}, \mathbf{C}_{l_s}\}$ sum to $\mathbf{I}$.

Proof.

- (a) $\bar{\mathbf{J}}_k$ is symmetric and $\bar{\mathbf{J}}_k^2 = k^{-2} \mathbf{1}(\mathbf{1}^\top \mathbf{1}) \mathbf{1}^\top = \bar{\mathbf{J}}_k$. Its trace is 1. Then $\mathbf{C}_k = \mathbf{I} - \bar{\mathbf{J}}_k$ is the complementary projection, with trace $k - 1$, and $\bar{\mathbf{J}}_k \mathbf{C}_k = \bar{\mathbf{J}}_k - \bar{\mathbf{J}}_k^2 = \mathbf{0}$. Ranks equal traces by [Proposition 6.3.4](#). (b) By [Proposition 1.10.1\(e\)](#) a Kronecker product of symmetric idempotent matrices is symmetric and idempotent, and by [Proposition 1.10.1\(c\)](#) its rank is the product of the ranks. (c) By the mixed-product rule the product equals $\mathbf{E}_1 \mathbf{F}_1 \otimes \dots \otimes \mathbf{E}_t \mathbf{F}_t$, and the factor with $\mathbf{E}_s \neq \mathbf{F}_s$ is $\bar{\mathbf{J}} \mathbf{C} = \mathbf{0}$ or $\mathbf{C} \bar{\mathbf{J}} = \mathbf{0}$. (d) Expand $\mathbf{I} = (\bar{\mathbf{J}}_{l_1} + \mathbf{C}_{l_1}) \otimes \dots \otimes (\bar{\mathbf{J}}_{l_t} + \mathbf{C}_{l_t})$ by bilinearity of the Kronecker product.

The rank $k - 1$ of $\mathbf{C}_k$ is the source of every “levels minus one” in the analysis of variance, and part (d) is the source of every analysis of variance table in this chapter. Part (b) allows $k = 1$: then $\bar{\mathbf{J}}_1 = \mathbf{1}$ and $\mathbf{C}_1 = \mathbf{0}$.

```

    return P

def rank(A):
    return int(round(np.trace(A)))           # rank = trace for a projection
```

16.1.2 The additive model

The **additive two-way model** is

$$E(y_{ijk}) = \mu + \alpha_i + \beta_j, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}, \quad (16.1.1)$$

with model matrix $\mathbf{X} = [\mathbf{1}_n, \mathbf{Z}_A, \mathbf{Z}_B]$, where $\mathbf{Z}_A = \mathbf{I}_a \otimes \mathbf{1}_b \otimes \mathbf{1}_m$ and $\mathbf{Z}_B = \mathbf{1}_a \otimes \mathbf{I}_b \otimes \mathbf{1}_m$ are the indicator matrices of the two factors. It says that the difference between two levels of A is the same in every column and, symmetrically, that the difference between two levels of B is the same in every row. The model has $1 + a + b$ parameters and, by [Theorem 8.6.1\(a\)](#), rank $a + b - 1$. Define

$$\begin{aligned}
\mathbf{P}_0 &= \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, \\
\mathbf{P}_A &= \mathbf{C}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, \\
\mathbf{P}_B &= \bar{\mathbf{J}}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m,
\end{aligned} \tag{16.1.2}$$

and $\mathbf{R} = \mathbf{I} - \mathbf{P}_0 - \mathbf{P}_A - \mathbf{P}_B$. By the table of means above, $\mathbf{P}_A \mathbf{y}$ has entry $\bar{y}_{i..} - \bar{y}_{...}$ in every position of row i , and $\mathbf{P}_B \mathbf{y}$ has entry $\bar{y}_{.j.} - \bar{y}_{...}$ in every position of column j .

16.1.3 Additivity with one observation per cell

Many two-factor data sets have one observation per cell, such as methods each run once on several test problems. By [Example \(Additive two-factor model, one observation per cell\)](#) the residual space of the additive model then has dimension $(a-1)(b-1)$, and the residuals are the interaction terms $y_{ij} - \bar{y}_{i.} - \bar{y}_{.j} + \bar{y}_{...}$. The residual sum of squares then serves two purposes. It estimates σ^2 if the model is additive, and it is the only place where nonadditivity could show. There is no model-free estimate of σ^2 , and no test of additivity against a general alternative.

A test is still possible against a *specific* kind of departure. Suppose the cell means are additive on some other scale, $\mu_{ij} = f(\nu + a_i + b_j)$, for a smooth increasing function f and small effects a_i, b_j with $\sum a_i = \sum b_j = 0$. A second-order Taylor expansion about ν gives

$$\mu_{ij} \approx f(\nu) + f'(\nu)(a_i + b_j) + \frac{1}{2}f''(\nu)(a_i^2 + b_j^2) + f''(\nu)a_i b_j.$$

The terms in a_i^2 and b_j^2 are additive. Only the product term is not. To first order the row and column effects of μ_{ij} are $\alpha_i \approx f'(\nu)a_i$ and $\beta_j \approx f'(\nu)b_j$, so the interaction is approximately

$$\mu_{ij} - \bar{\mu}_{i.} - \bar{\mu}_{.j} + \bar{\mu}_{...} \approx \theta \alpha_i \beta_j, \quad \theta = \frac{f''(\nu)}{f'(\nu)^2}. \tag{16.1.3}$$

Tukey (1949) proposed to look for interaction of exactly this shape. The row and column effects are estimated by $r_i = \bar{y}_{i.} - \bar{y}_{...}$ and $c_j = \bar{y}_{.j} - \bar{y}_{...}$ (with $m = 1$ we drop the third subscript). The residuals are then regressed on the products $r_i c_j$. The table $(r_i c_j)$ has zero row and column sums, so it lies in the residual space. The regression through the origin of the residual table on it has slope and sum of squares

$$\hat{\theta} = \frac{\sum_{i,j} r_i c_j y_{ij}}{\sum_i r_i^2 \sum_j c_j^2}, \quad \text{SS}_N = \frac{(\sum_{i,j} r_i c_j y_{ij})^2}{\sum_i r_i^2 \sum_j c_j^2}. \tag{16.1.4}$$

The regressor is computed from the same data, so [Proposition 14.7.1](#) does not apply. But a regressor that is a function of the fitted values alone leaves the F test exact ([Theorem 14.7.2](#)), and part (f) of the next theorem shows that Tukey's regressor is of this kind.

16.1.4 Estimation and tests

The following theorem collects what the additive model delivers in a balanced layout, with and without replication.

Theorem 16.1.2 — The additive two-way model

Assume Eq. 16.1.1 with $m \geq 1$ observations in every cell.

- (a) $\mathbf{P}_0, \mathbf{P}_A, \mathbf{P}_B$ and $\mathbf{R}$ are mutually orthogonal projections summing to $\mathbf{I}$, with ranks 1, $a-1$, $b-1$ and $n-a-b+1$. The projection onto $\mathcal{C}(\mathbf{X})$ is $\mathbf{M} = \mathbf{P}_0 + \mathbf{P}_A + \mathbf{P}_B$, and the fitted values are $\hat{y}_{ijk} = \bar{y}_{i..} + \bar{y}_{.j.} - \bar{y}_{...}$.
- (b) $\lambda_0\mu + \sum_i \lambda_i \alpha_i + \sum_j \kappa_j \beta_j$ is estimable iff $\lambda_0 = \sum_i \lambda_i = \sum_j \kappa_j$. The BLUE of a contrast $\sum_i c_i \alpha_i$ is $\sum_i c_i \bar{y}_{i..}$, with variance $\sigma^2 \sum_i c_i^2 / (bm)$. These are the estimate and variance of the one-way layout in A that ignores B . The estimate of a contrast in the α_i is uncorrelated with the estimate of any contrast in the β_j .
- (c) Under normal errors, $SS_A = \|\mathbf{P}_A \mathbf{y}\|^2 = bm \sum_i (\bar{y}_{i..} - \bar{y}_{...})^2$, $SS_B = \|\mathbf{P}_B \mathbf{y}\|^2 = am \sum_j (\bar{y}_{.j.} - \bar{y}_{...})^2$ and $SSE = \|\mathbf{R} \mathbf{y}\|^2$ are independent, $SSE/\sigma^2 \sim \chi^2(n-a-b+1)$, and

$$F_A = \frac{SS_A/(a-1)}{SSE/(n-a-b+1)} \sim F(a-1, n-a-b+1, \gamma_A), \quad \gamma_A = \frac{bm}{\sigma^2} \sum_i (\alpha_i - \bar{\alpha})^2,$$

with $\bar{\alpha} = a^{-1} \sum_i \alpha_i$. So F_A is an exact test of $\alpha_1 = \cdots = \alpha_a$. Its numerator is that of the one-way F test in A that ignores B (Theorem 15.3.1); only the error term differs. The same holds for B , with $\gamma_B = (am/\sigma^2) \sum_j (\beta_j - \bar{\beta})^2$.

- (d) If $m \geq 2$, then $\mathbf{R} = \mathbf{P}_{AB} + \mathbf{P}_E$ with $\mathbf{P}_{AB} = \mathbf{C}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m$ and $\mathbf{P}_E = \mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{C}_m$, of ranks $(a-1)(b-1)$ and $ab(m-1)$. The squared lengths $\|\mathbf{P}_{AB} \mathbf{y}\|^2$ and $\|\mathbf{P}_E \mathbf{y}\|^2$ are the lack-of-fit and pure-error sums of squares of the additive model (Definition 14.6.1). If the cell means μ_{ij} are arbitrary, the lack-of-fit F test of additivity has noncentrality

$$\gamma_{AB} = \frac{m}{\sigma^2} \sum_{i,j} (\mu_{ij} - \bar{\mu}_{i.} - \bar{\mu}_{.j} + \bar{\mu}_{..})^2.$$

- (e) If $m = 1$, then $\mathbf{R} = \mathbf{C}_a \otimes \mathbf{C}_b$, and the residual space consists of the $a \times b$ tables whose rows and columns all sum to zero. There is no pure error.
- (f) (*Tukey's test.*) If $m = 1$, the errors are normal and $(a-1)(b-1) \geq 2$, then with SS_N as in Eq. 16.1.4,

$$F_N = \frac{SS_N}{(SSE - SS_N)/((a-1)(b-1)-1)} \sim F(1, (a-1)(b-1)-1).$$

Proof.

- (a) By Lemma 16.1.1(c) the three projections $\mathbf{P}_0, \mathbf{P}_A, \mathbf{P}_B$ are mutually orthogonal, and their ranks are 1, $a-1$, $b-1$ by Lemma 16.1.1(b). Moreover $\mathbf{P}_0 + \mathbf{P}_A = \mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m$ replaces each observation by its row mean. It is the projection onto $\mathcal{C}(\mathbf{Z}_A)$, the vectors that are constant on rows (Example (The one-way layout)). Likewise $\mathbf{P}_0 + \mathbf{P}_B$ projects onto $\mathcal{C}(\mathbf{Z}_B)$. Hence

$$\mathcal{C}(\mathbf{X}) = \mathcal{C}(\mathbf{Z}_A) + \mathcal{C}(\mathbf{Z}_B) = (\mathcal{C}(\mathbf{P}_0) \oplus \mathcal{C}(\mathbf{P}_A)) + (\mathcal{C}(\mathbf{P}_0) \oplus \mathcal{C}(\mathbf{P}_B)) = \mathcal{C}(\mathbf{P}_0) \oplus \mathcal{C}(\mathbf{P}_A) \oplus \mathcal{C}(\mathbf{P}_B),$$

a sum of mutually orthogonal subspaces. By Theorem 6.3.7 its projection is $\mathbf{P}_0 + \mathbf{P}_A + \mathbf{P}_B$. Then $\mathbf{R} = \mathbf{I} - \mathbf{M}$ is the complementary projection, orthogonal to the other three, with rank $n - (a+b-1)$. The fitted values are $\mathbf{M} \mathbf{y} = (\mathbf{P}_0 + \mathbf{P}_A) \mathbf{y} +$

$$(\mathbf{P}_0 + \mathbf{P}_B)\mathbf{y} - \mathbf{P}_0\mathbf{y}.$$

- (b) The design is complete, hence connected, and the estimability condition is [Exercise \(C1\)](#) with a single component. For the estimator, $E(\bar{y}_{i..}) = \mu + \alpha_i + \bar{\beta}$, so $\sum_i c_i \bar{y}_{i..}$ is unbiased for $\sum_i c_i \alpha_i$ when $\sum_i c_i = 0$. It equals $\boldsymbol{\rho}^\top \mathbf{y}$ with $\boldsymbol{\rho} = (bm)^{-1} \mathbf{c} \otimes \mathbf{1}_b \otimes \mathbf{1}_m$, and $\boldsymbol{\rho} = \mathbf{P}_A \boldsymbol{\rho} \in \mathcal{C}(\mathbf{X})$ because $\mathbf{c} \perp \mathbf{1}_a$. So $(\mathbf{I} - \mathbf{M})\boldsymbol{\rho} = \mathbf{0}$, and by [Eq. 7.2.1](#) its variance equals that of the BLUE. By [Theorem 7.2.1\(c\)](#) it is the BLUE. Its variance is $\sigma^2 \|\boldsymbol{\rho}\|^2 = \sigma^2 \sum_i c_i^2 / (bm)$. The one-way layout in A has bm observations per level, and [Theorem 8.7.1](#) gives the same estimator and variance. A contrast in the β_j has coefficient vector $\boldsymbol{\rho}_B \in \mathcal{C}(\mathbf{P}_B)$, and $\text{Cov}(\boldsymbol{\rho}^\top \mathbf{Y}, \boldsymbol{\rho}_B^\top \mathbf{Y}) = \sigma^2 \boldsymbol{\rho}^\top \boldsymbol{\rho}_B = 0$.
- (c) The spaces $\mathcal{C}(\mathbf{P}_0), \mathcal{C}(\mathbf{P}_A), \mathcal{C}(\mathbf{P}_B)$ form an analysis of variance decomposition of $\mathcal{C}(\mathbf{X})$ ([Definition 9.1.1](#)), so [Corollary 9.6.2](#) applies. The mean vector has entries $\mu + \alpha_i + \beta_j$. Its row means minus its grand mean are $\alpha_i - \bar{\alpha}$, so $\|\mathbf{P}_A \boldsymbol{\mu}\|^2 = bm \sum_i (\alpha_i - \bar{\alpha})^2$. This is zero iff all α_i are equal. The formula for SS_A is the same computation applied to $\mathbf{y}$.
- (d) By [Lemma 16.1.1\(d\)](#) with $t = 3$, $\mathbf{I}$ is the sum of the eight products $\mathbf{E}_a \otimes \mathbf{E}_b \otimes \mathbf{E}_m$. The four with $\mathbf{E}_m = \bar{\mathbf{J}}_m$ are $\mathbf{P}_0, \mathbf{P}_A, \mathbf{P}_B, \mathbf{P}_{AB}$. The four with $\mathbf{E}_m = \mathbf{C}_m$ add up to $\mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{C}_m = \mathbf{P}_E$. So $\mathbf{R} = \mathbf{P}_{AB} + \mathbf{P}_E$, with ranks from [Lemma 16.1.1\(b\)](#). The matrix $\mathbf{I} - \mathbf{P}_E = \mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m$ replaces each observation by its cell mean. It is the projection $\mathbf{M}_Z$ onto the cell-indicator space, the $\mathbf{Z}$ of [Definition 14.6.1](#). Hence $\mathbf{P}_E = \mathbf{I} - \mathbf{M}_Z$ and $\mathbf{P}_{AB} = \mathbf{M}_Z - \mathbf{M}$. By [Theorem 14.6.2](#) the noncentrality is $\|(\mathbf{I} - \mathbf{M})\boldsymbol{\theta}\|^2 / \sigma^2$, where $\boldsymbol{\theta}$ has entries μ_{ij} . Here $(\mathbf{I} - \mathbf{M})\boldsymbol{\theta} = \mathbf{P}_{AB}\boldsymbol{\theta}$, because $\mathbf{P}_E\boldsymbol{\theta} = \mathbf{0}$. Its entries are the displayed interaction terms, each repeated m times.
- (e) With $m = 1$, $\bar{\mathbf{J}}_1 = \mathbf{1}$ and $\mathbf{C}_1 = \mathbf{0}$, so $\mathbf{P}_E = \mathbf{0}$ and $\mathbf{R} = \mathbf{P}_{AB} = \mathbf{C}_a \otimes \mathbf{C}_b$. A vector $\mathbf{v}$, read as an $a \times b$ table $\mathbf{V}$, satisfies $(\mathbf{C}_a \otimes \mathbf{C}_b)\mathbf{v} = \mathbf{v}$ iff $\mathbf{C}_a \mathbf{V} \mathbf{C}_b = \mathbf{V}$, which holds iff $\mathbf{V} \mathbf{1}_b = \mathbf{0}$ and $\mathbf{1}_a^\top \mathbf{V} = \mathbf{0}^\top$.
- (f) Write $\hat{y}_{ij} = \bar{y}_{..} + r_i + c_j$, let $\mathbf{r} = (r_i)$ and $\mathbf{c} = (c_j)$, and put $\mathbf{U} = \mathbf{r} \otimes \mathbf{c}$, the table $(r_i c_j)$. Expanding,

$$\hat{y}_{ij}^2 = (\bar{y}_{..}^2 + r_i^2 + 2\bar{y}_{..}r_i) + (c_j^2 + 2\bar{y}_{..}c_j) + 2r_i c_j.$$

The first bracket depends on i alone and the second on j alone, so both lie in $\mathcal{C}(\mathbf{X})$. Since $\mathbf{1}_a^\top \mathbf{r} = \mathbf{1}_b^\top \mathbf{c} = 0$, $\mathbf{R}\mathbf{U} = \mathbf{C}_a \mathbf{r} \otimes \mathbf{C}_b \mathbf{c} = \mathbf{U}$ by (e). Hence the column $\mathbf{W} = (\hat{y}_{ij}^2)$, a function of $\mathbf{M}\mathbf{Y}$, satisfies $(\mathbf{I} - \mathbf{M})\mathbf{W} = 2\mathbf{U}$. By [Theorem 9.2.2](#) the extra sum of squares from adding $\mathbf{W}$ to the additive model is $(\mathbf{U}^\top \mathbf{y})^2 / \mathbf{U}^\top \mathbf{U}$, and $\mathbf{U}^\top \mathbf{U} = \sum_i r_i^2 \sum_j c_j^2$, so it is SS_N , and $\text{SSE} - \text{SS}_N$ is the residual sum of squares of the augmented model. The rank condition of [Theorem 14.7.2](#) holds because $\mathbf{U} \neq \mathbf{0}$ with probability one: $\mathbf{U} = \mathbf{0}$ only if $\mathbf{P}_A \mathbf{Y} = \mathbf{0}$ or $\mathbf{P}_B \mathbf{Y} = \mathbf{0}$, and each event has probability zero, because $\|\mathbf{P}_A \mathbf{Y}\|^2 / \sigma^2$ has a continuous (noncentral χ^2) distribution on $a - 1 \geq 1$ degrees of freedom, and likewise for B . So $\text{rank}[\mathbf{X}, \mathbf{W}] = a + b$, which is less than $n = ab$ because $(a - 1)(b - 1) \geq 2$. [Theorem 14.7.2](#) with $q = 1$ and $n - r - q = (a - 1)(b - 1) - 1$ gives the distribution of F_N .

■

Part (b) is the practical content of balance: rows are compared exactly as if the columns did not exist. The columns still matter, because they remove their own variation from the error.

The listing builds the five projections of part (d) for $a = 3$, $b = 4$, $m = 2$ and checks their ranks, orthogonality and sum. The script also checks each identification in the proof against projections computed from indicator columns.

```

a, b, m = 3, 4, 2
P = factorial_projections([a, b], m)
names = {(0, 0): "mean", (1, 0): "A", (0, 1): "B", (1, 1): "AB", "error": "error"}
for key, name in names.items():
    print(f"{name:6s} rank {rank(P[key])}")
keys = list(names)
worst = max(np.abs(P[s] @ P[t]).max() for s, t in itertools.combinations(keys, 2))
print("largest entry of any product P_s P_t, s != t:", f"{worst:.1e}")
print("sum is the identity:", np.allclose(sum(P[k] for k in keys), np.eye(a * b * m)
))

```

16.1.5 Tukey's test in practice

Tukey's test ([Theorem 16.1.2\(f\)](#)) is exact against every additive model, whatever the values of μ , α_i , β_j . It has power against interactions roughly proportional to $\alpha_i\beta_j$, the kind produced by measuring on the wrong scale, and little against anything else. The estimated slope says which scale. If f is the inverse of a power transformation, so that y^p is additive, then $f(t) = t^{1/p}$, and [Eq. 16.1.3](#) gives $\theta = (1 - p)/f(\nu)$ ([Exercise \(B3\)](#)). Replacing $f(\nu)$ by the grand mean suggests the power

$$\hat{p} = 1 - \hat{\theta} \bar{y}_{..}, \quad (16.1.5)$$

with $\hat{p} = 0$ read as the logarithm. The rule is rough, but it turns a vague complaint into a specific suggestion.

Example. (Solvers on benchmark problems)

Six solvers were each run once on eight benchmark problems, and the running time was recorded in seconds. The data are synthetic, generated by the script `tukey_runtime.py` so that the logarithm of time is additive in solver and problem, with a little noise:

	P1	P2	P3	P4	P5	P6	P7	P8
S1	1.7	3.4	5.6	14.1	28.1	50.2	82.9	249.4
S2	2.1	5.7	9.0	14.7	36.9	76.0	116.7	292.0
S3	1.3	3.1	5.1	10.5	18.8	37.6	82.2	148.3
S4	3.3	9.1	12.7	19.1	52.8	110.0	183.1	371.8
S5	2.0	4.7	7.2	13.5	31.4	65.2	111.1	289.3
S6	1.5	3.4	5.4	10.4	26.0	43.2	106.3	172.0

Figure 16.1.1: Tukey's diagnostic plot for the solver data: residuals of the additive fit against the comparison values $r_i c_j / \bar{y}_{..}$, with the fitted line of slope $\hat{\theta}\bar{y}_{..} = 1 - \hat{p}$. (a) In seconds the residuals lie along a line of slope near one, which points to the logarithm. (b) In log seconds there is no trend.

The additive model in seconds leaves a residual sum of squares of 29396 on 35 degrees of freedom. Tukey's single direction takes $SS_N = 26126$ of it, a fraction 0.889, and $F_N = 271.7$ on 1 and 34 degrees of freedom ($p = 9 \times 10^{-18}$). The interaction has exactly the shape of Eq. 16.1.3: fast problems separate the solvers by fractions of a second, slow problems by minutes. The slope is $\hat{\theta} = 0.01563$ and the grand mean is 61.46, so Eq. 16.1.5 suggests the power 0.04, essentially the logarithm. Figure 16.1.1 shows the diagnostic plot. On the log scale, $F_N = 0.27$ ($p = 0.60$), and the residuals show no trend against $r_i c_j / \bar{y}_{..}$.

The scale changes the conclusion about the solvers. In seconds, $F_A = 3.88$ ($p = 0.007$), because the nonadditivity inflates the error term. In log seconds, $F_A = 77.7$. The residual standard deviation is $s = 0.105$, so differences between solvers are measured in proportions of about ten per cent. By Exercise (B1) the solver means of log time are independent with common variance $\sigma^2/8$ and independent of s^2 . Tukey's method therefore gives simultaneous intervals for all 15 ratios of solver speeds, with multiplier $q_{0.05}(6, 35) = 4.261$. Solver 4, the slowest, takes 2.50 times as long as solver 3, the fastest, with simultaneous 95% interval [2.14, 2.94].

```
import numpy as np
from scipy import stats

gen_rng = np.random.default_rng(16_01)
a, b = 6, 8
solver_log = np.array([0.0, 0.25, -0.35, 0.55, 0.1, -0.2]) # log speed
factors
problem_log = np.log([2.0, 4.5, 7.0, 12.0, 25.0, 60.0, 110.0, 240.0]) # typical
seconds
noise = gen_rng.normal(scale=0.12, size=(a, b))
times = np.round(np.exp(solver_log[:, None] + problem_log[None, :] + noise), 1)

def additive_fit(Y):
    """Row effects, column effects and residuals of the additive fit to an a x b
    table."""
    g = Y.mean()
```

```

r = Y.mean(axis=1) - g                                # ybar_i. - ybar..
c = Y.mean(axis=0) - g                                # ybar_.j - ybar..
resid = Y - g - r[:, None] - c[None, :]
return g, r, c, resid

def tukey_test(Y):
    """Tukey's one-degree-of-freedom test for nonadditivity in an a x b table."""
    a, b = Y.shape
    g, r, c, resid = additive_fit(Y)
    u = np.outer(r, c)                                # lies in the interaction space
    ss_n = (u * Y).sum() ** 2 / (u * u).sum()
    sse = (resid ** 2).sum()
    df = (a - 1) * (b - 1) - 1
    F = ss_n / ((sse - ss_n) / df)
    theta = (u * Y).sum() / (u * u).sum()             # coefficient of a_i b_j
    return F, stats.f.sf(F, 1, df), theta, g, sse, ss_n

for label, Y in [("seconds", times), ("log seconds", np.log(times))]:
    F, p, theta, g, sse, ss_n = tukey_test(Y)
    print(f"{label:12s} F = {F:9.2f}  p = {p:.2g}  theta = {theta:.4f}"
          f"   suggested power 1 - theta*ybar = {1 - theta * g:.2f}")

```

The listing below checks [Theorem 16.1.2\(f\)](#) by simulation. It draws 20000 tables from an additive normal model with $a = 6$ and $b = 8$. The 5% test rejects in a fraction 0.0508 of them, and a Kolmogorov–Smirnov comparison of the simulated statistics with $F(1, 34)$ gives $p = 0.98$.

```

rng = np.random.default_rng(20260919)
reps = 20_000
Fs = np.empty(reps)
for t in range(reps):
    Y = 3.0 + np.arange(a)[:, None] * 0.5 + np.arange(b)[None, :] + rng.normal(size=(a, b))
    Fs[t] = tukey_test(Y)[0]
size = np.mean(Fs > stats.f.ppf(0.95, 1, (a - 1) * (b - 1) - 1))
ks = stats.kstest(Fs, stats.f(1, (a - 1) * (b - 1) - 1).cdf)
print(f"simulated size of the 5% test: {size:.4f}   Kolmogorov-Smirnov p-value: {ks.pvalue:.2f}")

```

Warning. A nonsignificant Tukey test does not establish additivity. It rules out only interaction of the form $\theta\alpha_i\beta_j$. A single aberrant cell or row can leave F_N small and still distort every conclusion, so look at the residual table and an interaction plot ([Section 16.2](#)) as well.

16.1.6 Exercises

16.1.6.1 A. Check your understanding

Exercise A1.

For $a = b = 2$ and $m = 1$, write out the 4×4 matrices $\mathbf{P}_0$, $\mathbf{P}_A$, $\mathbf{P}_B$ and $\mathbf{R}$ of [Eq. 16.1.2](#). Show that $\mathbf{R}\mathbf{y} = \frac{1}{4}(y_{11} - y_{12} - y_{21} + y_{22})(1, -1, -1, 1)^\top$, and explain why Tukey's test

is not available here.

Exercise A2.

In the additive model with m observations per cell, show that the sum of squares for testing a single contrast $\sum_i c_i \alpha_i = 0$ is $(\sum_i c_i \bar{y}_{i..})^2 / (\sum_i c_i^2 / (bm))$, the same as in the one-way layout in A ([Proposition 15.2.1](#)). What differs between the two F tests of this contrast, the one here and the one-way test that ignores B ?

16.1.6.2 B. Practice

Exercise B1.

In the additive model, suppose $\alpha_1 = \delta$ and $\alpha_2 = \dots = \alpha_a = 0$. Find γ_A . With $a = 4$, $b = 5$ and $\delta = \sigma$, compare the power of the 5% test for $m = 1$ and $m = 2$ using [Theorem 11.5.1](#), and explain why doubling m more than doubles the error degrees of freedom.

Solution. Here $\bar{\alpha} = \delta/a$, and $\sum_i (\alpha_i - \bar{\alpha})^2 = \delta^2(1 - 1/a)^2 + (a - 1)\delta^2/a^2 = \delta^2(a - 1)/a$. So $\gamma_A = bm\delta^2(a - 1)/(a\sigma^2)$. With $a = 4$, $b = 5$, $\delta = \sigma$ this is $3.75m$. The error degrees of freedom are $n - a - b + 1 = 20m - 8$, which is 12 for $m = 1$ and 32 for $m = 2$. The power is $\Pr\{F(3, 20m - 8, 3.75m) > F_{0.05}(3, 20m - 8)\}$, about 0.25 for $m = 1$ and 0.56 for $m = 2$ (computed by the script `exercise_checks.py`). The noncentrality doubles, and the error degrees of freedom more than double because the $a + b - 1$ degrees of freedom spent on the mean structure are a fixed cost. Both effects raise the power.

Exercise B2.

Show that Tukey's statistic F_N is unchanged if $\mathbf{y}$ is replaced by $\lambda\mathbf{y} + \mathbf{t}$, where $\lambda \neq 0$ and $\mathbf{t}$ is any additive table $t_{ij} = u_i + v_j$. Conclude that F_N has the same distribution under every additive model with the same σ^2 .

Exercise B3.

Suppose y^p is additive for some $p \neq 0$, so that $\mu_{ij} = f(\nu + a_i + b_j)$ with $f(t) = t^{1/p}$. Verify that $\theta = f''(\nu)/f'(\nu)^2 = (1 - p)/f(\nu)$, and derive [Eq. 16.1.5](#). What does $\hat{\theta}\bar{y}_{..} \approx 1$ suggest, and why is $p = 0$ the right reading?

Solution. $f'(t) = p^{-1}t^{1/p-1}$ and $f''(t) = p^{-1}(p^{-1} - 1)t^{1/p-2}$. So

$$\frac{f''(\nu)}{f'(\nu)^2} = \frac{p^{-1}(p^{-1} - 1)\nu^{1/p-2}}{p^{-2}\nu^{2/p-2}} = p\left(\frac{1}{p} - 1\right)\nu^{-1/p} = \frac{1 - p}{f(\nu)}.$$

Solving $\theta = (1 - p)/f(\nu)$ for p , and estimating θ by $\hat{\theta}$ and $f(\nu)$, the typical size of a cell mean, by $\bar{y}_{..}$, gives $\hat{p} = 1 - \hat{\theta}\bar{y}_{..}$. A value $\hat{\theta}\bar{y}_{..} \approx 1$ gives $\hat{p} \approx 0$. For $f(t) = e^t$, which makes $\log y$ additive, $f''/f'^2 = e^{-\nu} = 1/f(\nu)$, which is the limit $p \rightarrow 0$ of the power formula. This matches the convention that $(y^p - 1)/p \rightarrow \log y$.

Exercise B4.

With $m = 1$ and normal errors, suppose the cell means are $\mu_{ij} = \mu + \alpha_i + \beta_j + \theta\alpha_i\beta_j$ with $\sum_i \alpha_i = \sum_j \beta_j = 0$, exactly the shape of [Eq. 16.1.3](#). Show that $r_i = \alpha_i + \bar{\varepsilon}_{i\cdot} - \bar{\varepsilon}_{\cdot\cdot}$, and that, given $\mathbf{P}_A \mathbf{Y}$ and $\mathbf{P}_B \mathbf{Y}$,

$$E(\hat{\theta} \mid \mathbf{P}_A \mathbf{Y}, \mathbf{P}_B \mathbf{Y}) = \theta \frac{\sum_i r_i \alpha_i}{\sum_i r_i^2} \cdot \frac{\sum_j c_j \beta_j}{\sum_j c_j^2}.$$

Explain why $\hat{\theta}$ is nearly unbiased when the row and column effects are large compared with σ , and why it tends to be pulled towards zero when they are not. What does this imply for the power rule [Eq. 16.1.5](#)?

Solution. The interaction terms $\theta\alpha_i\beta_j$ have zero row and column means, so $\bar{\mu}_{i\cdot} - \bar{\mu}_{\cdot\cdot} = \alpha_i$ and $r_i = \alpha_i + \bar{\varepsilon}_{i\cdot} - \bar{\varepsilon}_{\cdot\cdot}$; likewise for c_j . With $\mathbf{U} = \mathbf{r} \otimes \mathbf{c}$ as in the proof of [Theorem 16.1.2\(f\)](#), $\hat{\theta} = \mathbf{U}^\top \mathbf{R} \mathbf{Y} / \mathbf{U}^\top \mathbf{U}$. By [Theorem 4.4.4](#), $\mathbf{R} \mathbf{Y}$ is independent of $(\mathbf{P}_A \mathbf{Y}, \mathbf{P}_B \mathbf{Y})$, whatever the mean, so given those two vectors $\mathbf{U}$ is fixed and $E(\mathbf{R} \mathbf{Y}) = \mathbf{R} \boldsymbol{\mu}$, the table $(\theta\alpha_i\beta_j)$. Hence the conditional mean is $\theta \sum_{i,j} r_i c_j \alpha_i \beta_j / (\sum_i r_i^2 \sum_j c_j^2)$, which factorizes as displayed. If the effects dominate the noise, $\mathbf{r} \approx \boldsymbol{\alpha}$ and both factors are near one. If not, $\sum_i r_i^2$ carries the extra noise $\sigma^2(a-1)/b$ on average while $\sum_i r_i \alpha_i$ does not: the attenuation of a regression on a noisy regressor. The power rule then suggests a $\hat{p}$ too close to one, too weak a transformation.

16.1.6.3 C. Going deeper**Exercise C1.**

Extend Tukey's test to $m \geq 2$ observations per cell. Replace y_{ij} by the cell mean $\bar{y}_{ij}$ in [Eq. 16.1.4](#) and multiply the result by m , and compare it with the pure-error mean square. Show that under the additive model the resulting statistic has the $F(1, ab(m-1))$ distribution. Show also that $SS_{AB} - SS_N$ gives a test of the remaining nonadditivity.

16.2 Interaction and its interpretation

The additive model says that the difference between two levels of A is the same at every level of B . *Interaction* is the failure of that statement. This section defines interaction through the cell means, so that its meaning does not depend on a parameterization. It then shows how to see interaction in a plot and when a change of scale removes it, and explains why a “main effect” in the presence of interaction is a weighted average whose weights someone has to choose.

16.2.1 Cell means and the definition of interaction

Write μ_{ij} for the mean response in cell (i, j) . The **cell-means model** $E(y_{ijk}) = \mu_{ij}$ places no restriction on the ab means. By [Proposition 8.6.2\(a\)](#) it has the same mean space as the overparameterized model $\mu + \alpha_i + \beta_j + \gamma_{ij}$, and every cell mean of an occupied cell is estimable. Averages with equal weights split the table of means into four parts:

$$\mu_{ij} = \bar{\mu}_{..} + (\bar{\mu}_{i.} - \bar{\mu}_{..}) + (\bar{\mu}_{.j} - \bar{\mu}_{..}) + (\mu_{ij} - \bar{\mu}_{i.} - \bar{\mu}_{.j} + \bar{\mu}_{..}). \quad (16.2.1)$$

This is an algebraic identity. The four parts are the images of the vector of cell means under $\bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b$, $\mathbf{C}_a \otimes \bar{\mathbf{J}}_b$, $\bar{\mathbf{J}}_a \otimes \mathbf{C}_b$ and $\mathbf{C}_a \otimes \mathbf{C}_b$, which are mutually orthogonal projections (Lemma 16.1.1).

Definition 16.2.1 — Interaction

Let μ_{ij} be the cell means of a two-way layout.

- (a) An **interaction contrast** is a linear function $\sum_{i,j} d_{ij} \mu_{ij}$ whose coefficient table (d_{ij}) is not zero and has every row sum and every column sum equal to zero. The simplest is the **tetrad difference** $\mu_{ij} - \mu_{il} - \mu_{kj} + \mu_{kl}$ of rows $i \neq k$ and columns $j \neq l$. It is the difference between columns j and l in row i , minus the same difference in row k .
- (b) The factors **interact** if some interaction contrast is nonzero. Otherwise the layout is **additive**.
- (c) In the *effects form* $\mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij}$ of Eq. 16.2.1, the **main effects** are $\alpha_i = \bar{\mu}_{i.} - \bar{\mu}_{..}$ and $\beta_j = \bar{\mu}_{.j} - \bar{\mu}_{..}$, and the **interaction effects** are $\gamma_{ij} = \mu_{ij} - \bar{\mu}_{i.} - \bar{\mu}_{.j} + \bar{\mu}_{..}$. They satisfy $\sum_i \alpha_i = \sum_j \beta_j = 0$, and every row and column of (γ_{ij}) sums to zero.

The cell means are what the data estimate. The effects in (c) are one coordinate system for them, fixed by the choice of equal weights. The next result shows that whether interaction is present does not depend on that choice.

Proposition 16.2.1 — Equivalent forms of additivity

For a table of cell means (μ_{ij}) , the following are equivalent:

- (i) every tetrad difference is zero;
- (ii) for all rows i, k , the difference $\mu_{ij} - \mu_{kj}$ does not depend on j ;
- (iii) $\mu_{ij} = u_i + v_j$ for some numbers $u_1, \dots, u_a$ and $v_1, \dots, v_b$;
- (iv) every interaction contrast is zero;
- (v) for some pair of weight vectors $\mathbf{s} \in \mathbb{R}^a$ and $\mathbf{w} \in \mathbb{R}^b$ with $\sum_k s_k = \sum_l w_l = 1$,

$$\mu_{ij} - \sum_l w_l \mu_{il} - \sum_k s_k \mu_{kj} + \sum_{k,l} s_k w_l \mu_{kl} = 0 \quad \text{for all } i, j;$$

- (vi) the condition in (v) holds for every such pair of weight vectors, in particular $\gamma_{ij} = 0$ for all i, j .

Moreover, the coefficient tables of interaction contrasts, together with the zero table, form a subspace of dimension $(a-1)(b-1)$, and $\sum_{i,j} d_{ij} \mu_{ij} = \sum_{i,j} d_{ij} \gamma_{ij}$ for each of them.

Proof. (i) $\Rightarrow$ (ii): a zero tetrad difference says $\mu_{ij} - \mu_{kj} = \mu_{il} - \mu_{kl}$. (ii) $\Rightarrow$ (iii): put $u_i = \mu_{i1} - \mu_{11}$ and $v_j = \mu_{1j}$. By (ii), $\mu_{ij} - \mu_{1j} = \mu_{i1} - \mu_{11}$, that is, $\mu_{ij} = u_i + v_j$. (iii) $\Rightarrow$ (iv): $\sum_{i,j} d_{ij}(u_i + v_j) = \sum_i u_i \sum_j d_{ij} + \sum_j v_j \sum_i d_{ij} = 0$. (iv) $\Rightarrow$ (i): a tetrad difference is an interaction contrast. (iii) $\Rightarrow$ (vi): substituting $u_i + v_j$, the four terms are

Figure 16.2.1: Three tables of cell means for a 2×3 layout. (a) Additive: parallel profiles. (b) Interaction that the logarithm removes: the means are exp of an additive table. (c) Crossing interaction: the order of the rows reverses between B_1 and B_3 , and no increasing transformation can make the profiles parallel.

$u_i + v_j$, $u_i + \sum_l w_l v_l$, $\sum_k s_k u_k + v_j$ and $\sum_k s_k u_k + \sum_l w_l v_l$, and the signed sum is zero. (vi) $\Rightarrow$ (v) is trivial. (v) $\Rightarrow$ (iii): (v) writes μ_{ij} as $\sum_l w_l \mu_{il}$, which depends only on i , plus $\sum_k s_k \mu_{kj} - \sum_{k,l} s_k w_l \mu_{kl}$, which depends only on j .

For the last statement, read tables as vectors in $\mathbb{R}^{ab}$ with j running fastest. A table has zero row and column sums iff it is fixed by $\mathbf{C}_a \otimes \mathbf{C}_b$, as in the proof of Theorem 16.1.2(e). So the coefficient tables form $\mathcal{C}(\mathbf{C}_a \otimes \mathbf{C}_b)$, of dimension $(a-1)(b-1)$ by Lemma 16.1.1(b). Such a table is orthogonal to the first three parts of Eq. 16.2.1, which leaves $\sum d_{ij} \gamma_{ij}$.

■

So interaction is a property of the table of cell means, with $(a-1)(b-1)$ dimensions. In the overparameterized model $\mu + \alpha_i + \beta_j + \gamma_{ij}$ without side conditions, $\alpha_i - \alpha_k$ is not estimable (Proposition 8.6.2). The function $\alpha_i - \alpha_k + \bar{\gamma}_i - \bar{\gamma}_k$ is estimable, because it equals $\bar{\mu}_{i\cdot} - \bar{\mu}_{k\cdot}$. Software that prints a “main effect” in such a model has chosen side conditions (Theorem 8.4.2) and hence a set of weights, and the printed number depends on that choice. The last part of this section explains why.

16.2.2 Interaction plots

An **interaction plot** draws the estimated cell means $\bar{y}_{ij}$ against the levels of one factor, with one line (a *profile*) for each level of the other. By Proposition 16.2.1(ii), the layout is additive iff the profiles of the true means are parallel, that is, vertical translates of each other. Figure 16.2.1 shows three patterns of true means. In (a) the profiles are parallel. In (b) they fan out, but the row that is higher in one column is higher in every column. In (c) they cross.

Estimated profiles are never exactly parallel. Whether the departures exceed the noise is a question for the F test of Section 16.3. The plot shows *where* the interaction is, which is usually more useful.

Example. (Flour and proofing temperature)

A bakery trial measured the volume (ml) of loaves made from three flours (white, whole-

Figure 16.2.2: Interaction plot for the bread trial: cell means of loaf volume against proofing temperature, one profile per flour, with the individual loaves as faint points.

meal and a rye blend), with the dough proofed at four temperatures (24, 28, 32 and 36 °C). Three loaves were baked for each of the 12 combinations, 36 in all, in random order. The data are synthetic, generated by the script `bread_factorial.py`. The cell means are

	24 °C	28 °C	32 °C	36 °C	mean
white	1885.7	2075.7	2127.0	2211.0	2074.8
wholemeal	1635.0	1699.0	1824.7	1749.7	1727.1
rye blend	1559.7	1554.0	1533.7	1613.3	1565.2
mean	1693.4	1776.2	1828.4	1858.0	1789.0

Figure 16.2.2 is the interaction plot. White flour gains volume steadily with temperature. Wholemeal gains up to 32 °C and then loses. The rye blend hardly responds. The profiles are far from parallel. The within-cell standard deviation, estimated in Section 16.3, is $s = 56.4$ ml, so a cell mean of three loaves has standard error $56.4/\sqrt{3} \approx 32.6$ ml, much smaller than the departures from parallelism. Yet the flours never change order: at every temperature white beats wholemeal, which beats the rye blend. The interaction changes the *size* of the flour differences but not their *direction*.

16.2.3 Removable and nonremovable interaction

Panel (b) of Figure 16.2.1 shows the pattern of the solver data of Example (Solvers on benchmark problems): the effect of A is a constant *ratio*, and on the logarithmic scale the table is additive. Such interaction is **removable**: some strictly increasing g makes the table $g(\mu_{ij})$ additive. When can no transformation remove an interaction?

Proposition 16.2.2 — An order condition for removable interaction

If g is strictly increasing and the table $g(\mu_{ij})$ is additive, then the rows are ordered in

the same way in every column, and the columns in the same way in every row. That is, for all i, k the sign of $\mu_{ij} - \mu_{kj}$ does not depend on j , and for all j, l the sign of $\mu_{ij} - \mu_{il}$ does not depend on i . In particular, if $\mu_{ij} > \mu_{kj}$ and $\mu_{il} < \mu_{kl}$ for some i, k, j, l , no strictly increasing transformation removes the interaction.

Proof. Write $g(\mu_{ij}) = u_i + v_j$ (Proposition 16.2.1(iii)). Since g is strictly increasing, $\mu_{ij} > \mu_{kj}$ iff $g(\mu_{ij}) > g(\mu_{kj})$ iff $u_i > u_k$, a condition that does not involve j . The same holds with $>$ replaced by $=$ or $<$. The statement for columns is symmetric. ■

This justifies a distinction that is often drawn informally. An interaction is **quantitative** (or *ordinal*) if the orders are consistent in the sense of the proposition, and **qualitative** (or *crossing, disordinal*) if the order of some pair of levels reverses. Qualitative interaction is a fact about the phenomenon on every monotone scale. Quantitative interaction may be a fact about the scale of measurement. Whether an interaction is qualitative can depend on which factor one looks along. In the bread trial the flours keep their order at every temperature, but the temperatures do not keep their order for every flour. White flour gives more volume at 36 °C than at 32 °C, and wholemeal gives less. If the true means follow the same pattern as the estimates, the proposition says that no rescaling of volume makes the table additive. The condition is necessary but not sufficient. With three or more levels of each factor, a table can have consistent orders and still admit no additive rescaling (Exercise (C1)).

The listing checks the three tables of Figure 16.2.1. It also shows that the logarithm *creates* interaction in the additive table (a). Additivity is a property of a table on a given scale, and so is its absence.

```
import itertools

import numpy as np

additive = np.array([[4.0, 6.0, 7.0], [2.0, 4.0, 5.0]])           # rows: levels of
A
removable = np.exp(np.array([[1.0, 1.6, 2.2], [0.4, 1.0, 1.6]])) # exp of an
additive table
crossing = np.array([[3.0, 5.0, 7.0], [6.0, 5.0, 4.0]])

def interaction(mu):
    """mu_ij - mu_i. - mu_.j + mu_.. (equal weights)."""
    return mu - mu.mean(1, keepdims=True) - mu.mean(0, keepdims=True) + mu.mean()

def same_orders(mu):
    """Necessary condition for removability: every column orders the rows alike, and
    every row the columns."""
    a, b = mu.shape
    rows_ok = all(len(set(np.sign(mu[i] - mu[k]))) == 1 for i, k in itertools.
combinations(range(a), 2))
    cols_ok = all(len(set(np.sign(mu[:, j] - mu[:, l]))) == 1 for j, l in itertools.
combinations(range(b), 2))
    return rows_ok and cols_ok

for name, mu in [("additive", additive), ("removable", removable), ("crossing",
```

```
crossing)]:
print(f"{name:9s} max |interaction| raw {np.abs(interaction(mu)).max():.3f}"
      f"   log {np.abs(interaction(np.log(mu))).max():.3f}   same orders: {
same_orders(mu)}")
```

Two cautions apply to transforming data rather than means. Since $E g(Y) \neq g(E Y)$ for nonlinear g , additivity of $g(y)$ and of $g(\mu_{ij})$ agree only approximately, for small errors. And a transformation also changes the shape and variance of the errors. In [Example \(Solvers on benchmark problems\)](#) the logarithm happened to fix both, because the noise was multiplicative. The choice of scale is the subject of [Chapter 22](#).

16.2.4 Main effects in the presence of interaction

Without interaction, “the effect of A ” is the common difference $\mu_{ij} - \mu_{kj}$. With interaction, the difference between rows i and k is a list of **simple effects** $\delta_j = \mu_{ij} - \mu_{kj}$, and a single summary must average them with weights. For a weight vector $\mathbf{w}$ with $w_j \geq 0$ and $\sum_j w_j = 1$, define the **w-weighted main effect** difference of rows i and k as $\sum_j w_j \delta_j = \sum_j w_j \mu_{ij} - \sum_j w_j \mu_{kj}$.

Proposition 16.2.3 — Main effects depend on the weights

Fix rows $i \neq k$ and let $\delta_j = \mu_{ij} - \mu_{kj}$.

- (a) If the δ_j are all equal, every weighted main effect difference equals their common value.
- (b) If they are not all equal, the values of $\sum_j w_j \delta_j$ over weight vectors with every $w_j > 0$ fill the open interval $(\min_j \delta_j, \max_j \delta_j)$. In particular, if the simple effects change sign, some weighting with all weights positive makes the main effect of A for these two rows exactly zero, and other weightings give it either sign.
- (c) If all $\delta_j > 0$, every weighted main effect difference is positive.

Proof.

- (a) and (c) are immediate, and a weighted average with positive weights of numbers that are not all equal lies strictly between their minimum and maximum. Conversely, let $\min_j \delta_j < t < \max_j \delta_j$, attained at columns j_0 and j_1 , and let $\bar{\delta} = b^{-1} \sum_j \delta_j$. For $0 < \varepsilon < 1$ put $t_\varepsilon = (t - \varepsilon \bar{\delta}) / (1 - \varepsilon)$. Since $t_\varepsilon \rightarrow t$ as $\varepsilon \rightarrow 0$, there is an ε with $\delta_{j_0} < t_\varepsilon < \delta_{j_1}$. Then $t_\varepsilon = \lambda \delta_{j_0} + (1 - \lambda) \delta_{j_1}$ for some $\lambda \in (0, 1)$. The weights ε/b on every column, plus $(1 - \varepsilon)\lambda$ on j_0 and $(1 - \varepsilon)(1 - \lambda)$ on j_1 , are all positive and give $\varepsilon \bar{\delta} + (1 - \varepsilon) t_\varepsilon = t$.

■

In table (c) of [Figure 16.2.1](#) the simple effects of A_1 against A_2 are $-3, 0$ and 3 . With equal weights the main effect of A is exactly zero, although A matters in two of the three columns. With weights $(\frac{1}{2}, \frac{1}{2}, 0)$ it is -1.5 , and with $(0, \frac{1}{2}, \frac{1}{2})$ it is $+1.5$.

The balanced analysis of [Section 16.3](#) uses equal weights: its sum of squares for A tests $\bar{\mu}_{1.} = \dots = \bar{\mu}_{a.}$. In unbalanced data the various sums of squares use different weights, some determined by the cell counts ([Theorem 9.3.2](#)), and [Chapter 17](#) sorts them out ([Theorem 17.2.2](#)). Equal

weights are a convention, natural when the levels of B were chosen as a representative spread.

For the bread trial the simple effects of white against wholemeal flour are 250.7, 376.7, 302.3 and 461.3 ml at the four temperatures. The equal-weight main effect is their average, 347.7 ml. A bakery that proofs mostly warm might weight the temperatures in the proportions 1 : 1 : 2 : 4, and then the relevant difference is 384.7 ml. Both figures answer different questions correctly. Because all four simple effects are positive, part (c) guarantees that white flour gives larger loaves than wholemeal under every weighting, a statement that needs no choice of weights.

Idea. Report main effects when the interaction is small or quantitative, and say what they average over. When the interaction is qualitative, report simple effects. A main effect that averages a positive and a negative effect answers a question nobody asked.

16.2.5 Exercises

16.2.5.1 A. Check your understanding

Exercise A1.

For the crossing table $\mu = \begin{pmatrix} 3 & 5 & 7 \\ 6 & 5 & 4 \end{pmatrix}$, compute $\bar{\mu}_{..}$, α_i , β_j and γ_{ij} of Definition 16.2.1(c). Check that the tetrad difference of columns 1 and 3 equals $\gamma_{11} - \gamma_{13} - \gamma_{21} + \gamma_{23}$.

Solution. $\bar{\mu}_{..} = 5$, row means 5, 5, so $\alpha_1 = \alpha_2 = 0$. Column means 4.5, 5, 5.5, so $\beta = (-0.5, 0, 0.5)$. Then $\gamma_{1j} = \mu_{1j} - 5 - \beta_j = (-1.5, 0, 1.5)$ and $\gamma_{2j} = (1.5, 0, -1.5)$. The tetrad difference is $3 - 7 - 6 + 4 = -6$, and $\gamma_{11} - \gamma_{13} - \gamma_{21} + \gamma_{23} = -1.5 - 1.5 - 1.5 - 1.5 = -6$.

Exercise A2.

From the table of cell means in Example (Flour and proofing temperature), compute the simple effects of wholemeal against the rye blend at the four temperatures. Is their interaction quantitative or qualitative? Which pair of temperatures, if any, reverses its order for some flour?

16.2.5.2 B. Practice

Exercise B1.

Show that the $(a-1)(b-1)$ tetrad differences $\mu_{ij} - \mu_{ib} - \mu_{aj} + \mu_{ab}$, $i < a$, $j < b$, have linearly independent coefficient tables. Conclude that they form a basis of the interaction contrasts, so that additivity is equivalent to $(a-1)(b-1)$ linear restrictions on the cell means.

Solution. The coefficient table of the (i, j) tetrad has entry 1 at (i, j) and its other nonzero entries in row a or column b . In a linear combination $\sum_{i < a, j < b} c_{ij}(\text{table}_{ij})$, the entry at position (i, j) with $i < a$, $j < b$ is c_{ij} , because no other table in the list has a nonzero entry there. So the combination vanishes only if all $c_{ij} = 0$. There are $(a-1)(b-1)$ independent tables in a space of that dimension (Proposition 16.2.1), so

they form a basis. Additivity means all interaction contrasts vanish, which is equivalent to the basis contrasts vanishing.

Exercise B2.

Let $\mu_{ij} = u_i + v_j > 0$ be an additive table. Show that $\log \mu_{ij}$ is additive only if all u_i are equal or all v_j are equal. So on a positive scale a transformation can create interaction as well as remove it.

Solution. By Proposition 16.2.1(i), $\log \mu_{ij}$ is additive iff $\mu_{ij}\mu_{kl} = \mu_{il}\mu_{kj}$ for all i, k, j, l . Expanding $(u_i + v_j)(u_k + v_l) - (u_i + v_l)(u_k + v_j) = u_i v_l + u_k v_j - u_i v_j - u_k v_l = -(u_i - u_k)(v_j - v_l)$. This vanishes for all index choices iff $u_i = u_k$ for all i, k or $v_j = v_l$ for all j, l , since if some $u_i \neq u_k$ and some $v_j \neq v_l$, that choice of indices gives a nonzero product.

Exercise B3.

Show that the converse of Proposition 16.2.2 holds for 2×2 tables. If the rows are ordered alike in both columns and the columns alike in both rows, then some strictly increasing function g makes $g(\mu_{ij})$ additive.

16.2.5.3 C. Going deeper

Exercise C1.

Consider the 3×3 table

$$\mu = \begin{pmatrix} 1 & 3 & 6 \\ 4 & 7 & 9 \\ 5 & 10 & 11 \end{pmatrix}.$$

Check that every row and every column is increasing, so that the order condition of Proposition 16.2.2 holds. Show that nevertheless no strictly increasing g makes $g(\mu_{ij})$ additive. (*Hint:* compare μ_{21} with μ_{12} , μ_{32} with μ_{23} , and μ_{31} with μ_{13} .) The condition violated here is the *double cancellation* axiom of conjoint measurement.

Solution. The rows $(1, 3, 6)$, $(4, 7, 9)$, $(5, 10, 11)$ and the columns $(1, 4, 5)$, $(3, 7, 10)$, $(6, 9, 11)$ are increasing. Suppose $g(\mu_{ij}) = u_i + v_j$ with g strictly increasing. From $\mu_{21} = 4 > 3 = \mu_{12}$ we get $u_2 + v_1 > u_1 + v_2$. From $\mu_{32} = 10 > 9 = \mu_{23}$ we get $u_3 + v_2 > u_2 + v_3$. Adding, $u_3 + v_1 > u_1 + v_3$, so $\mu_{31} > \mu_{13}$. But $\mu_{31} = 5 < 6 = \mu_{13}$, a contradiction.

Exercise C2.

For a weight vector $\mathbf{w}$, let $H_A^{\mathbf{w}}$ be the hypothesis that $\sum_j w_j \mu_{ij}$ is the same for all i . Show that $H_A^{\mathbf{w}}$ and $H_A^{\mathbf{w}'}$ define the same set of cell-mean tables only if $\mathbf{w} = \mathbf{w}'$. Show also that on the set of additive tables all of them coincide with $\alpha_1 = \cdots = \alpha_a$.

16.3 Balanced two-way layouts via orthogonal projections

With $m \geq 2$ observations in every cell, the replicates supply an estimate of σ^2 that is valid whatever the cell means are, and interaction can be tested without any assumption about its form. This section gives the complete analysis of the balanced two-way layout: the orthogonal decomposition, exact tests, contrasts, and simultaneous inference. [Exercise \(C1\)](#) asked for the five projections, and [Theorem 16.1.2\(d\)](#) has already met four of them.

16.3.1 The decomposition

The model is the cell-means model

$$E(y_{ijk}) = \mu_{ij}, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}, \quad i \leq a, j \leq b, k \leq m, \quad (16.3.1)$$

written in the effects form of [Definition 16.2.1](#) as $\mu_{ij} = \mu + \alpha_i + \beta_j + \gamma_{ij}$, with equal-weight effects. Its mean space $\mathcal{C}(\mathbf{X})$ is the set of vectors that are constant within cells, of dimension ab ([Proposition 8.6.2](#)). With the ordering and notation of [Section 16.1](#), define

$$\begin{aligned} \mathbf{P}_0 &= \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, & \mathbf{P}_A &= \mathbf{C}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, & \mathbf{P}_B &= \bar{\mathbf{J}}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m, \\ \mathbf{P}_{AB} &= \mathbf{C}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m, & \mathbf{P}_E &= \mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{C}_m. \end{aligned} \quad (16.3.2)$$

Theorem 16.3.1 — The balanced two-way layout

Assume [Eq. 16.3.1](#) with $a, b \geq 2$ and $m \geq 2$, and let $\alpha_i, \beta_j, \gamma_{ij}$ be the equal-weight effects of [Definition 16.2.1](#).

- (a) The five matrices [Eq. 16.3.2](#) are mutually orthogonal projections that sum to $\mathbf{I}$, with ranks 1, $a - 1$, $b - 1$, $(a - 1)(b - 1)$ and $ab(m - 1)$. The projection onto $\mathcal{C}(\mathbf{X})$ is $\mathbf{M} = \mathbf{P}_0 + \mathbf{P}_A + \mathbf{P}_B + \mathbf{P}_{AB}$, and that onto the additive model space is $\mathbf{P}_0 + \mathbf{P}_A + \mathbf{P}_B$. So $\mathcal{C}(\mathbf{P}_{AB})$ is the orthogonal complement of the additive model within the cell-means model.
- (b) The projections act by

$$\begin{aligned} (\mathbf{P}_A \mathbf{y})_{ijk} &= \bar{y}_{i..} - \bar{y}_{...}, \\ (\mathbf{P}_B \mathbf{y})_{ijk} &= \bar{y}_{.j.} - \bar{y}_{i..} - \bar{y}_{...} + \bar{y}_{...}, \\ (\mathbf{P}_E \mathbf{y})_{ijk} &= y_{ijk} - \bar{y}_{ij.}, \end{aligned}$$

and symmetrically for $\mathbf{P}_B$. The sums of squares are

$$\begin{aligned} \text{SS}_A &= bm \sum_i (\bar{y}_{i..} - \bar{y}_{...})^2, \\ \text{SS}_B &= am \sum_j (\bar{y}_{.j.} - \bar{y}_{...})^2, \\ \text{SS}_{AB} &= m \sum_{i,j} (\bar{y}_{ij.} - \bar{y}_{i..} - \bar{y}_{.j.} + \bar{y}_{...})^2, \\ \text{SSE} &= \sum_{i,j,k} (y_{ijk} - \bar{y}_{ij.})^2. \end{aligned}$$

(c) The mean squares have expectations

$$\begin{aligned} \text{E MS}_A &= \sigma^2 + \frac{bm}{a-1} \sum_i \alpha_i^2, \\ \text{E MS}_B &= \sigma^2 + \frac{am}{b-1} \sum_j \beta_j^2, \\ \text{E MS}_{AB} &= \sigma^2 + \frac{m}{(a-1)(b-1)} \sum_{i,j} \gamma_{ij}^2, \\ \text{E MSE} &= \sigma^2. \end{aligned}$$

(d) Under normal errors the four sums of squares are independent, $\text{SSE}/\sigma^2 \sim \chi^2(ab(m-1))$, and

$$\begin{aligned} F_A &= \frac{\text{MS}_A}{\text{MSE}} \sim F\left(a-1, ab(m-1), \frac{bm}{\sigma^2} \sum_i \alpha_i^2\right), \\ F_{AB} &= \frac{\text{MS}_{AB}}{\text{MSE}} \sim F\left((a-1)(b-1), ab(m-1), \frac{m}{\sigma^2} \sum_{i,j} \gamma_{ij}^2\right), \end{aligned}$$

and likewise for F_B . So F_{AB} is an exact test of additivity, F_A of $\bar{\mu}_{1.} = \cdots = \bar{\mu}_{a.}$, and F_B of $\bar{\mu}_{.1} = \cdots = \bar{\mu}_{.b}$.

(e) SS_A is the sum of squares of the hypothesis $\alpha_1 = \cdots = \alpha_a = 0$ in the cell-means model. It is also the sequential sum of squares of A whether A is entered before or after B , and it equals the Type II and Type III sums of squares of A . The same holds for B , and SS_{AB} is the sequential, Type II and Type III sum of squares of the interaction.

Proof.

- (a) Orthogonality, ranks and the sum $\mathbf{I}$ follow from [Lemma 16.1.1](#), as in the proof of [Theorem 16.1.2\(d\)](#). The sum of the first four is $(\bar{\mathbf{J}}_a + \mathbf{C}_a) \otimes (\bar{\mathbf{J}}_b + \mathbf{C}_b) \otimes \bar{\mathbf{J}}_m = \mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m$. This matrix replaces each observation by its cell mean, so it is the projection onto the vectors that are constant within cells, which is $\mathcal{C}(\mathbf{X})$. The additive projection is [Theorem 16.1.2\(a\)](#).
- (b) Expand each Kronecker product with $\mathbf{C} = \mathbf{I} - \bar{\mathbf{J}}$ and read off the means from the table in [Section 16.1](#). For example,

$$\begin{aligned} \mathbf{P}_{AB} &= \mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m - \mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m \\ &\quad - \bar{\mathbf{J}}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m + \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m. \end{aligned}$$

Each sum of squares is a sum over the n positions of a quantity that is constant over m , bm or am of them.

- (c) Apply (b) to the mean vector $\boldsymbol{\mu}$, whose entries are μ_{ij} . Then $\mathbf{P}_A \boldsymbol{\mu}$ has entries $\bar{\mu}_{i.} - \bar{\mu}_{..} = \alpha_i$, so $\|\mathbf{P}_A \boldsymbol{\mu}\|^2 = bm \sum_i \alpha_i^2$. Likewise $\|\mathbf{P}_{AB} \boldsymbol{\mu}\|^2 = m \sum_{i,j} \gamma_{ij}^2$, and $\mathbf{P}_E \boldsymbol{\mu} = \mathbf{0}$. The four subspaces $\mathcal{C}(\mathbf{P}_0), \dots, \mathcal{C}(\mathbf{P}_{AB})$ form an analysis of variance decomposition of $\mathcal{C}(\mathbf{X})$, so [Theorem 9.6.1](#) gives the expectations.
- (d) This is [Corollary 9.6.2](#) with the noncentralities of (c). The noncentrality of F_A vanishes iff every $\alpha_i = 0$, that is, iff the row means $\bar{\mu}_{i.}$ are equal. The noncentrality of F_{AB} vanishes iff every $\gamma_{ij} = 0$, which is additivity by [Proposition 16.2.1](#)(vi).
- (e) Each α_i is a linear function of the cell means, so the hypothesis is testable. The mean vectors it allows are the $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X})$ with $\mathbf{P}_A \boldsymbol{\mu} = \mathbf{0}$. Since $\boldsymbol{\mu} = \mathbf{P}_0 \boldsymbol{\mu} + \mathbf{P}_A \boldsymbol{\mu} + \mathbf{P}_B \boldsymbol{\mu} + \mathbf{P}_{AB} \boldsymbol{\mu}$, these form $\mathcal{S}_0 = \mathcal{C}(\mathbf{P}_0) \oplus \mathcal{C}(\mathbf{P}_B) \oplus \mathcal{C}(\mathbf{P}_{AB})$. By [Theorem 11.3.2](#)(b) the sum of squares of the hypothesis is $\|(\mathbf{M} - \mathbf{P}_{\mathcal{S}_0}) \mathbf{y}\|^2 = \|\mathbf{P}_A \mathbf{y}\|^2$. The rest is [Chapter 9](#): equal counts are proportional ([Theorem 9.4.3](#)), so [Theorem 9.4.1](#) applies, and [Exercise \(B1\)](#) shows that the sequential sums of squares of A in either order and its Type II and Type III sums of squares all equal $\|\mathbf{P}_A \mathbf{y}\|^2$. The interaction enters last in every order, so all its sums of squares are $\|(\mathbf{M} - \mathbf{P}_0 - \mathbf{P}_A - \mathbf{P}_B) \mathbf{y}\|^2 = \|\mathbf{P}_{AB} \mathbf{y}\|^2$.

■

The theorem is summarized in the analysis of variance table:

Source	df	Sum of squares	E(MS)
A	$a - 1$	$\ \mathbf{P}_A \mathbf{y}\ ^2$	$\sigma^2 + bm \sum_i \alpha_i^2 / (a - 1)$
B	$b - 1$	$\ \mathbf{P}_B \mathbf{y}\ ^2$	$\sigma^2 + am \sum_j \beta_j^2 / (b - 1)$
AB	$(a - 1)(b - 1)$	$\ \mathbf{P}_{AB} \mathbf{y}\ ^2$	$\sigma^2 + m \sum_{i,j} \gamma_{ij}^2 / ((a - 1)(b - 1))$
error	$ab(m - 1)$	$\ \mathbf{P}_E \mathbf{y}\ ^2$	σ^2
corrected total	$abm - 1$	$\ (\mathbf{I} - \mathbf{P}_0) \mathbf{y}\ ^2$	

The test for A is valid with or without interaction, because $\mathcal{C}(\mathbf{P}_{AB}) \perp \mathcal{C}(\mathbf{P}_A)$. What the interaction changes is the *meaning* of H_A : equality of equal-weight row means is one hypothesis among many when the simple effects differ ([Section 16.2](#)). Part (e) is special to balance. With unequal cell counts the sequential, Type II and Type III sums of squares of A test hypotheses with different weights ([Theorem 9.3.2](#)), the subject of [Chapter 17](#).

16.3.2 Contrasts and their sums of squares

The F tests say whether a term matters. Contrasts say how. A **main-effect contrast** in A is $\psi = \sum_i c_i \bar{\mu}_{i.} = \sum_i c_i \alpha_i$ with $\sum_i c_i = 0$. An **interaction contrast** is $\sum_{i,j} d_{ij} \mu_{ij} = \sum_{i,j} d_{ij} \gamma_{ij}$, with (d_{ij}) having zero row and column sums ([Proposition 16.2.1](#)). Their least squares estimators replace means by sample means. Since $\bar{y}_{i.}$ averages bm independent observations and $\bar{y}_{ij.}$ averages m ,

$$\text{Var}\left(\sum_i c_i \bar{y}_{i.}\right) = \frac{\sigma^2}{bm} \sum_i c_i^2, \quad \text{Var}\left(\sum_{i,j} d_{ij} \bar{y}_{ij.}\right) = \frac{\sigma^2}{m} \sum_{i,j} d_{ij}^2.$$

The sums of squares of the corresponding single-degree-of-freedom hypotheses are the squared estimates divided by these variances without the σ^2 ([Theorem 9.4.4](#)), as for a one-way contrast

(Proposition 15.2.1):

$$SS(\mathbf{c}) = \frac{(\sum_i c_i \bar{y}_{i\cdot})^2}{\sum_i c_i^2 / (bm)}, \quad SS(\mathbf{d}) = \frac{(\sum_{i,j} d_{ij} \bar{y}_{ij\cdot})^2}{\sum_{i,j} d_{ij}^2 / m}. \quad (16.3.3)$$

For main effects, a complete set of $a - 1$ mutually orthogonal contrasts ($\sum_i c_i c'_i = 0$) splits SS_A into $a - 1$ independent pieces. This is the one-way result [Theorem 15.4.1](#) applied to the row means, which are one-way means with bm observations each. For interaction, orthogonal contrasts are most easily built as products.

Proposition 16.3.2 — Product contrasts

Let $\mathbf{c}^{(1)}, \dots, \mathbf{c}^{(a-1)}$ be mutually orthogonal contrast vectors in $\mathbb{R}^a$, and $\mathbf{e}^{(1)}, \dots, \mathbf{e}^{(b-1)}$ mutually orthogonal contrast vectors in $\mathbb{R}^b$. Then the $(a - 1)(b - 1)$ tables $\mathbf{d}^{(rs)} = \mathbf{c}^{(r)} \mathbf{e}^{(s)\top}$, with entries $c_i^{(r)} e_j^{(s)}$, are coefficient tables of mutually orthogonal interaction contrasts, and

$$\sum_{r=1}^{a-1} \sum_{s=1}^{b-1} SS(\mathbf{d}^{(rs)}) = SS_{AB}.$$

Under normality the $(a - 1)(b - 1)$ sums of squares are independent of each other and of SSE.

Proof. The row sums of $\mathbf{d}^{(rs)}$ are $c_i^{(r)} \sum_j e_j^{(s)} = 0$ and the column sums vanish likewise. Let $\mathbf{v}_{rs} = \mathbf{c}^{(r)} \otimes \mathbf{e}^{(s)} \otimes \mathbf{1}_m \in \mathbb{R}^n$. Since $\mathbf{C}_a \mathbf{c}^{(r)} = \mathbf{c}^{(r)}$ and $\mathbf{C}_b \mathbf{e}^{(s)} = \mathbf{e}^{(s)}$, the mixed-product rule gives $\mathbf{P}_{AB} \mathbf{v}_{rs} = \mathbf{v}_{rs}$, so $\mathbf{v}_{rs} \in \mathcal{C}(\mathbf{P}_{AB})$. Also $\mathbf{v}_{rs}^\top \mathbf{v}_{r's'} = m (\mathbf{c}^{(r)\top} \mathbf{c}^{(r')})(\mathbf{e}^{(s)\top} \mathbf{e}^{(s')})$, which is zero unless $r = r'$ and $s = s'$. So the $\mathbf{v}_{rs}$ are $(a - 1)(b - 1)$ nonzero orthogonal vectors in a space of that dimension, an orthogonal basis of $\mathcal{C}(\mathbf{P}_{AB})$. Hence $\|\mathbf{P}_{AB} \mathbf{y}\|^2 = \sum_{r,s} (\mathbf{v}_{rs}^\top \mathbf{y})^2 / \|\mathbf{v}_{rs}\|^2$. Finally $\mathbf{v}_{rs}^\top \mathbf{y} = m \sum_{i,j} d_{ij}^{(rs)} \bar{y}_{ij\cdot}$ and $\|\mathbf{v}_{rs}\|^2 = m \sum_{i,j} (d_{ij}^{(rs)})^2$, so each term is $SS(\mathbf{d}^{(rs)})$ of [Eq. 16.3.3](#). Independence follows from [Theorem 4.4.4](#) applied to the projections onto the lines $\text{span}(\mathbf{v}_{rs})$ and $\mathbf{P}_E$. ■

Product contrasts suit factors with structure. If $\mathbf{c}$ compares a control with the treatments and $\mathbf{e}$ is a linear trend in a quantitative factor, then $\mathbf{c}\mathbf{e}^\top$ asks whether the trend differs between them. The cell-means model of a balanced layout with quantitative levels w_i and z_j is the same as the polynomial model with all terms $w^r z^s$, $r < a$, $s < b$ ([Exercise \(B3\)](#)), and the product contrasts of orthogonal polynomials give its sequential sums of squares.

16.3.3 Simultaneous inference

The tests and contrasts above come in families, and the methods of [Chapter 13](#) apply directly.

- **Tukey for the levels of one factor.** The row means $\bar{y}_{i\cdot}$ are independent, each with variance $\sigma^2 / (bm)$. They are functions of $(\mathbf{I} - \mathbf{P}_E) \mathbf{Y}$, hence independent of MSE, with or without interaction ([Exercise \(B2\)](#)). So [Theorem 13.3.2](#) applies with $g = a$, multiplier $q_\alpha(a, ab(m - 1))$ and standard error $s / \sqrt{bm}$.

- **Scheffé for interaction contrasts.** Taking $\mathcal{V} = \mathcal{C}(\mathbf{P}_{AB})$ in [Theorem 13.2.2](#) gives intervals for all interaction contrasts at once, with multiplier $\sqrt{(a-1)(b-1)F_\alpha((a-1)(b-1), ab(m-1))}$. By [Corollary 13.2.3](#), some interaction contrast is Scheffé-significant iff the F_{AB} test rejects. This is the honest way to report a contrast suggested by the interaction plot. The most extreme contrast always accounts for the whole interaction sum of squares ([Exercise \(C1\)](#)); the question is whether it is interpretable.
- **Bonferroni or Holm for planned families** ([Theorem 13.4.1](#), [Theorem 13.4.5](#)), such as the comparison of two levels of A separately at each level of B .

Example. (Analysis of the bread trial)

For the data of [Example \(Flour and proofing temperature\)](#), the decomposition of [Theorem 16.3.1](#) gives

Source	df	Sum of squares	Mean square	F	p
flour	2	1627629	813814	255.74	6.6×10^{-17}
temperature	3	140499	46833	14.72	1.2×10^{-5}
interaction	6	98947	16491	5.18	1.5×10^{-3}
error	24	76373	3182		

so $s = 56.4$ ml, and the interaction is clearly present. The script confirms that statsmodels reports the same sums of squares for Types I, II and III, as part (e) says.

Where is the interaction? Take the flour contrasts $(2, -1, -1)$ (white against the other two) and $(0, 1, -1)$ (wholemeal against rye), and the orthogonal polynomial contrasts $(-3, -1, 1, 3)$, $(1, -1, -1, 1)$, $(-1, 3, -3, 1)$ for the equally spaced temperatures. The six products split SS_{AB} as in [Proposition 16.3.2](#):

	linear	quadratic	cubic
white vs others	52152 ($F = 16.39$)	3134 ($F = 0.98$)	6011 ($F = 1.89$)
wholemeal vs rye	8118 ($F = 2.55$)	18872 ($F = 5.93$)	10660 ($F = 3.35$)

The six add up to 98947. The largest piece, a fraction 0.527 of the interaction, says that white flour responds to temperature more steeply than the others. The second is the wholemeal peak at 32 °C. Does the white-by-linear component survive the most generous correction? Its estimate is 1444.3. The temperature contrast has $\sum_j e_j t_j = -72 - 28 + 32 + 108 = 40$, and the flour contrast is twice “white minus the average of the others”, so the estimate divided by 80 is the difference between white flour’s slope and the average slope of the other two: 18.05 ml per °C. The Scheffé multiplier for interaction contrasts is 3.879, and the simultaneous interval for this slope difference is $[0.75, 35.35]$ ml per °C. It excludes zero even though Scheffé’s correction allows for every contrast the plot might have suggested. The temperature main effect is almost entirely linear, with sequential sums of squares 134098, 6373 and 28 for the linear, quadratic and cubic components.

Comparing the flours. The equal-weight flour means are 2074.8, 1727.1 and 1565.2 ml. Tukey’s multiplier $q_{0.05}(3, 24) = 3.532$ with standard error $s/\sqrt{12}$ gives half-width 57.5 ml. White minus wholemeal is 347.7, with interval $[290.2, 405.3]$. White minus rye blend is 509.7 $[452.2, 567.2]$, and wholemeal minus rye blend is 161.9 $[104.4, 219.4]$. Because of the interaction, these average over the four temperatures the trial happened to use. The simple effects of white against wholemeal, with Bonferroni intervals for the four temperatures (multiplier $t_{24, 0.05/8} = 2.700$, half-width 124.4), are 250.7 $[126.3, 375.0]$, 376.7 $[252.3, 501.0]$, 302.3 $[178.0, 426.7]$ and 461.3 $[337.0, 585.7]$. All four lie above zero, so with simultaneous confidence 95% white flour is better at every temperature, and hence ([Proposition 16.2.3\(c\)](#)) under any weighting of the temperatures.

```
import itertools

import numpy as np
from scipy import stats

flours = ["white", "wholemeal", "rye blend"]
temps = [24, 28, 32, 36]

temperature
half_simple = t_bonf * s * np.sqrt(2 / m)
for j in range(b):
    d = cell[0, j] - cell[1, j]
    print(f"white - wholemeal at {temps[j]} C: {d:6.1f}  Bonferroni [{d -

```

```
half_simple:6.1f}, {d + half_simple:6.1f}])")
c_scheffe = np.sqrt(df["interaction"] * stats.f.ppf(0.95, df["interaction"], nu))
```

Warning. It is tempting to drop a nonsignificant interaction and “pool” its sum of squares into the error. With $ab(m-1)$ error degrees of freedom already available this gains little. If the interaction is real, the pooled mean square overestimates σ^2 , and if the decision to pool depends on the data, the nominal levels no longer hold (Section 16.4).

16.3.4 Exercises

16.3.4.1 A. Check your understanding

Exercise A1.

Let $SS_{\text{cells}} = m \sum_{i,j} (\bar{y}_{ij} - \bar{y}_{...})^2$, the between-cells sum of squares of the one-way layout with ab groups. Show that $SS_{\text{cells}} = SS_A + SS_B + SS_{AB}$, and identify each term with a projection.

16.3.4.2 B. Practice

Exercise B1.

Suppose all cell means are equal except μ_{11} , which is larger by δ . Find α_i , β_j and γ_{ij} , and show that the noncentralities of F_A , F_B and F_{AB} are

$$\frac{m\delta^2}{\sigma^2} \cdot \frac{a-1}{ab}, \quad \frac{m\delta^2}{\sigma^2} \cdot \frac{b-1}{ab}, \quad \frac{m\delta^2}{\sigma^2} \cdot \frac{(a-1)(b-1)}{ab}.$$

Which test is most likely to detect a single deviant cell when a and b are large?

Solution. The row means are $\bar{\mu}_{1.} = \mu + \delta/b$ and $\bar{\mu}_{i.} = \mu$ otherwise, and the grand mean is $\mu + \delta/(ab)$. So $\alpha_1 = \delta(a-1)/(ab)$ and $\alpha_i = -\delta/(ab)$ for $i \geq 2$, and

$$\sum_i \alpha_i^2 = \frac{\delta^2}{a^2 b^2} ((a-1)^2 + (a-1)) = \frac{\delta^2(a-1)}{ab^2},$$

so $bm \sum_i \alpha_i^2 / \sigma^2 = m\delta^2(a-1)/(ab\sigma^2)$. By symmetry the noncentrality for B is $m\delta^2(b-1)/(ab\sigma^2)$. For the interaction, $\gamma_{ij} = \delta(g_i - 1/a)(h_j - 1/b)$, where $g_1 = h_1 = 1$ and $g_i = h_j = 0$ for $i, j \geq 2$, so $\sum \gamma_{ij}^2 = \delta^2 \cdot \frac{a-1}{a} \cdot \frac{b-1}{b}$, and the noncentrality is $m\delta^2(a-1)(b-1)/(ab\sigma^2)$. For large a, b the interaction noncentrality approaches $m\delta^2/\sigma^2$, while the main-effect noncentralities approach $m\delta^2/(b\sigma^2)$ and $m\delta^2/(a\sigma^2)$. Almost all of a single deviant cell shows up as interaction. It is, however, spread over $(a-1)(b-1)$ degrees of freedom, and the Scheffé-type contrast aimed at that cell is the one to look at.

Exercise B2.

In the cell-means model Eq. 16.3.1 with normal errors, show that $\bar{y}_{1..}, \dots, \bar{y}_{a..}$ are in-

dependent, each with variance $\sigma^2/(bm)$, and jointly independent of SSE, whatever the μ_{ij} . Deduce Tukey intervals for all $\bar{\mu}_{i.} - \bar{\mu}_{k.}$ with exact simultaneous coverage.

Solution. Different rows use disjoint sets of the independent observations, so the row means are independent, and each averages bm observations. The vector of row means is a linear function of $(\mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m)\mathbf{Y}$, whose range lies in $\mathcal{C}(\mathbf{P}_0 + \mathbf{P}_A) \perp \mathcal{C}(\mathbf{P}_E)$. By [Theorem 4.4.4](#), $(\mathbf{P}_0 + \mathbf{P}_A)\mathbf{Y}$ and $\mathbf{P}_E\mathbf{Y}$ are independent, and $\text{SSE} = \|\mathbf{P}_E\mathbf{Y}\|^2$. The row means have expectations $\bar{\mu}_{i.}$. These are exactly the conditions used in the proof of [Theorem 13.3.2](#), with $g = a$, common variance $\sigma^2/(bm)$ and $\nu = ab(m-1)$. So the intervals $\bar{y}_{i.} - \bar{y}_{k.} \pm q_\alpha(a, ab(m-1)) s/\sqrt{bm}$ have simultaneous coverage exactly $1 - \alpha$.

Exercise B3.

Let the levels of A and B be distinct numbers $w_1, \dots, w_a$ and $z_1, \dots, z_b$. Show that the vectors with entries $w_i^r z_j^s$ (repeated over replicates), $0 \leq r < a$, $0 \leq s < b$, span the cell-means space $\mathcal{C}(\mathbf{X})$. Show that the additive model corresponds to the terms with $r = 0$ or $s = 0$. What does the coefficient of wz measure?

16.3.4.3 C. Going deeper

Exercise C1.

Let $\hat{\gamma}_{ij} = \bar{y}_{ij.} - \bar{y}_{i.} - \bar{y}_{.j} + \bar{y}_{...}$. Show that among all interaction contrasts, $\text{SS}(\mathbf{d})$ of [Eq. 16.3.3](#) is largest for $d_{ij} \propto \hat{\gamma}_{ij}$, and that the maximum is SS_{AB} . Relate this to [Corollary 13.2.3\(a\)](#). Why does it mean that the F statistic of a contrast chosen after inspecting the interaction plot cannot be compared with $F(1, ab(m-1))$?

Solution. Since (d_{ij}) has zero margins, $\sum d_{ij}\bar{y}_{ij.} = \sum d_{ij}\hat{\gamma}_{ij}$ ([Proposition 16.2.1](#) applied to the table of cell means). By the Cauchy–Schwarz inequality, $(\sum d_{ij}\hat{\gamma}_{ij})^2 \leq \sum d_{ij}^2 \sum \hat{\gamma}_{ij}^2$, with equality iff $\mathbf{d} \propto \hat{\boldsymbol{\gamma}}$. Hence $\text{SS}(\mathbf{d}) \leq m \sum \hat{\gamma}_{ij}^2 = \text{SS}_{AB}$, with equality at $\mathbf{d} = \hat{\boldsymbol{\gamma}}$, which is itself a zero-margin table. In the notation of [Corollary 13.2.3\(a\)](#) this says that the largest single-contrast F ratio is $(a-1)(b-1)F_{AB}$. A contrast chosen for its large value is, in the extreme, this maximizing contrast. Its null distribution is that of $(a-1)(b-1)$ times an $F((a-1)(b-1), ab(m-1))$ variable, not $F(1, ab(m-1))$.

Exercise C2.

For each column j , let $\text{SS}_{A|j} = m \sum_i (\bar{y}_{ij.} - \bar{y}_{.j})^2$ be the sum of squares for A computed within column j alone. Show that $\sum_j \text{SS}_{A|j} = \text{SS}_A + \text{SS}_{AB}$, and find the projection whose squared length is the left side. What hypothesis does the corresponding F test with $b(a-1)$ numerator degrees of freedom address?

16.4 Higher-way layouts

Nothing in the two-way analysis depended on there being two factors. With t crossed factors, all combinations observed equally often, the observation space splits into 2^t mutually orthogonal

pieces plus error, one for each set of factors. This section proves that decomposition, interprets the interaction of three or more factors, specializes to two-level factorial designs, and ends with a warning about pooling “negligible” terms into error.

16.4.1 The general balanced factorial

Let factors $F_1, \dots, F_t$ have $l_1, \dots, l_t \geq 2$ levels. Suppose all $N = l_1 \cdots l_t$ combinations are observed $m \geq 1$ times each, so $n = Nm$. Stack the observations with the replicate index fastest, then the level of F_t , and so on, with F_1 slowest. For a subset $S \subseteq \{1, \dots, t\}$, a *term*, define

$$\begin{aligned} \mathbf{P}_S &= \mathbf{E}_1 \otimes \cdots \otimes \mathbf{E}_t \otimes \bar{\mathbf{J}}_m, & \mathbf{E}_s &= \begin{cases} \mathbf{C}_{l_s}, & s \in S, \\ \bar{\mathbf{J}}_{l_s}, & s \notin S, \end{cases} \\ \mathbf{P}_E &= \mathbf{I}_{l_1} \otimes \cdots \otimes \mathbf{I}_{l_t} \otimes \mathbf{C}_m, \end{aligned} \quad (16.4.1)$$

and the **marginal averaging operator**

$$\mathbf{A}_S = \mathbf{G}_1 \otimes \cdots \otimes \mathbf{G}_t \otimes \bar{\mathbf{J}}_m, \quad \mathbf{G}_s = \begin{cases} \mathbf{I}_{l_s}, & s \in S, \\ \bar{\mathbf{J}}_{l_s}, & s \notin S. \end{cases}$$

The operator $\mathbf{A}_S$ replaces each observation by the mean of all observations that share its levels of the factors in S . For example, with three factors A, B, C , $\mathbf{A}_{\{A,C\}}\mathbf{y}$ has entries $\bar{y}_{i.k..}$. Let $\mathcal{V}_S$ be the set of vectors whose entries depend only on the levels of the factors in S . It is the column space of the indicator matrix of the combinations of those factors. So $\mathcal{V}_\emptyset = \text{span}(\mathbf{1})$, and $\mathcal{V}_{\{1, \dots, t\}}$ is the space of the full cell-means model.

Theorem 16.4.1 — The balanced factorial decomposition

In the setting above:

- (a) The 2^t matrices $\mathbf{P}_S$ and $\mathbf{P}_E$ are mutually orthogonal projections that sum to $\mathbf{I}$. Their ranks are $r_S = \prod_{s \in S} (l_s - 1)$ (with $r_\emptyset = 1$) and $N(m - 1)$.
- (b) $\mathbf{A}_S$ is the orthogonal projection onto $\mathcal{V}_S$, and $\mathbf{A}_S = \sum_{T \subseteq S} \mathbf{P}_T$. So $\mathcal{V}_S = \bigoplus_{T \subseteq S} \mathcal{C}(\mathbf{P}_T)$.
- (c) $\mathbf{P}_S = \sum_{T \subseteq S} (-1)^{|S|-|T|} \mathbf{A}_T$. Thus $\mathbf{P}_S \mathbf{y}$ is the alternating sum of the marginal means over the subsets of S .
- (d) Let $\mathcal{H}$ be a *hierarchical* family of terms: $\emptyset \in \mathcal{H}$, and $T \subseteq S \in \mathcal{H}$ implies $T \in \mathcal{H}$. The model $\mathbf{E}(\mathbf{Y}) \in \sum_{S \in \mathcal{H}} \mathcal{V}_S$, which contains the terms in $\mathcal{H}$ and nothing else, has projection $\sum_{S \in \mathcal{H}} \mathbf{P}_S$. If terms are entered one at a time so that each term follows all of its subsets, the sequential sum of squares of term S is $\|\mathbf{P}_S \mathbf{y}\|^2$, whatever the order.
- (e) If $\mathbf{E}(\mathbf{Y}) = \boldsymbol{\mu} \in \mathcal{V}_{\{1, \dots, t\}}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, then $\mathbf{E}\|\mathbf{P}_S \mathbf{Y}\|^2 = \sigma^2 r_S + \|\mathbf{P}_S \boldsymbol{\mu}\|^2$. Under normality the $\|\mathbf{P}_S \mathbf{Y}\|^2$ and $\text{SSE} = \|\mathbf{P}_E \mathbf{Y}\|^2$ are independent. When $m \geq 2$,

$$F_S = \frac{\|\mathbf{P}_S \mathbf{Y}\|^2 / r_S}{\text{SSE} / (N(m - 1))} \sim F(r_S, N(m - 1), \|\mathbf{P}_S \boldsymbol{\mu}\|^2 / \sigma^2).$$

Proof.

- (a) By Lemma 16.1.1(d) with $t + 1$ factors, $\mathbf{I}$ is the sum of the 2^{t+1} products with $\bar{\mathbf{J}}$ or

- $\mathbf{C}$ in each position. Those with $\bar{\mathbf{J}}_m$ last are the $\mathbf{P}_S$. Those with $\mathbf{C}_m$ last add up to $\mathbf{I} \otimes \cdots \otimes \mathbf{I} \otimes \mathbf{C}_m = \mathbf{P}_E$. Orthogonality and ranks come from [Lemma 16.1.1](#)(b) and (c).
- (b) In each position $s \in S$ write $\mathbf{I}_{l_s} = \bar{\mathbf{J}}_{l_s} + \mathbf{C}_{l_s}$ and expand. This gives $\mathbf{A}_S = \sum_{T \subseteq S} \mathbf{P}_T$, a sum of orthogonal projections, hence a projection ([Theorem 6.3.7](#)) onto $\bigoplus_{T \subseteq S} \mathcal{C}(\mathbf{P}_T)$. The entries of $\mathbf{A}_S \mathbf{y}$ are means over sets of observations with the same levels of the factors in S , so $\mathcal{C}(\mathbf{A}_S) \subseteq \mathcal{V}_S$. Conversely, averaging a vector in $\mathcal{V}_S$ over such a set leaves it unchanged, so $\mathcal{V}_S \subseteq \mathcal{C}(\mathbf{A}_S)$.
- (c) In each position $s \in S$ write $\mathbf{C}_{l_s} = \mathbf{I}_{l_s} - \bar{\mathbf{J}}_{l_s}$ and expand. Choosing $\mathbf{I}$ in the positions of $T \subseteq S$ and $-\bar{\mathbf{J}}$ in the rest of S gives $(-1)^{|S|-|T|} \mathbf{A}_T$.
- (d) By (b), $\sum_{S \in \mathcal{H}} \mathcal{V}_S = \sum_{S \in \mathcal{H}} \bigoplus_{T \subseteq S} \mathcal{C}(\mathbf{P}_T)$. Every T appearing belongs to $\mathcal{H}$, and every $T \in \mathcal{H}$ appears (take $S = T$). So the model space is $\bigoplus_{T \in \mathcal{H}} \mathcal{C}(\mathbf{P}_T)$, with projection $\sum_{T \in \mathcal{H}} \mathbf{P}_T$ ([Theorem 6.3.7](#)). If the terms enter in an order in which each follows its subsets, every intermediate model is hierarchical. Two consecutive models differ by one term S , so their projections differ by $\mathbf{P}_S$ ([Definition 9.3.1](#)).
- (e) The subspaces $\mathcal{C}(\mathbf{P}_S)$ form an analysis of variance decomposition of $\mathcal{V}_{\{1, \dots, t\}}$ by (a) and (b). Apply [Theorem 9.6.1](#) and [Corollary 9.6.2](#).

■

With $t = 2$ the theorem is [Theorem 16.3.1](#), since $\mathbf{P}_{\{1\}} = \mathbf{P}_A$, $\mathbf{P}_{\{2\}} = \mathbf{P}_B$ and $\mathbf{P}_{\{1,2\}} = \mathbf{P}_{AB}$. Part (c) gives the familiar formulas. For three factors A, B, C with levels indexed by i, j, k and replicates by r , the three-factor term has entries

$$(\mathbf{P}_{ABC} \mathbf{Y})_{ijk r} = \bar{y}_{ijk \cdot} - \bar{y}_{ij \cdot \cdot} - \bar{y}_{i \cdot k \cdot} - \bar{y}_{\cdot j k \cdot} + \bar{y}_{i \cdot \cdot} + \bar{y}_{\cdot j \cdot \cdot} + \bar{y}_{\cdot \cdot k \cdot} - \bar{y}_{\cdot \cdot \cdot \cdot}.$$

Part (d) explains why balanced factorials have one analysis of variance table and not several. The qualification “each term follows its subsets” matters: entering AB before A gives A nothing, because $\mathcal{V}_A \subseteq \mathcal{V}_{AB}$ ([Exercise \(B1\)](#)). The listing builds the decomposition for a $2 \times 3 \times 4$ layout with $m = 2$ and checks the ranks of part (a). The script also checks parts (b), (c) and (d).

```

        continue
    label = "".join(f for f, s in zip("ABC", S) if s) or "mean"
    print(f"{label:5s} rank {rank(P3[S]):2d}    predicted {int(np.prod([1 - 1 for l,
s in zip(levels, S) if s]))}")
print("error rank", rank(P3["error"]), "    n =", int(np.prod(levels)) * m3)

```

16.4.2 Three-factor interaction

In a three-factor layout with cell means μ_{ijk} , the two-factor interaction of A and B can be computed separately at each level k of C :

$$\gamma_{ij}^{(k)} = \mu_{ijk} - \bar{\mu}_{i..k} - \bar{\mu}_{.jk} + \bar{\mu}_{...k}.$$

The AB interaction of the analysis of variance, the entries of $\mathbf{P}_{AB}\boldsymbol{\mu}$, is the average of these over k . A three-factor interaction is present when they are not all the same.

Proposition 16.4.2 — Three-factor interaction

For the cell means μ_{ijk} of a three-factor layout, the following are equivalent:

- (i) $\mathbf{P}_{ABC}\boldsymbol{\mu} = \mathbf{0}$;
- (ii) the AB interaction effects $\gamma_{ij}^{(k)}$ at level k of C do not depend on k ;
- (iii) every AB interaction contrast $\sum_{i,j} d_{ij}\mu_{ijk}$ has the same value at every level k of C ;
- (iv) statements (ii) and (iii) with the roles of the three factors permuted in any way;
- (v) $\mu_{ijk} = f_{ij} + g_{ik} + h_{jk}$ for some numbers f_{ij}, g_{ik}, h_{jk} .

Proof. It suffices to consider $m = 1$, since the replicate factor $\bar{\mathbf{J}}_m$ only repeats entries. Then $\mathbf{P}_{ABC} = \mathbf{C}_a \otimes \mathbf{C}_b \otimes \mathbf{C}_c = \mathbf{C}_a \otimes \mathbf{C}_b \otimes \mathbf{I}_c - \mathbf{C}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_c$. Applied to $\boldsymbol{\mu}$, the first term produces $\gamma_{ij}^{(k)}$ in position (i, j, k) , because it centres over i and over j within each k . The second produces the average of $\gamma_{ij}^{(k)}$ over k . So (i) holds iff $\gamma_{ij}^{(k)}$ equals its average over k for all i, j, k , which is (ii). By Proposition 16.2.1, $\sum_{i,j} d_{ij}\mu_{ijk} = \sum_{i,j} d_{ij}\gamma_{ij}^{(k)}$ for every zero-margin table (d_{ij}) . Since the tables $\gamma^{(k)}$ themselves have zero margins, $\gamma^{(k)} = \gamma^{(k')}$ iff their inner products with every zero-margin $\mathbf{d}$ agree (take $\mathbf{d} = \gamma^{(k)} - \gamma^{(k')}$). This proves (ii) $\Leftrightarrow$ (iii). Statement (i) is symmetric in the three factors, which gives (iv).

Finally, the vectors of the form in (v) make up $\mathcal{V}_{AB} + \mathcal{V}_{AC} + \mathcal{V}_{BC}$, the model space of the hierarchical family of all terms except ABC . By [Theorem 16.4.1\(d\)](#) this is the orthogonal complement of $\mathcal{C}(\mathbf{P}_{ABC})$ in the cell-means space, so $\boldsymbol{\mu}$ lies in it iff $\mathbf{P}_{ABC}\boldsymbol{\mu} = \mathbf{0}$. ■

So the three-factor interaction is an “interaction of interactions”. It measures how much the pattern of AB interaction changes from one level of C to another, and by (iv) it measures the same thing whichever factor plays the role of C . When it is present, the AB interaction in the table is an equal-weight average over the levels of C , with all the caveats of [Section 16.2](#). Interpretation proceeds from the top down: examine the highest-order interactions clearly present, then read lower-order terms as averages or look at simple effects. Models are usually required to be hierarchical, because a model with AB but without A constrains the equal-weight average $\bar{\mu}_{i..}$, and so depends on an arbitrary choice of weights.

16.4.3 Two-level factorial designs

When every factor has two levels, each $\mathbf{C}_2$ has rank one, and every term of [Theorem 16.4.1](#) has a single degree of freedom. Code the levels of each factor as -1 (“low”) and $+1$ (“high”). For a nonempty term S , let $\mathbf{x}_S$ be the column whose entry for an observation is the product of the codes of the factors in S . For example, $\mathbf{x}_{AC}$ is $+1$ when A and C are at the same level and -1 otherwise. The **effect** of S is

$$\hat{E}_S = \bar{y}(\mathbf{x}_S = +1) - \bar{y}(\mathbf{x}_S = -1),$$

the mean response where $\mathbf{x}_S$ is $+1$ minus the mean where it is -1 . For a main effect this is the average change in response when the factor moves from low to high. For AC it is half the difference between the effect of C at high A and at low A ([Exercise \(B2\)](#)).

Proposition 16.4.3 — Effects in a 2^t factorial

In a 2^t factorial with m replicates, $n = 2^t m$, and a nonempty term S :

- (a) $\mathbf{P}_S = \mathbf{x}_S \mathbf{x}_S^\top / n$. The columns $\mathbf{x}_S$ are mutually orthogonal and orthogonal to $\mathbf{1}$.
- (b) $\hat{E}_S = 2\mathbf{x}_S^\top \mathbf{y} / n$, and $\text{Var}(\hat{E}_S) = 4\sigma^2 / n$. Estimated effects of different terms are uncorrelated.
- (c) The sum of squares of S is $\|\mathbf{P}_S \mathbf{y}\|^2 = n\hat{E}_S^2 / 4$.
- (d) In the regression of $\mathbf{y}$ on $\mathbf{1}$ and all $2^t - 1$ columns $\mathbf{x}_S$, the coefficient of $\mathbf{x}_S$ is $\hat{E}_S / 2$, and it is the same in every submodel that contains $\mathbf{x}_S$.

Proof.

- (a) With $\mathbf{u} = (-1, 1)^\top$, $\mathbf{C}_2 = \frac{1}{2}\mathbf{u}\mathbf{u}^\top$ and $\bar{\mathbf{J}}_2 = \frac{1}{2}\mathbf{1}_2\mathbf{1}_2^\top$. By the mixed-product rule $\mathbf{P}_S = (2^t m)^{-1} \mathbf{x} \mathbf{x}^\top$, where $\mathbf{x}$ is the Kronecker product with $\mathbf{u}$ in the positions of S , $\mathbf{1}_2$ elsewhere, and $\mathbf{1}_m$ last. Its entries are the products of the codes of the factors in S , so $\mathbf{x} = \mathbf{x}_S$. Orthogonality follows from [Theorem 16.4.1\(a\)](#), since $\mathbf{x}_S \in \mathcal{C}(\mathbf{P}_S)$ and $\mathbf{1} \in \mathcal{C}(\mathbf{P}_\emptyset)$.
- (b) Since $\mathbf{x}_S \perp \mathbf{1}$, exactly $n/2$ entries are $+1$, so $\mathbf{x}_S^\top \mathbf{y} = \frac{n}{2}(\bar{y}(+) - \bar{y}(-))$. Then $\text{Var}(\hat{E}_S) = (4/n^2)\sigma^2 \|\mathbf{x}_S\|^2 = 4\sigma^2/n$. Covariances are $(4/n^2)\sigma^2 \mathbf{x}_S^\top \mathbf{x}_T = 0$.

- (c) $\|\mathbf{P}_S \mathbf{y}\|^2 = (\mathbf{x}_S^\top \mathbf{y})^2 / n = n \hat{E}_S^2 / 4$.
- (d) With orthogonal columns each coefficient is $\mathbf{x}_S^\top \mathbf{y} / \|\mathbf{x}_S\|^2 = \mathbf{x}_S^\top \mathbf{y} / n$ and does not depend on the other columns (Proposition 7.2.4).

■

Example. (Heat seals: an unreplicated 2^4 design)

A packaging line makes heat seals on plastic film. Four factors were each set at two levels: A , jaw temperature; B , jaw pressure; C , dwell time; D , film gauge. One seal was made at each of the 16 combinations, in random order, and its peel strength was measured in newtons. The data are synthetic, generated by the script `two_level.py`. In standard order (A changing fastest), the strengths are

run	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
A		+		+		+		+		+		+		+		+
B			+	+			+	+			+	+			+	+
C					+	+	+	+					+	+	+	+
D									+	+	+	+	+	+	+	+
y	28.5	32.1	26.7	31.1	29.0	37.4	27.2	37.4	25.8	26.6	24.2	28.8	24.9	34.3	25.9	36.7

The mean is 29.79. The largest estimated effects are A (6.52), C (3.62), AC (3.17) and D (−2.78). They are followed by BD (1.08) and AB (0.98), and none of the other nine exceeds 0.53 in absolute value. There is no pure error. The experimenters had decided *before the trial* to treat the five interactions of three or four factors as negligible and to use their sums of squares as error. That gives $s^2 = 0.514$ on 5 degrees of freedom. Against the critical value $F_{0.05}(1, 5) = 6.61$, the tests reject for A , C and AC ($F = 331.0, 102.2, 78.4$, each $p < 0.001$), for D ($F = 59.9, p = 0.001$), and, nominally, for BD ($p = 0.030$) and AB ($p = 0.042$). The last two are among ten tests, however. Holm's procedure at familywise level 0.05 (Theorem 13.4.5) accepts A , C , AC and D and stops at BD , whose p -value exceeds 0.05/6. The data were in fact generated with exactly those four effects.

The interaction AC matters in practice. The effect of dwell time is $\hat{E}_C + \hat{E}_{AC} = 3.62 + 3.17 = 6.79$ N at high temperature and $\hat{E}_C - \hat{E}_{AC} = 0.45$ N at low temperature (Exercise B2)). Longer dwell helps only when the jaws are hot. Figure 16.4.1 shows the half-normal plot of Daniel (1959): absolute effects against half-normal quantiles. Noise falls near a line through the origin and real effects stand out above it, with no estimate of σ needed.

```
import itertools

import numpy as np
from scipy import stats

k = 4
runs = np.array(list(itertools.product([-1, 1], repeat=k))[:, :-1]) # standard
                        order: A changes fastest
names = []
columns = []
```

Figure 16.4.1: Half-normal plot of the 15 absolute effects of the heat-seal experiment. The dashed line through the origin is fitted to the ten smallest. *A*, *C*, *AC* and *D* stand clear of it.

```
for size in range(1, k + 1):
    for S in itertools.combinations(range(k), size):
        names.append("".join("ABCD"[i] for i in S))
        columns.append(np.prod(runs[:, list(S)], axis=1))
Xc = np.column_stack(columns)           # 16 x 15 matrix of +-1 contrast
columns
print("columns orthogonal:", np.allclose(Xc.T @ Xc, 16 * np.eye(15)))
```

```
true = 30 + 3.0 * runs[:, 0] + 2.0 * runs[:, 2] + 1.5 * runs[:, 0] * runs[:, 2] -
    1.25 * runs[:, 3]
rng = np.random.default_rng(16_04)
y = np.round(true + rng.normal(scale=1.0, size=16), 1)
n = len(y)
effects = Xc.T @ y / (n / 2)           # mean at + minus mean at -
ss = n * effects ** 2 / 4              # one degree of freedom each
order = np.argsort(-np.abs(effects))
for i in order[:6]:
    print(f"{names[i]:4s} effect {effects[i]:6.2f}    SS {ss[i]:7.2f}")
high = [i for i, nm in enumerate(names) if len(nm) >= 3]  # ABC, ABD, ACD, BCD,
ABCD
ss_pooled = ss[high].sum()
s2 = ss_pooled / len(high)
F = ss / s2
p = stats.f.sf(F, 1, len(high))
for i in order[:6]:
    print(f"{names[i]:4s} F = {F[i]:7.2f}    p = {p[i]:.3f}")
```

Two-level designs are economical: every main effect is estimated with the precision $4\sigma^2/n$ of the whole experiment, as if each factor had been studied alone with all n runs. With many factors, *fractional* factorials use a chosen subset of the 2^t runs and deliberately confound some effects with others. Box, Hunter and Hunter (2005) and Wu and Hamada (2009) develop that theory.

16.4.4 Pooling and its dangers

In [Example \(Heat seals: an unreplicated \$2^4\$ design\)](#) the error was built from the sums of squares of terms assumed to be zero. This is **pooling**: replacing SSE by $\text{SSE} + \sum_{T \in \mathcal{Q}} \|\mathbf{P}_T \mathbf{y}\|^2$, with $\nu_E + \sum_{T \in \mathcal{Q}} r_T$ degrees of freedom, for a set $\mathcal{Q}$ of terms. Without replication it is the only source of an error term. The theory is simple when $\mathcal{Q}$ is fixed in advance.

Proposition 16.4.4 — Pooling a fixed set of terms

In the setting of [Theorem 16.4.1\(e\)](#) with normal errors, let $\mathcal{Q}$ be a set of terms fixed before the data are seen. Let ν be the pooled degrees of freedom and MS_{pool} the pooled mean square. Let $S \notin \mathcal{Q}$ and $F_S^{\text{pool}} = (\|\mathbf{P}_S \mathbf{Y}\|^2 / r_S) / \text{MS}_{\text{pool}}$.

- (a) $\text{E MS}_{\text{pool}} = \sigma^2 + \nu^{-1} \sum_{T \in \mathcal{Q}} \|\mathbf{P}_T \boldsymbol{\mu}\|^2$.
- (b) If $\mathbf{P}_T \boldsymbol{\mu} = \mathbf{0}$ for every $T \in \mathcal{Q}$, then $F_S^{\text{pool}} \sim F(r_S, \nu, \|\mathbf{P}_S \boldsymbol{\mu}\|^2 / \sigma^2)$. The pooled test is exact and has more denominator degrees of freedom.
- (c) If $\mathbf{P}_S \boldsymbol{\mu} = \mathbf{0}$ but some pooled term is not null, then $\Pr\{F_S^{\text{pool}} > F_\alpha(r_S, \nu)\} < \alpha$. The test is conservative, and its power is reduced for the same reason.

Proof. The matrix $\mathbf{P}_{\text{pool}} = \mathbf{P}_E + \sum_{T \in \mathcal{Q}} \mathbf{P}_T$ is a projection of rank ν , orthogonal to $\mathbf{P}_S$ ([Theorem 16.4.1\(a\)](#)). By [Theorem 4.4.4](#), $U = \|\mathbf{P}_S \mathbf{Y}\|^2 / \sigma^2$ and $V = \|\mathbf{P}_{\text{pool}} \mathbf{Y}\|^2 / \sigma^2$ are independent, with $V \sim \chi^2(\nu, \delta)$ and $\delta = \sum_{T \in \mathcal{Q}} \|\mathbf{P}_T \boldsymbol{\mu}\|^2 / \sigma^2$, because $\mathbf{P}_E \boldsymbol{\mu} = \mathbf{0}$. Part (a) is the mean $\nu + \delta$ of V , times σ^2 / ν . If $\delta = 0$, (b) is the definition of the F distribution. For (c), $U \sim \chi^2(r_S)$, and with $c = F_\alpha(r_S, \nu)$,

$$\Pr\{F_S^{\text{pool}} > c\} = \text{E}\left[\Pr\left\{V < \frac{\nu U}{r_S c} \mid U\right\}\right].$$

By [Proposition 4.1.3](#), $\Pr\{\chi^2(\nu, \delta) < x\}$ is strictly smaller for $\delta > 0$ than for $\delta = 0$, for every $x > 0$. Taking expectations gives a probability smaller than its value at $\delta = 0$, which is α . ■

The dangers come when the choice of $\mathcal{Q}$ depends on the data. There are two common ways that happens.

Pooling after a preliminary test. A common rule pools an interaction into error if its own F test is not significant at a lenient level such as 0.25. Consider a $2 \times 3 \times 4$ layout with $m = 2$, so $\nu_E = 24$ and $r_{ABC} = 6$, and test a null main effect A at level 0.05 after this preliminary test of ABC . By [Theorem 16.4.1\(e\)](#), SS_A , SS_{ABC} and SSE are independent, with distributions $\sigma^2 \chi^2(1)$, $\sigma^2 \chi^2(6, \gamma_{ABC})$ and $\sigma^2 \chi^2(24)$. So the rule can be simulated exactly by drawing these three variables ([Figure 16.4.2](#)). When ABC is absent, the rule pools in 75% of samples, precisely those with small MS_{ABC} . The pooled denominator is biased downwards, and the test of A rejects a true null with probability 0.0551 instead of 0.05. When ABC is large the rule rarely pools, and the level returns to 0.05 (0.0504 at $\gamma_{ABC} = 30$). Always pooling is very conservative there (0.0064), as [Proposition 16.4.4\(c\)](#) predicts. Here the damage is modest, but a preliminary test buys degrees of freedom with a size that is no longer what it claims to be (Bancroft 1944).

```
import numpy as np
from scipy import stats
```

Figure 16.4.2: Rejection rate of the level-0.05 test of a true null main effect in a $2 \times 3 \times 4$ layout with two replicates, as the three-factor noncentrality γ_{ABC} grows. Never pooling is exact. Always pooling is conservative once ABC is present. Pooling after a preliminary test at level 0.25 is anticonservative near $\gamma_{ABC} = 0$. Each point is based on 400000 simulated samples.

```

alpha, alpha_pre = 0.05, 0.25
df_A, df_ABC, df_E = 1, 6, 24

def rejection_rates(gamma, reps, rng):
    """Size of the level-0.05 test of A under three pooling rules, when A has no
    effect."""
    ssA = rng.chisquare(df_A, reps)
    ssABC = rng.noncentral_chisquare(df_ABC, gamma, reps) if gamma > 0 else rng.
    chisquare(df_ABC, reps)
    ssE = rng.chisquare(df_E, reps)
    never = ssA / (ssE / df_E) > stats.f.ppf(1 - alpha, df_A, df_E)
    pooled_F = ssA / ((ssE + ssABC) / (df_E + df_ABC))
    always = pooled_F > stats.f.ppf(1 - alpha, df_A, df_E + df_ABC)
    pool = ssABC / df_ABC / (ssE / df_E) <= stats.f.ppf(1 - alpha_pre, df_ABC, df_E)
    pretest = np.where(pool, always, never)
    return never.mean(), always.mean(), pretest.mean(), pool.mean()

rng = np.random.default_rng(20260919)
gammas = np.array([0, 2, 4, 6, 8, 10, 12, 16, 20, 25, 30])
rates = np.array([rejection_rates(g, 400_000, rng) for g in gammas])
for g, (nv, al, pt, pl) in zip(gammas, rates):
    print(f"gamma {g:3d}: never {nv:.4f}  always {al:.4f}  pre-test {pt:.4f} (
    pooled in {pl:.2f})")

```

Pooling the smallest effects. The second temptation is much worse. In an unreplicated 2^t design one may look at the estimated effects, declare the smallest few to be “error”, and test the rest against them. If no factor does anything, the 15 estimated effects of a 2^4 design are independent normal variables with a common variance (Proposition 16.4.3(b)). Pool the five smallest in absolute value and test the largest against them with the $F(1, 5)$ critical value. It is declared significant in a fraction 0.999 of null data sets (and so, of course, at least one effect is declared significant). The five smallest of fifteen normal variables are the bottom third of the noise, and a mean square built from them underestimates the variance by a factor of 11.5 on average. This

is why the error terms in [Example \(Heat seals: an unreplicated \$2^4\$ design\)](#) were chosen before the data were seen, and why the half-normal plot and Lenth's (1989) robust standard error ([Exercise \(C1\)](#)) are the standard tools for unreplicated designs.

```
rng2 = np.random.default_rng(16_0404)
reps = 200_000
effects = rng2.normal(size=(reps, 15))           # 15 null effect
           estimates, common variance
sq = np.sort(effects ** 2, axis=1)
F_largest = sq[:, -1] / sq[:, :5].mean(axis=1)    # largest against the
           five smallest
size_largest = np.mean(F_largest > stats.f.ppf(1 - alpha, 1, 5))
pooled_ms = sq[:, :5].mean(axis=1)               # the "error" mean
           square; true variance 1
underestimate = 1 / pooled_ms.mean()             # factor by which it
           falls short on average
print(f"largest effect declared significant: {size_largest:.3f};"
      f" pooled mean square averages {pooled_ms.mean():.3f}, an underestimate by a
      factor {underestimate:.1f}")
```

Idea. Pooling is safe when the pooled terms are chosen before the data are seen and are genuinely negligible. It is conservative when they are chosen in advance but are not negligible. It is invalid when they are chosen because they look small.

16.4.5 Exercises

16.4.5.1 A. Check your understanding

Exercise A1.

List the terms and their degrees of freedom for a balanced $3 \times 2 \times 4$ layout with $m = 2$, and check that they add up to $n - 1$.

Exercise A2.

For t factors each with l levels, show that the number of terms involving exactly q factors is $\binom{t}{q}$, each with $(l - 1)^q$ degrees of freedom, and that these add up to $l^t - 1$.

16.4.5.2 B. Practice

Exercise B1.

In a balanced two-way layout, show that if AB (the cell indicators) is entered before A , the sequential sum of squares of A is zero. What does that say about software output for models written in a non-hierarchical order?

Exercise B2.

In a 2^t factorial, show that the effect of C computed only from the runs with A at its

high level is $\hat{E}_C + \hat{E}_{AC}$, and at the low level it is $\hat{E}_C - \hat{E}_{AC}$. Conclude that $\hat{E}_{AC}$ is half the difference between the two simple effects of C .

Solution. Let $\bar{y}_{ac}$ be the mean of the runs with codes $a, c \in \{-1, 1\}$ for A and C , each averaging $n/4$ runs. Then $\hat{E}_C = \frac{1}{2}(\bar{y}_{1,1} + \bar{y}_{-1,1}) - \frac{1}{2}(\bar{y}_{1,-1} + \bar{y}_{-1,-1})$, and, since $\mathbf{x}_{AC} = +1$ when the codes agree, $\hat{E}_{AC} = \frac{1}{2}(\bar{y}_{1,1} + \bar{y}_{-1,-1}) - \frac{1}{2}(\bar{y}_{1,-1} + \bar{y}_{-1,1})$. Adding, $\hat{E}_C + \hat{E}_{AC} = \bar{y}_{1,1} - \bar{y}_{-1,-1}$, the effect of C at high A . Subtracting gives $\bar{y}_{-1,1} - \bar{y}_{1,-1}$. Half the difference of the two is $\hat{E}_{AC}$.

Exercise B3.

Use [Theorem 16.4.1\(c\)](#) to derive the displayed formula for $(\mathbf{P}_{ABC}\mathbf{y})_{ijkl}$. Write the analogous formula for $(\mathbf{P}_{AB}\mathbf{y})_{ijkl}$ in a three-factor layout, and check that it does not involve k .

16.4.5.3 C. Going deeper

Exercise C1.

In an unreplicated 2^t design, let $\hat{E}_1, \dots, \hat{E}_K$ be the $K = 2^t - 1$ estimated effects. Lenth (1989) proposed $s_0 = 1.5 \text{median}|\hat{E}_S|$ and the *pseudo standard error* $\text{PSE} = 1.5 \text{median}\{|\hat{E}_S| : |\hat{E}_S| < 2.5s_0\}$. Show that if all effects are null and $\tau^2 = 4\sigma^2/n$, then $\text{median}|\hat{E}_S| \rightarrow 0.6745\tau$ as $K \rightarrow \infty$, so that s_0 estimates 1.01τ . Explain why the trimming at $2.5s_0$ makes PSE insensitive to a few large active effects, and why that is the property pooling lacks.

Solution. Under the null hypothesis the $\hat{E}_S$ are independent $N(0, \tau^2)$ variables ([Proposition 16.4.3\(b\)](#)), so $|\hat{E}_S|$ has the half-normal distribution with median $\tau \Phi^{-1}(0.75) = 0.6745\tau$. The sample median converges to it, and $1.5 \times 0.6745 \approx 1.01$, so $s_0 \approx \tau$. The median is unaffected by a few large values. The trimmed median in PSE additionally removes effects that are large compared with the first estimate before re-estimating, so active effects enter neither estimate as long as they are few (*effect sparsity*). Pooling the smallest effects uses the bottom of the distribution only and so is biased downwards. The median of all effects is instead a consistent estimate of the scale when most effects are null.

16.5 Nested factors

So far every level of one factor has appeared with every level of the other. Many studies are built differently. Pupils are taught in classrooms, and each classroom follows one curriculum. Specimens are cut from batches, and each batch comes from one supplier. Classroom 3 under one curriculum has nothing to do with classroom 3 under another: the factors are *nested*, not crossed. This section gives the decomposition for balanced nested layouts, explains why a nested factor has no main effect, and shows why the right denominator for the outer factor depends on what the inner levels represent.

16.5.1 Nested and crossed factors

Definition 16.5.1 — Nested factors

Factor B is **nested** in factor A if every level of B occurs together with exactly one level of A . Factors A and B are **crossed** if every level of B occurs with every level of A . A **balanced nested layout** has a levels of A , b levels of B within each level of A , and m observations at each level of B . We write $B(A)$ for the nested factor, index its levels within level i of A by $j = 1, \dots, b$, and write y_{ijk} , $k = 1, \dots, m$.

The labels j are local: (i, j) names a level of B , but j alone names nothing. The model is

$$E(y_{ijk}) = \mu + \alpha_i + \beta_{j(i)}, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}, \quad (16.5.1)$$

with $1 + a + ab$ parameters. Every level of B has its own mean $\mu_{ij} = \mu + \alpha_i + \beta_{j(i)}$, so the mean space is the set of vectors constant on each level of B , of dimension ab . This is the mean space of the crossed cell-means model [Eq. 16.3.1](#) on an array of the same shape. Nesting changes not the space of possible means but which questions about them make sense. In a crossed layout, averaging over i at fixed j is meaningful. In a nested layout it is not, so there is no main effect of B and no AB interaction, only variation among the levels of B within each level of A .

16.5.2 The nested decomposition

With the observations stacked as in [Section 16.1](#) (k fastest, then j , then i), define

$$\begin{aligned} \mathbf{P}_0 &= \bar{\mathbf{J}}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, & \mathbf{P}_A &= \mathbf{C}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m, \\ \mathbf{P}_{B(A)} &= \mathbf{I}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m, & \mathbf{P}_E &= \mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{C}_m. \end{aligned} \quad (16.5.2)$$

Theorem 16.5.1 — The balanced nested layout

Assume [Eq. 16.5.1](#) for a balanced nested layout with $a \geq 2$, $b \geq 2$, $m \geq 2$. Write μ_{ij} for the mean of level (i, j) of B and $\bar{\mu}_i = b^{-1} \sum_j \mu_{ij}$.

- (a) The four matrices [Eq. 16.5.2](#) are mutually orthogonal projections summing to $\mathbf{I}$, with ranks 1, $a - 1$, $a(b - 1)$ and $ab(m - 1)$. The first three sum to the projection onto the mean space. Moreover $\mathbf{P}_{B(A)} = \mathbf{P}_B + \mathbf{P}_{AB}$, where $\mathbf{P}_B$ and $\mathbf{P}_{AB}$ are the projections [Eq. 16.3.2](#) of the crossed layout of the same shape.
- (b) The sums of squares are

$$SS_A = bm \sum_i (\bar{y}_{i..} - \bar{y}_{...})^2, \quad SS_{B(A)} = m \sum_i \sum_j (\bar{y}_{ij.} - \bar{y}_{i..})^2, \quad SSE = \sum_{i,j,k} (y_{ijk} - \bar{y}_{ij.})^2.$$

So $SS_{B(A)}$ is the sum over i of the between-levels sums of squares of B computed separately within each level of A .

- (c) The function $\lambda_0 \mu + \sum_i \lambda_i \alpha_i + \sum_{i,j} \kappa_{ij} \beta_{j(i)}$ is estimable iff $\lambda_i = \sum_j \kappa_{ij}$ for every i and $\lambda_0 = \sum_i \lambda_i$. In particular $\beta_{j(i)} - \beta_{l(i)}$ is estimable, but $\beta_{j(i)} - \beta_{l(k)}$ with $i \neq k$

is not, and $\alpha_i - \alpha_k$ is not, while $\alpha_i - \alpha_k + \bar{\beta}_{\cdot(i)} - \bar{\beta}_{\cdot(k)} = \bar{\mu}_{i\cdot} - \bar{\mu}_{k\cdot}$ is.

(d) The expected mean squares are

$$E \text{ MS}_A = \sigma^2 + \frac{bm}{a-1} \sum_i (\bar{\mu}_{i\cdot} - \bar{\mu}_{\cdot\cdot})^2, \quad E \text{ MS}_{B(A)} = \sigma^2 + \frac{m}{a(b-1)} \sum_{i,j} (\mu_{ij} - \bar{\mu}_{i\cdot})^2, \quad E \text{ MSE} = \sigma^2.$$

Under normal errors the three sums of squares are independent, and $F_A = \text{MS}_A/\text{MSE}$ and $F_{B(A)} = \text{MS}_{B(A)}/\text{MSE}$ have noncentral F distributions with $(a-1, ab(m-1))$ and $(a(b-1), ab(m-1))$ degrees of freedom and noncentralities equal to σ^{-2} times the sums in the numerators above. So F_A is an exact test of $\bar{\mu}_{1\cdot} = \cdots = \bar{\mu}_{a\cdot}$, and $F_{B(A)}$ of $\mu_{ij} = \bar{\mu}_{i\cdot}$ for all i, j .

Proof.

- (a) Ranks and symmetric idempotence follow from [Lemma 16.1.1\(b\)](#). The mixed-product rule gives $\mathbf{P}_0 \mathbf{P}_A = \mathbf{0}$ (from $\bar{\mathbf{J}}_a \mathbf{C}_a$), $\mathbf{P}_0 \mathbf{P}_{B(A)} = \mathbf{P}_A \mathbf{P}_{B(A)} = \mathbf{0}$ (from $\bar{\mathbf{J}}_b \mathbf{C}_b$), and each of the first three is orthogonal to $\mathbf{P}_E$ (from $\bar{\mathbf{J}}_m \mathbf{C}_m$). Next, $\mathbf{P}_0 + \mathbf{P}_A = \mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m$, and adding $\mathbf{P}_{B(A)}$ gives $\mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m$, the projection onto the vectors constant on each level of B , which is the mean space. Adding $\mathbf{P}_E$ gives $\mathbf{I}$. Finally, $\mathbf{I}_a \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m = (\bar{\mathbf{J}}_a + \mathbf{C}_a) \otimes \mathbf{C}_b \otimes \bar{\mathbf{J}}_m = \mathbf{P}_B + \mathbf{P}_{AB}$.
- (b) $\mathbf{P}_{B(A)} = \mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m - \mathbf{I}_a \otimes \bar{\mathbf{J}}_b \otimes \bar{\mathbf{J}}_m$ maps y_{ijk} to $\bar{y}_{ij\cdot} - \bar{y}_{i\cdot\cdot}$. The other two are as in [Theorem 16.3.1\(b\)](#).
- (c) By [Theorem 8.2.2](#) the estimable functions are the linear combinations $\sum_{i,j} w_{ij}(\mu + \alpha_i + \beta_{j(i)})$ of the expected responses. Such a combination has $\kappa_{ij} = w_{ij}$, $\lambda_i = \sum_j w_{ij}$ and $\lambda_0 = \sum_{i,j} w_{ij}$, which gives the conditions. Conversely, if they hold, $w_{ij} = \kappa_{ij}$ reproduces the function. The three examples follow by checking the conditions. For $\alpha_i - \alpha_k$ all κ are zero but $\lambda_i = 1 \neq 0$.
- (d) Apply [Theorem 9.6.1](#) and [Corollary 9.6.2](#) to the decomposition in (a). The vector $\mathbf{P}_A \boldsymbol{\mu}$ has entries $\bar{\mu}_{i\cdot} - \bar{\mu}_{\cdot\cdot}$, repeated bm times, and $\mathbf{P}_{B(A)} \boldsymbol{\mu}$ has entries $\mu_{ij} - \bar{\mu}_{i\cdot}$, repeated m times.

■

Part (a) is the precise sense in which a nested factor “absorbs” the interaction. If nested data are analysed as though crossed, with the local labels j treated as real levels, the sums of squares for B and AB add up to $\text{SS}_{B(A)}$, but each depends on the arbitrary labelling ([Exercise \(B1\)](#)). Part (c) is the nested analogue of [Proposition 8.6.2](#). The contrasts among the outer levels that can be estimated are contrasts among averages over their own inner levels.

More stages work the same way. With A, B nested in A , and C nested in B , the projections are $\mathbf{C} \otimes \bar{\mathbf{J}} \otimes \bar{\mathbf{J}} \otimes \bar{\mathbf{J}}, \mathbf{I} \otimes \mathbf{C} \otimes \bar{\mathbf{J}} \otimes \bar{\mathbf{J}}, \mathbf{I} \otimes \mathbf{I} \otimes \mathbf{C} \otimes \bar{\mathbf{J}}$ and the error $\mathbf{I} \otimes \mathbf{I} \otimes \mathbf{I} \otimes \mathbf{C}$ ([Exercise \(B3\)](#)). Each nested term has an identity matrix in the positions of the factors it is nested in and a centring matrix in its own position. The listing checks the identity of part (a) and the ranks for $a = 3, b = 4, m = 2$.

```
import itertools

import numpy as np

def Jbar(k):
    return np.full((k, k), 1.0 / k)          # averaging: replaces a k-vector by its
```

```

mean

def Cen(k):
    return np.eye(k) - Jbar(k)          # centring: subtracts the mean

def kron_all(mats):
    out = np.ones((1, 1))
    for A in mats:
        out = np.kron(out, A)
    return out

def factorial_projections(levels, m):
    """P_S for every subset S of the factors (a 0/1 tuple), and the error projection
    ."""
    P = {}
    for S in itertools.product([0, 1], repeat=len(levels)):
        P[S] = kron_all([Cen(l) if s else Jbar(l) for l, s in zip(levels, S)] + [
            Jbar(m)])
    P["error"] = kron_all([np.eye(l) for l in levels] + [Cen(m)])
    return P

def rank(A):
    return int(round(np.trace(A)))        # rank = trace for a projection

a, b, m = 3, 4, 2
PB_in_A = kron_all([np.eye(a), Cen(b), Jbar(m)])          # B within A
P2 = factorial_projections([a, b], m)
print("B(A) = B + AB of the crossed layout:", np.allclose(PB_in_A, P2[(0, 1)] + P2
    [(1, 1)]))
print("rank of B(A):", rank(PB_in_A), " = a(b-1) =", a * (b - 1))

```

16.5.3 What the inner levels represent

The tests of [Theorem 16.5.1\(d\)](#) treat the levels of B as fixed. Then H_A says that the averages over *these particular* inner levels are equal, and the error is the variation within inner levels. That is right when the inner levels matter in themselves, such as three specific machines in each of two factories.

Often, though, the inner levels are a sample. The classrooms in a curriculum study stand for all classrooms that might follow that curriculum. Then the question about A concerns populations of inner levels, and the variation *between* inner levels is part of the noise against which A must be judged. A preview of [Chapters 32](#) and [33](#) makes this precise. If the $\beta_{j(i)}$ are independent $N(0, \sigma_B^2)$ variables, independent of normal errors, then $E MS_{B(A)} = \sigma^2 + m\sigma_B^2$, and $E MS_A$ has the same expression plus a term that vanishes under H_A ([Exercise \(C1\)](#)). The ratio $MS_A/MS_{B(A)}$ then has an exact $F(a-1, a(b-1))$ null distribution. The ratio MS_A/MSE does not, because its numerator is inflated by $m\sigma_B^2$ even when H_A is true. With $a(b-1)$ denominator degrees of freedom instead of $ab(m-1)$, the correct test is based, in effect, on the number of inner levels rather than the number of observations ([Exercise \(B2\)](#)).

Example. (Curricula and classrooms)

Seventy-two pupils took the same reading test after a year in one of three reading curricula. Each curriculum was followed in four classrooms, with six pupils tested per classroom. The data are synthetic, generated by the script `nested_classrooms.py` with random classroom effects (standard deviation 4 points), pupil-level noise (standard deviation 8), and curriculum means differing by a few points. The classroom means are

curriculum	classroom 1	classroom 2	classroom 3	classroom 4	mean
phonics	77.0	67.8	68.7	60.8	68.6
whole language	52.7	64.8	64.3	60.8	60.7
mixed	61.8	61.8	63.8	58.5	61.5

and the nested analysis of variance is

Source	df	Sum of squares	Mean square
curriculum	2	908.3	454.2
classroom(curriculum)	9	1445.8	160.6
pupils (error)	60	3063.3	51.1

Classrooms within curricula differ: $F_{B(A)} = 3.15$ on 9 and 60 degrees of freedom, $p = 0.004$. For curricula, the fixed-effects test of [Theorem 16.5.1\(d\)](#) gives $F = 8.90$ on 2 and 60 degrees of freedom ($p = 0.0004$). It says, correctly, that these twelve classrooms differ between curricula on average. Against the classroom mean square the ratio is $F = 2.83$ on 2 and 9 degrees of freedom ($p = 0.111$). For classrooms in general, no difference has been shown. [Figure 16.5.1](#) shows why: with only four classrooms per curriculum, the gap rests on a handful of classroom means. One phonics classroom (77.0) contributes much of it, and the lowest phonics classroom (60.8) sits among those of the other curricula.

The listing checks by simulation which test to trust. It generates 20000 data sets from the same design with random classroom effects and *no* curriculum effect. The test against pupils rejects at the nominal 5% level in a fraction 0.289 of them, and the test against classrooms in a fraction 0.051. Under the null hypothesis the ratio of the two expected mean squares is $(8^2 + 6 \cdot 4^2)/8^2 = 2.5$.

```
import numpy as np
from scipy import stats

a, b, m = 3, 4, 6
data_rng = np.random.default_rng(16_05)
curriculum_effect = np.array([3.0, -2.0, 0.0])
classroom_effect = data_rng.normal(scale=4.0, size=(a, b))
scores = np.round(62 + curriculum_effect[:, None, None] + classroom_effect[:, :,
    None]
    + data_rng.normal(scale=8.0, size=(a, b, m)))

def Jbar(k):
    return np.full((k, k), 1.0 / k)
```

Figure 16.5.1: Reading scores of the 72 pupils by classroom, grouped by curriculum. Solid bars mark classroom means and dashed lines curriculum means. Classrooms vary visibly within each curriculum.

```
def Cen(k):
    return np.eye(k) - Jbar(k)

y = scores.ravel()                                # pupils fastest, then
                                                # classroom, then curriculum
P = {"curriculum": np.kron(np.kron(Cen(a), Jbar(b)), Jbar(m)),
     "classroom(curriculum)": np.kron(np.kron(np.eye(a), Cen(b)), Jbar(m)),
     "error": np.kron(np.kron(np.eye(a), np.eye(b)), Cen(m))}
ss = {k: y @ Pk @ y for k, Pk in P.items()}
df = {k: int(round(np.trace(Pk))) for k, Pk in P.items()}
ms = {k: ss[k] / df[k] for k in P}
for k in P:
    print(f"{k:22s} df {df[k]:2d} SS {ss[k]:8.1f} MS {ms[k]:7.1f}")
F_cls = ms["classroom(curriculum)"] / ms["error"]
F_cur_fixed = ms["curriculum"] / ms["error"]
F_cur_random = ms["curriculum"] / ms["classroom(curriculum)"]
print(f"classrooms within curricula: F = {F_cls:.2f}, p = {stats.f.sf(F_cls, df['classroom(curriculum)'], df['error']):.3f}")
print(f"curricula against pupils: F = {F_cur_fixed:.2f}, p = {stats.f.sf(F_cur_fixed, 2, df['error']):.3f}")
print(f"curricula against classrooms: F = {F_cur_random:.2f}, p = {stats.f.sf(F_cur_random, 2, df['classroom(curriculum)']):.3f}")
```

```
rng = np.random.default_rng(20260919)
reps = 20_000
Pc, Pb, Pe = P["curriculum"], P["classroom(curriculum)"], P["error"]
rej_fixed = rej_random = 0
for _ in range(reps):
    sim = (rng.normal(scale=4.0, size=(a, b))[:, :, None] + rng.normal(scale=8.0,
    size=(a, b, m))).ravel()
    msc, msb, mse = sim @ Pc @ sim / 2, sim @ Pb @ sim / 9, sim @ Pe @ sim / 60
    rej_fixed += msc / mse > stats.f.ppf(0.95, 2, 60)
    rej_random += msc / msb > stats.f.ppf(0.95, 2, 9)
```

```
print(f"no curriculum effect, random classrooms: rejection rate {rej_fixed / reps:.3f} "
      f"against pupils, {rej_random / reps:.3f} against classrooms")
```

Warning. The mistake of testing an outer factor against the within-level error, when the inner levels are a sample, is common enough to have a name, *pseudoreplication* (Hurlbert 1984). The pupils are not independent replicates of a curriculum. The classrooms are. With a fixed number of pupils, adding classrooms improves the curriculum comparison much more than adding pupils per classroom.

Nested and crossed structure are often combined, for example when every classroom is tested both before and after the year. The balanced decomposition is again a sum of Kronecker products, one for each meaningful term ([Exercise \(C2\)](#)). Unbalanced nested data lose the Kronecker structure, and random inner levels lead to the mixed models of Chapters 32 and 33 ([Definition 32.2.1](#)).

16.5.4 Exercises

16.5.4.1 A. Check your understanding

Exercise A1.

Say whether each pair of factors is crossed or nested, and if nested, which is inside which. (a) Four fertilizers applied to plots of each of three wheat varieties. (b) Two suppliers, each delivering five batches, with several specimens tested from each batch. (c) Hospitals within regions, with patients within hospitals. (d) Three laboratories, each measuring portions of the same six reference samples.

16.5.4.2 B. Practice

Exercise B1.

In a balanced nested layout, permute the local labels j of B within one level i of A , leaving the data unchanged. Show that $SS_{B(A)}$ does not change, but that SS_B and SS_{AB} of the crossed analysis generally do. Conclude that only their sum has a meaning for nested data.

Solution. $SS_{B(A)} = m \sum_i \sum_j (\bar{y}_{ij.} - \bar{y}_{i..})^2$ sums over j within each i , so the order of the j within a level of A does not matter. $SS_B = am \sum_j (\bar{y}_{.j.} - \bar{y}_{...})^2$ depends on which inner levels share a label j across different i . For example, with $a = b = 2$, $m = 1$ and inner means $(1, 3)$ and $(1, 3)$, the column means are 1 and 3 and $SS_B = 4$. Swapping the labels in the second row gives inner means $(1, 3)$ and $(3, 1)$, column means 2 and 2, and $SS_B = 0$. By [Theorem 16.5.1\(a\)](#), $SS_B + SS_{AB} = SS_{B(A)}$ is unchanged, so the interaction absorbs the difference.

Exercise B2.

Show that $MS_A/MS_{B(A)}$ equals the one-way F statistic for A computed from the ab

inner-level means $\bar{y}_{ij\cdot}$, treated as b observations at each of the a levels. Interpret this as an analysis in which the inner level is the unit.

Solution. Let $z_{ij} = \bar{y}_{ij\cdot}$. The one-way analysis of the z_{ij} has between sum of squares $b \sum_i (\bar{z}_i - \bar{z}_{..})^2$ on $a - 1$ degrees of freedom and within sum of squares $\sum_{i,j} (z_{ij} - \bar{z}_i)^2$ on $a(b - 1)$. Since $\bar{z}_i = \bar{y}_{i..}$, these are SS_A/m and $SS_{B(A)}/m$ by [Theorem 16.5.1\(b\)](#). The factor m cancels in the ratio of mean squares. So the test of A against $B(A)$ is exactly the one-way analysis of variance of the inner-level means. The individual observations enter only through those means.

Exercise B3.

For a three-stage nested layout (a levels of A , b levels of B in each, c levels of C in each level of B , m observations at each level of C), verify that the four projections given in the text and $\mathbf{P}_0$ are mutually orthogonal and sum to $\mathbf{I}$, and find their ranks. Give the sum of squares for $C(B)$ in terms of means.

16.5.4.3 C. Going deeper

Exercise C1.

In the balanced nested layout of [Theorem 16.5.1](#), let $y_{ijk} = \mu + \alpha_i + b_{ij} + \varepsilon_{ijk}$, where the b_{ij} and ε_{ijk} are uncorrelated random variables with means zero and variances σ_B^2 and σ^2 . Show that $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I} + m\sigma_B^2(\mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m)$, and use [Theorem 2.3.1](#) to show that

$$E \text{MS}_A = \sigma^2 + m\sigma_B^2 + \frac{bm}{a-1} \sum_i (\alpha_i - \bar{\alpha})^2, \quad E \text{MS}_{B(A)} = \sigma^2 + m\sigma_B^2.$$

Compare [Exercise \(B1\)](#).

Solution. The vector of b_{ij} , each repeated m times, is $(\mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{1}_m)\mathbf{b}$, with covariance $\sigma_B^2(\mathbf{I}_a \otimes \mathbf{I}_b \otimes \mathbf{1}_m \mathbf{1}_m^\top) = m\sigma_B^2(\mathbf{I}_a \otimes \mathbf{I}_b \otimes \bar{\mathbf{J}}_m)$. Adding the error covariance gives $\Sigma = \text{Cov}(\mathbf{Y})$. By [Theorem 2.3.1](#), $E(\mathbf{Y}^\top \mathbf{P} \mathbf{Y}) = \text{tr}(\mathbf{P} \Sigma) + \boldsymbol{\mu}^\top \mathbf{P} \boldsymbol{\mu}$. For $\mathbf{P} = \mathbf{P}_A$: $\mathbf{P}_A(\mathbf{I} \otimes \mathbf{I} \otimes \bar{\mathbf{J}}_m) = \mathbf{P}_A$, so $\text{tr}(\mathbf{P}_A \Sigma) = (\sigma^2 + m\sigma_B^2)(a - 1)$, and $\boldsymbol{\mu}^\top \mathbf{P}_A \boldsymbol{\mu} = bm \sum_i (\alpha_i - \bar{\alpha})^2$. For $\mathbf{P}_{B(A)}$ likewise $\text{tr} = (\sigma^2 + m\sigma_B^2)a(b - 1)$, and $\mathbf{P}_{B(A)} \boldsymbol{\mu} = \mathbf{0}$ because the mean $\mu + \alpha_i$ does not vary within levels of A . Dividing by the degrees of freedom gives the result. Under H_A both mean squares have expectation $\sigma^2 + m\sigma_B^2$, which is why the ratio $\text{MS}_A/\text{MS}_{B(A)}$ is the natural test statistic.

Exercise C2.

Suppose each classroom of [Example \(Curricula and classrooms\)](#) is tested on two occasions (factor C , crossed with classroom), with m pupils per classroom and occasion. Order the observations by curriculum, classroom, occasion and replicate. Write the Kronecker projections for the terms A , $B(A)$, C , AC , $C \times B(A)$ and error, check that they are mutually orthogonal and sum to $\mathbf{I}$, and find their ranks.

16.6 Summary and Notes

16.6.1 Summary

Idea.

1. In a balanced layout every projection of interest is a Kronecker product of averaging matrices $\bar{\mathbf{J}}$, centring matrices $\mathbf{C}$ and identities. Products that differ by $\bar{\mathbf{J}}$ against $\mathbf{C}$ in some position are orthogonal, and ranks multiply ([Lemma 16.1.1](#)).
2. The additive two-way model has projection $\mathbf{P}_0 + \mathbf{P}_A + \mathbf{P}_B$. Row contrasts are estimated and judged as in a one-way layout that ignores the columns. With replication, the residual splits into interaction (lack of fit) and pure error. With one observation per cell, Tukey's one-degree-of-freedom test is an exact test against the kind of nonadditivity a wrong scale produces, and its slope suggests a power transformation ([Theorem 16.1.2](#)).
3. Interaction is a property of the table of cell means. It is present iff some interaction contrast (a zero-margin combination of cell means) is nonzero, and it has $(a - 1)(b - 1)$ dimensions whatever parameterization is used ([Definition 16.2.1](#), [Proposition 16.2.1](#)).
4. An increasing transformation can remove interaction only if the orders of the levels are the same everywhere. Qualitative (crossing) interaction cannot be removed. Main effects in the presence of interaction are weighted averages of simple effects, and their values, even their signs, depend on the weights ([Proposition 16.2.2](#), [Proposition 16.2.3](#)).
5. The balanced two-way layout with replication splits into grand mean, A , B , AB and error, with ranks 1, $a - 1$, $b - 1$, $(a - 1)(b - 1)$, $ab(m - 1)$. The F tests are exact, and the sequential, Type II and Type III sums of squares all coincide ([Theorem 16.3.1](#)).
6. Products of orthogonal contrasts split the interaction sum of squares into single degrees of freedom. Tukey's method covers the levels of one factor, Scheffé's all interaction contrasts, and Bonferroni or Holm planned families ([Proposition 16.3.2](#)).
7. A balanced factorial with t factors has one term for each subset of factors, with projection $\mathbf{P}_S$ built from centring matrices in the positions of S . Hierarchical models have order-free sums of squares, and $\mathbf{P}_S \mathbf{y}$ is an alternating sum of marginal means ([Theorem 16.4.1](#)). The three-factor interaction measures how a two-factor interaction changes across the third factor ([Proposition 16.4.2](#)).
8. In a 2^t factorial every term has one degree of freedom, and its effect is a difference of two means with variance $4\sigma^2/n$ ([Proposition 16.4.3](#)). Pooling terms into error is exact if they are null and chosen in advance, and conservative if they are chosen in advance but not null. It is invalid if they are chosen because they look small ([Proposition 16.4.4](#)).
9. A nested factor has no main effect. Its sum of squares is the crossed B plus AB , the variation among inner levels within each outer level ([Definition 16.5.1](#), [Theorem 16.5.1](#)). When the inner levels are a sample, the outer factor must be tested against the inner mean square, not against the within-level error.

16.6.2 Notes and sources

Sources. The coverage of this chapter was checked against Rencher and Schaalje (2008, chapter 14), Christensen (2020, chapter 7) and Seber and Lee (2003, sections 8.4–8.6). The projection approach follows the vector-space treatment of Christensen (2020), which develops interaction contrasts and their product construction ([Proposition 16.3.2](#)) with particular care. Rencher and Schaalje compute the expected mean squares directly, and projections replace that computation here. Scheffé (1959) remains the classical account of fixed-effects multiway layouts, including main effects and interactions defined with general weights (compare [Proposition 16.2.1\(v\)](#)).

Factorial experiments. Fisher (1935) argued for factorial experiments over one-factor-at-a-time trials: every observation contributes to every main effect, and interactions can be studied at all. Yates (1937) developed the analysis of 2^t and 3^t designs, including the algorithm for 2^t effects that carries his name. Box, Hunter and Hunter (2005) and Wu and Hamada (2009) are standard modern texts.

Tukey's test. The one-degree-of-freedom test is due to Tukey (1949). Its exact distribution follows from the theorem of Milliken and Graybill (1970) on regressors computed from the fitted values ([Theorem 14.7.2](#)), because Tukey's regressor is, after the additive model is projected out, the table of squared fitted values; [Exercise \(C1\)](#) made the same connection. The power rule [Eq. 16.1.5](#) is a heuristic, and [Chapter 22](#) treats transformations systematically.

Interaction and scale. The dependence of interaction on the scale of measurement, and the order condition of [Proposition 16.2.2](#), belong to the theory of conjoint measurement of Luce and Tukey (1964). The counterexample of [Exercise \(C1\)](#) is an instance of their double cancellation condition. In clinical trials a treatment effect that changes sign across patient subgroups is called a *qualitative interaction*, and Gail and Simon (1985) gave a likelihood ratio test for it.

Unreplicated factorials and pooling. The half-normal plot is due to Daniel (1959), and the pseudo standard error of [Exercise \(C1\)](#) to Lenth (1989). The effect of preliminary tests on subsequent inference was first studied by Bancroft (1944), and the simulation of [Figure 16.4.2](#) illustrates his conclusions in a simple case.

Nested designs. Hurlbert (1984) named *pseudoreplication*, treating observations within an experimental unit as independent replicates of the unit's treatment, and documented how widespread it was in ecology. Random inner levels are taken up with variance components in [Chapters 32](#) and [33](#). Unbalanced multiway data are the subject of [Chapter 17](#), and randomized blocks and Latin squares, additive layouts whose structure comes from randomization, of [Chapter 18](#).

Chapter 17

Unbalanced Data, Cell Means and Empty Cells

Balanced layouts give orthogonal decompositions, and then every sum of squares answers one clear question. Real experiments lose plots and patients, and observational data are unbalanced from the start. With unequal cell counts the same data produce several different “sums of squares for A ”, each testing its own hypothesis. This chapter starts from the parameterization in which nothing is ambiguous, a mean for every cell, and writes every hypothesis as linear constraints on the cell means. That shows exactly what the Type I, II and III sums of squares test, why Type III needs contrast codings, how the additive model is a constrained cell-means model, and which questions survive when some cells are empty.

What you need. Projections and nested models from [Chapter 6](#) ([Theorem 6.5.1](#), [Theorem 6.5.2](#)). Estimability, factor codings and connectedness from [Chapter 8](#) ([Theorem 8.3.1](#), [Definition 8.5.1](#), [Theorem 8.6.1](#), [Proposition 8.6.2](#)). The definitions of the Type I, II and III sums of squares and the first cell-mean results in [Chapter 9](#) ([Definition 9.3.1](#), [Definition 9.3.2](#), [Theorem 9.3.2](#), [Theorem 9.2.4](#)). Testable hypotheses and restricted least squares from [Chapter 11](#) ([Theorem 11.3.2](#), [Proposition 11.3.3](#)). The one-way layout of [Chapter 15](#) and the balanced two-way layout of [Chapter 16](#).

- [Constrained models](#)
- [Empty cells and estimability](#)
- [Summary and notes](#)

17.1 The cell-means model

With several factors the observations fall into *cells*, one for each combination of levels. The effects model of [Chapter 8](#) writes the mean of a cell as $\mu + \alpha_i + \beta_j + \gamma_{ij}$ and pays for it with side conditions and codings. The cell-means model gives each cell its own parameter and nothing

else. It fits the same values as the effects model with all interactions, but every question about the factors becomes a statement about a table of means, and the counts enter only through the precision with which that table is estimated.

17.1.1 The model

Definition 17.1.1 — Cell-means model

Let factors $F_1, \dots, F_k$ have $a_1, \dots, a_k$ levels. A **cell** is a combination $\omega = (i_1, \dots, i_k)$ of levels, and there are $p = a_1 a_2 \cdots a_k$ cells. Cell ω contains $n_\omega \geq 0$ observations $y_{\omega 1}, \dots, y_{\omega n_\omega}$. It is **occupied** if $n_\omega \geq 1$ and **empty** otherwise. Write O for the set of occupied cells, $m = |O|$ and $n = \sum_\omega n_\omega$. The **cell-means model** is

$$y_{\omega l} = \mu_\omega + \varepsilon_{\omega l}, \quad l = 1, \dots, n_\omega,$$

with errors that are uncorrelated with mean zero and variance σ^2 , and independent $N(0, \sigma^2)$ when we test. In matrix form $E(\mathbf{Y}) = \mathbf{W}\boldsymbol{\mu}$, where $\boldsymbol{\mu} \in \mathbb{R}^p$ collects the cell means and $\mathbf{W}$ is the $n \times p$ matrix whose column ω indicates the observations in cell ω . We write $\mathbf{D} = \mathbf{W}^\top \mathbf{W} = \text{diag}(n_\omega)$, and $\bar{y}_\omega$ for the average of an occupied cell.

Empty cells keep their entries in $\boldsymbol{\mu}$: their means do not enter the distribution of the data, but they are properties of the population (Section 17.4). In two-factor notation, cells are pairs (i, j) , counts are n_{ij} , and we order the cells row by row: $\boldsymbol{\mu} = (\mu_{11}, \dots, \mu_{1b}, \mu_{21}, \dots, \mu_{ab})^\top$. With this ordering, a Kronecker product $\mathbf{P} \otimes \mathbf{Q}$ acts on $\boldsymbol{\mu}$ by transforming the $a \times b$ table (μ_{ij}) into $\mathbf{P}(\mu_{ij})\mathbf{Q}^\top$ (Proposition 1.10.1(f) applied to the transposed table).

By Proposition 8.6.2(a), the overparameterized two-way model with interaction has column space $\mathcal{C}(\mathbf{W})$, so the cell-means model is its identifiable parameterization. It is also a one-way layout (Definition 15.1.1) whose groups are the m occupied cells. The factorial structure plays no part in fitting.

Proposition 17.1.1 — Inference with cell means

In the model of Definition 17.1.1, let $\mathbf{D}^+$ be the diagonal matrix with entries $1/n_\omega$ for occupied cells and 0 for empty ones, and let $\bar{\mathbf{y}} \in \mathbb{R}^p$ hold $\bar{y}_\omega$ for occupied cells and 0 for empty ones. Then:

- (a) $\text{rank}(\mathbf{W}) = m$, and $\mathbf{M} = \mathbf{W}\mathbf{D}^+\mathbf{W}^\top$ replaces each observation by the average of its cell;
- (b) $\boldsymbol{\lambda}^\top \boldsymbol{\mu}$ is estimable iff $\lambda_\omega = 0$ for every empty cell. Its best linear unbiased estimator is $\boldsymbol{\lambda}^\top \bar{\mathbf{y}} = \sum_{\omega \in O} \lambda_\omega \bar{y}_\omega$, with variance $\sigma^2 \sum_{\omega \in O} \lambda_\omega^2 / n_\omega$;
- (c) $\text{SSE} = \sum_{\omega \in O} \sum_l (y_{\omega l} - \bar{y}_\omega)^2$ has $n - m$ degrees of freedom, and $s^2 = \text{SSE} / (n - m)$, the pooled within-cell variance, is unbiased for σ^2 ;
- (d) if $\mathbf{L}$ is a $q \times p$ matrix of rank q whose rows vanish on the empty cells, $\mathbf{d} \in \mathbb{R}^q$, and $n > m$, the F statistic for $H : \mathbf{L}\boldsymbol{\mu} = \mathbf{d}$ is

$$F = \frac{(\mathbf{L}\bar{\mathbf{y}} - \mathbf{d})^\top (\mathbf{L}\mathbf{D}^+\mathbf{L}^\top)^{-1} (\mathbf{L}\bar{\mathbf{y}} - \mathbf{d})}{q s^2} \sim F(q, n - m, \gamma_H), \quad (17.1.1)$$

where $\gamma_H = (\mathbf{L}\boldsymbol{\mu} - \mathbf{d})^\top (\mathbf{L}\mathbf{D}^+ \mathbf{L}^\top)^{-1} (\mathbf{L}\boldsymbol{\mu} - \mathbf{d}) / \sigma^2$.

Proof.

- (a) The columns of $\mathbf{W}$ for occupied cells are nonzero indicators with disjoint supports, and those for empty cells are zero. So $\text{rank}(\mathbf{W}) = m$. Since $\mathbf{D}\mathbf{D}^+\mathbf{D} = \mathbf{D}$, $\mathbf{D}^+$ is a generalized inverse of $\mathbf{W}^\top \mathbf{W}$, and $\mathbf{M} = \mathbf{W}\mathbf{D}^+ \mathbf{W}^\top$ by [Theorem 6.3.6](#). The entry of $\mathbf{W}\mathbf{D}^+ \mathbf{W}^\top \mathbf{y}$ for an observation in cell ω is $n_\omega^{-1} \sum_l y_{\omega l} = \bar{y}_\omega$.
- (b) The rows of $\mathbf{W}$ are the coordinate vectors $\mathbf{e}_\omega^\top$ of the occupied cells, so $\mathcal{C}(\mathbf{W}^\top) = \text{span}\{\mathbf{e}_\omega : \omega \in O\}$, and [Theorem 8.3.1](#) gives the criterion. The vector $\mathbf{D}^+ \mathbf{W}^\top \mathbf{y} = \bar{\mathbf{y}}$ solves the normal equations ([Theorem 6.4.2](#)), so $\boldsymbol{\lambda}^\top \bar{\mathbf{y}}$ is the least squares estimator of an estimable $\boldsymbol{\lambda}^\top \boldsymbol{\mu}$, and it is best linear unbiased by the Gauss–Markov theorem ([Theorem 7.2.1](#)). The cell averages are uncorrelated with variances σ^2/n_ω , which gives the variance.
- (c) $\text{SSE} = \|(\mathbf{I} - \mathbf{M})\mathbf{y}\|^2$ is the displayed sum by (a), and $E(\text{SSE}) = \sigma^2 \text{tr}(\mathbf{I} - \mathbf{M}) = \sigma^2(n - m)$ by [Theorem 2.3.1](#), since $(\mathbf{I} - \mathbf{M})\mathbf{W}\boldsymbol{\mu} = \mathbf{0}$.
- (d) Apply [Theorem 11.3.2](#) with $\mathbf{G} = \mathbf{D}^+$, $\hat{\boldsymbol{\beta}} = \bar{\mathbf{y}}$ and $\boldsymbol{\Lambda}^\top = \mathbf{L}$, which is testable by (b). The matrix $\mathbf{L}\mathbf{D}^+ \mathbf{L}^\top$ is nonsingular: for $\mathbf{x} \neq \mathbf{0}$, $\mathbf{x}^\top \mathbf{L}\mathbf{D}^+ \mathbf{L}^\top \mathbf{x} = \sum_{\omega \in O} (\mathbf{L}^\top \mathbf{x})_\omega^2 / n_\omega$. If this were zero, $\mathbf{L}^\top \mathbf{x}$ would vanish on O , and hence everywhere, because the rows of $\mathbf{L}$ vanish off O . That contradicts $\text{rank}(\mathbf{L}) = q$.

■

The counts enter only through $\mathbf{D}^+$, the variances of the cell averages. An unbalanced cell-means analysis has one fitting step, averaging within cells, and one inferential tool, [Eq. 17.1.1](#). The work lies in choosing $\mathbf{L}$.

17.1.2 Standard hypotheses as Kronecker products

Let every cell of a two-way layout be occupied. Let $\mathbf{C}_a$ be an $a \times (a - 1)$ matrix whose columns form a basis of the contrasts $\{\mathbf{u} \in \mathbb{R}^a : \mathbf{1}^\top \mathbf{u} = 0\}$, and define $\mathbf{C}_b$ in the same way. These are coding matrices in the sense of [Definition 8.5.1](#). The $a \times a$ centring matrix of [Chapter 16](#) has the same column space, but its columns are linearly dependent, so we keep the thinner matrix here and count restrictions by its columns. The three classical hypotheses are

$$H_A : (\mathbf{C}_a^\top \otimes b^{-1} \mathbf{1}_b^\top) \boldsymbol{\mu} = \mathbf{0}, \quad H_B : (a^{-1} \mathbf{1}_a^\top \otimes \mathbf{C}_b^\top) \boldsymbol{\mu} = \mathbf{0}, \quad H_{AB} : (\mathbf{C}_a^\top \otimes \mathbf{C}_b^\top) \boldsymbol{\mu} = \mathbf{0}. \quad (17.1.2)$$

By the remark on Kronecker products above, H_A says that $\mathbf{C}_a^\top$ annihilates the vector of **unweighted row means** $\bar{\mu}_{i\cdot} = b^{-1} \sum_j \mu_{ij}$, that is, that these means are all equal. H_B says the same of the unweighted column means. H_{AB} says that $\mathbf{C}_a^\top (\mu_{ij}) \mathbf{C}_b = \mathbf{0}$. Because $\mathcal{C}(\mathbf{C}_a) = \mathbf{1}_a^\perp$ and $\mathcal{C}(\mathbf{C}_b) = \mathbf{1}_b^\perp$, this holds iff the doubly centred table $\mu_{ij} - \bar{\mu}_{i\cdot} - \bar{\mu}_{\cdot j} + \bar{\mu}_{\cdot\cdot}$ vanishes, that is, iff the cell means are additive ([Definition 16.2.1](#)). The ranks are $a - 1$, $b - 1$ and $(a - 1)(b - 1)$ ([Proposition 1.10.1\(c\)](#)), and the hypotheses do not depend on the basis of contrasts ([Exercise \(B2\)](#)). They are the hypotheses tested in the balanced layout by [Theorem 16.3.1](#), where every type of sum of squares tests them.

17.1.3 Weighted and unweighted marginal means

A row of the table can be summarized by any average of its cells. Two choices dominate practice. The **weighted row mean** $\bar{\mu}_i^w = n_{i\cdot}^{-1} \sum_j n_{ij} \mu_{ij}$ weights each cell by its count. Its natural estimator is the raw average $\bar{y}_{i\cdot}$ of all observations in row i . The **unweighted row mean** $\bar{\mu}_i$ gives each column the same weight. Its estimator is the average of the cell averages, $\bar{y}_i = b^{-1} \sum_j \bar{y}_{ij}$. More generally, one may fix weights $w_1, \dots, w_b$ summing to one, such as the shares of the levels of B in a target population, and estimate $\sum_j w_j \mu_{ij}$.

Proposition 17.1.2 — Precision of marginal means

Fix a row i with all $n_{ij} \geq 1$, and weights $w_1, \dots, w_b$ with $\sum_j w_j = 1$. The estimator $\sum_j w_j \bar{y}_{ij}$ of $\sum_j w_j \mu_{ij}$ is unbiased with variance $\sigma^2 \sum_j w_j^2 / n_{ij}$. Among all such weights the variance is smallest, and equal to $\sigma^2 / n_{i\cdot}$, exactly for the count weights $w_j = n_{ij} / n_{i\cdot}$. In particular

$$\text{Var}(\bar{y}_i) = \frac{\sigma^2}{b^2} \sum_j \frac{1}{n_{ij}} \geq \frac{\sigma^2}{n_{i\cdot}} = \text{Var}(\bar{y}_{i\cdot}),$$

with equality iff the counts $n_{i1}, \dots, n_{ib}$ are equal.

Proof. Unbiasedness and the variance come from Proposition 17.1.1(b). By the Cauchy–Schwarz inequality,

$$1 = \left(\sum_j \frac{w_j}{\sqrt{n_{ij}}} \sqrt{n_{ij}} \right)^2 \leq \left(\sum_j \frac{w_j^2}{n_{ij}} \right) n_{i\cdot},$$

with equality iff $w_j / \sqrt{n_{ij}}$ is proportional to $\sqrt{n_{ij}}$, that is, $w_j \propto n_{ij}$. The unweighted mean is the case $w_j = 1/b$, which is proportional to n_{ij} iff the counts are equal. ■

The count weights are the most *precise*, but precision is the wrong criterion for choosing a target. The weighted mean $\bar{\mu}_i^w$ is the mean of row i with the levels of B mixed as they happened to be mixed in this study. If the counts are an accident of the design, such as lost plots, that mixture describes nothing. If they are proportional to a real population, as in a random sample, $\bar{\mu}_i^w$ may be exactly the target. When the rows have different mixes, comparing weighted means also compares mixes of B , and that is what the Type I sum of squares of a factor entered first tests (Section 17.2). Choose the weights to describe a population, and accept the variance that follows.

17.1.4 An unbalanced field trial

Example. (Three varieties at three sites)

A (synthetic) trial compared three wheat varieties V1, V2 and V3 at three sites S1, S2 and S3, with yield in tonnes per hectare. Each site grew mostly the variety it already knew. There are 37 plots in the $m = 9$ cells:

Figure 17.1.1: Cell means of the variety trial; point areas and labels give the cell counts.

	S1	S2	S3	all sites
V1	7 plots, 5.73	4, 7.12	2, 7.45	13, 6.423
V2	3, 4.67	5, 6.98	4, 7.53	12, 6.583
V3	2, 4.55	3, 5.73	7, 7.00	12, 6.275

The last column gives each variety's raw average, the estimate of its weighted mean $\bar{\mu}_i^w$. The pooled within-cell variance is $s^2 = 0.3136$ on $n - m = 28$ degrees of freedom, so the standard errors of the cell averages range from 0.212 (seven plots) to 0.396 (two plots).

Figure 17.1.1 shows the table. V1 is the best variety at S1 and S2 and nearly ties with V2 at S3, yet its raw average, 6.423, is below that of V2, 6.583, because V1 was grown mostly at the poorest site. The unweighted means 6.768, 6.391 and 5.761 compare the varieties over the same three sites, and V1 comes first. Their standard errors, 0.176, 0.165 and 0.184, exceed those of the raw averages (0.155, 0.162 and 0.162), as Proposition 17.1.2 requires. For V1 the ratio depends only on the counts: $\sqrt{13(1/7 + 1/4 + 1/2)}/3 = \sqrt{11.607}/3 \approx 1.136$.

The tests Eq. 17.1.2, computed with Eq. 17.1.1, give $F = 7.90$ on 2 and 28 degrees of freedom for equal unweighted variety means ($p = 0.0019$), $F = 44.06$ for equal unweighted site means, and $F = 1.71$ on 4 and 28 degrees of freedom for additivity ($p = 0.1755$). The difference between V1 and V2, averaged over sites without weights, is estimated as 0.377 with standard error 0.242. With $t_{28,0.025} = 2.048$, the 95% interval is from -0.12 to 0.87 . The raw averages give a difference of -0.160 , with the opposite sign.

    ss, q, F, p = hypothesis_test(L, ybar, n_ij, s2, n - m)
    print(f"{name:12s} SS = {ss:6.3f} df = {q} F = {F:6.2f} p = {p:.4f}")
```

The script also checks that the variety sum of squares 4.958 is the increase in residual sum of squares when the cell means are fitted subject to H_A (Theorem 11.3.2(b)), and that a Helmert-type contrast matrix gives the same test. With one factor, counts only decide which contrasts split the between-groups sum of squares orthogonally (Theorem 15.4.1). With several they decide which hypotheses the printed sums of squares address.

17.1.5 Exercises

17.1.5.1 A. Check your understanding

Exercise A1.

A 2×3 layout has counts $n_{11} = 4$, $n_{12} = 0$, $n_{13} = 2$, $n_{21} = 3$, $n_{22} = 5$, $n_{23} = 1$. Give m ,

n , the rank of $\mathbf{W}$ and the error degrees of freedom of the cell-means model. Which of $\mu_{11} - \mu_{21}$, $\bar{\mu}_{1\cdot} - \bar{\mu}_{2\cdot}$ and $(\mu_{11} + \mu_{13})/2 - (\mu_{21} + \mu_{23})/2$ are estimable?

Exercise A2.

In [Example \(Three varieties at three sites\)](#), compute from the counts alone the ratio of the standard errors of the unweighted and weighted means of V3, and check it against the quoted standard errors.

17.1.5.2 B. Practice

Exercise B1.

Show that the F statistic of [Eq. 17.1.1](#) for a single contrast $\boldsymbol{\lambda}^\top \boldsymbol{\mu}$ with all cells occupied is the one-way contrast statistic of [Proposition 15.2.1](#), applied to the one-way layout whose groups are the cells. Which t statistic is it the square of, and what is its distribution under the hypothesis?

Solution. With $q = 1$, $\mathbf{L} = \boldsymbol{\lambda}^\top$ and $\mathbf{d} = 0$, [Eq. 17.1.1](#) is $F = (\sum_{\omega} \lambda_{\omega} \bar{y}_{\omega})^2 / (s^2 \sum_{\omega} \lambda_{\omega}^2 / n_{\omega})$. This is the contrast sum of squares $(\sum \lambda_{\omega} \bar{y}_{\omega})^2 / \sum (\lambda_{\omega}^2 / n_{\omega})$ of the one-way layout with groups ω , divided by the one-way error mean square, which is the pooled within-cell variance. Its signed root is $t = \boldsymbol{\lambda}^\top \bar{\mathbf{y}} / (s \sqrt{\sum \lambda_{\omega}^2 / n_{\omega}})$, which has a $t(n - m)$ distribution under the hypothesis. The factorial labels of the cells play no role.

Exercise B2.

Let $\mathbf{C}_a$ and $\mathbf{C}'_a$ be two $a \times (a - 1)$ matrices whose columns are bases of $\mathbf{1}_a^\perp$. Show that $\mathbf{C}'_a = \mathbf{C}_a \mathbf{T}$ for a nonsingular $\mathbf{T}$, and deduce that the hypotheses H_A and H_{AB} of [Eq. 17.1.2](#), and their F statistics, are the same for both.

Solution. Both column spaces equal $\mathbf{1}_a^\perp$, so each column of $\mathbf{C}'_a$ is a combination of the columns of $\mathbf{C}_a$: $\mathbf{C}'_a = \mathbf{C}_a \mathbf{T}$. The rank of $\mathbf{C}'_a$ is $a - 1$, so $\mathbf{T}$ is nonsingular. By [Proposition 1.10.1\(a\)](#), $(\mathbf{C}'_a)^\top \otimes \mathbf{v}^\top = (\mathbf{T}^\top \otimes \mathbf{1})(\mathbf{C}_a^\top \otimes \mathbf{v}^\top)$ for any row vector $\mathbf{v}^\top$, and similarly for $(\mathbf{C}'_a)^\top \otimes \mathbf{C}_b^\top$. So the new hypothesis matrix is $\mathbf{S}\mathbf{L}$ with $\mathbf{S}$ nonsingular. Then $\mathbf{S}\mathbf{L}\boldsymbol{\mu} = \mathbf{0}$ iff $\mathbf{L}\boldsymbol{\mu} = \mathbf{0}$. In [Eq. 17.1.1](#),

$$(\mathbf{S}\mathbf{L}\bar{\mathbf{y}})^\top (\mathbf{S}\mathbf{L}\mathbf{D}^+ \mathbf{L}^\top \mathbf{S}^\top)^{-1} \mathbf{S}\mathbf{L}\bar{\mathbf{y}} = (\mathbf{L}\bar{\mathbf{y}})^\top (\mathbf{L}\mathbf{D}^+ \mathbf{L}^\top)^{-1} \mathbf{L}\bar{\mathbf{y}}.$$

Exercise B3.

In [Example \(Three varieties at three sites\)](#), suppose that sites like S1, S2 and S3 make up 50%, 30% and 20% of the region where the varieties would be grown. Write down the estimate of the region-weighted mean yield of V1 and its standard error, and do the same for the region-weighted difference between V1 and V3. Compute them with the listing. Which of the three kinds of marginal mean in this section would you report to a grower in the region?

17.1.5.3 C. Going deeper

Exercise C1.

A row of a two-way layout will receive N observations, to be allocated as $n_{i1}, \dots, n_{ib}$, with the aim of estimating $\sum_j w_j \mu_{ij}$ for fixed weights $w_j > 0$ summing to one. Treating the n_{ij} as real numbers, show that the variance of $\sum_j w_j \bar{y}_{ij}$ is minimized by $n_{ij} = N w_j$, with minimum σ^2/N . What does this say about how the counts should relate to the target of inference?

Solution. Minimize $\sum_j w_j^2/n_{ij}$ subject to $\sum_j n_{ij} = N$. By Cauchy–Schwarz, $1 = (\sum_j w_j)^2 = (\sum_j (w_j/\sqrt{n_{ij}})\sqrt{n_{ij}})^2 \leq N \sum_j w_j^2/n_{ij}$, with equality iff $n_{ij} \propto w_j$, that is, $n_{ij} = N w_j$. So the variance is at least σ^2/N , with equality exactly there. When the counts are proportional to the weights of the target, the target is estimated by the raw row average, the weighted and target means coincide, and no precision is lost. A design should allocate observations in proportion to the target weights, which for an unweighted target means equal replication.

Exercise C2.

In an $a \times b \times d$ layout, where C has d levels and all cells are occupied, order the cells lexicographically. Write, as Kronecker products, hypothesis matrices for: (a) equality of the unweighted A means $\bar{\mu}_{i..}$; (b) absence of the AB interaction in the table $\bar{\mu}_{ij.}$ of means averaged over C ; (c) absence of the three-factor interaction ([Proposition 16.4.2](#)). Give their ranks.

17.2 Types of sums of squares and what they test

[Section 9.3](#) defined the Type I, II and III sums of squares by the subspaces they project onto ([Definition 9.3.1](#), [Definition 9.3.2](#)). It also found the cell-mean hypotheses of three of them in the two-way layout: equal weighted row means for a factor entered first, equal unweighted row means for Type III, and a single column of the table for last-in sums of squares under reference coding ([Theorem 9.3.2](#)). This section completes the list with one lemma, and then shows that the hypothesis of a main effect's last-in sum of squares is decided by the coding of the *other* factor.

17.2.1 One lemma for every sum of squares

Every term of a factorial model has columns that are constant within cells, so every model matrix we meet has the form $\mathbf{W}\mathbf{A}$ for a matrix $\mathbf{A}$ with p rows, one for each cell. On the cell scale, projections become weighted by the counts: write

$$\mathbf{H}_{\mathbf{A}} = \mathbf{A}(\mathbf{A}^{\top} \mathbf{D} \mathbf{A})^{-} \mathbf{A}^{\top} \mathbf{D},$$

the operator that fits a table of cell means by the columns of $\mathbf{A}$ with weights n_{ω} .

Lemma 17.2.1 — The hypothesis of an extra sum of squares

Let $\mathbf{X}_1 = \mathbf{W}\mathbf{A}_1$ and $\mathbf{X}_2 = \mathbf{W}\mathbf{A}_2$, let $\mathbf{P}_1$ project onto $\mathcal{C}(\mathbf{X}_1)$, and let $\mathbf{Q}$ be the projection onto $\mathcal{C}([\mathbf{X}_1, \mathbf{X}_2])$ minus $\mathbf{P}_1$, so that $\text{SS}(\mathbf{X}_2 \mid \mathbf{X}_1) = \mathbf{y}^\top \mathbf{Q}\mathbf{y}$. For every table of cell means $\boldsymbol{\mu}$:

- (a) $\mathbf{P}_1 \mathbf{W}\boldsymbol{\mu} = \mathbf{W}\mathbf{H}_{\mathbf{A}_1} \boldsymbol{\mu}$;
- (b) $\mathbf{Q}\mathbf{W}\boldsymbol{\mu} = \mathbf{0}$ iff $\mathbf{A}_2^\top \mathbf{D}(\mathbf{I} - \mathbf{H}_{\mathbf{A}_1})\boldsymbol{\mu} = \mathbf{0}$;
- (c) in the cell-means model, $\text{SS}(\mathbf{X}_2 \mid \mathbf{X}_1)$ is the sum of squares of the hypothesis in (b), and its F ratio with the cell-means error mean square is the F statistic Eq. 17.1.1 of that hypothesis.

Proof.

- (a) $\mathbf{X}_1^\top \mathbf{X}_1 = \mathbf{A}_1^\top \mathbf{D}\mathbf{A}_1$, so by Theorem 6.3.6 $\mathbf{P}_1 \mathbf{W}\boldsymbol{\mu} = \mathbf{W}\mathbf{A}_1(\mathbf{A}_1^\top \mathbf{D}\mathbf{A}_1)^{-1} \mathbf{A}_1^\top \mathbf{W}^\top \mathbf{W}\boldsymbol{\mu} = \mathbf{W}\mathbf{H}_{\mathbf{A}_1} \boldsymbol{\mu}$.
- (b) By Lemma 9.2.1, $\mathbf{Q}$ projects onto $\mathcal{C}(\mathbf{T})$ with $\mathbf{T} = (\mathbf{I} - \mathbf{P}_1)\mathbf{X}_2$. A projection annihilates a vector iff the vector is orthogonal to its range, so $\mathbf{Q}\mathbf{W}\boldsymbol{\mu} = \mathbf{0}$ iff $\mathbf{T}^\top \mathbf{W}\boldsymbol{\mu} = \mathbf{0}$. By (a),

$$\mathbf{T}^\top \mathbf{W}\boldsymbol{\mu} = \mathbf{X}_2^\top (\mathbf{I} - \mathbf{P}_1) \mathbf{W}\boldsymbol{\mu} = \mathbf{A}_2^\top \mathbf{W}^\top \mathbf{W}(\mathbf{I} - \mathbf{H}_{\mathbf{A}_1})\boldsymbol{\mu} = \mathbf{A}_2^\top \mathbf{D}(\mathbf{I} - \mathbf{H}_{\mathbf{A}_1})\boldsymbol{\mu}.$$

- (c) Let $\mathcal{S}_0 = \{\mathbf{W}\boldsymbol{\mu} : \mathbf{Q}\mathbf{W}\boldsymbol{\mu} = \mathbf{0}\}$, the mean vectors allowed by the hypothesis. Since $\mathcal{C}(\mathbf{Q}) \subseteq \mathcal{C}(\mathbf{W})$, the orthogonal complement of $\mathcal{S}_0$ within $\mathcal{C}(\mathbf{W})$ is $\mathcal{C}(\mathbf{Q})$, and $\mathbf{y}^\top \mathbf{Q}\mathbf{y}$ is the drop in residual sum of squares from $\mathcal{S}_0$ to $\mathcal{C}(\mathbf{W})$ (Eq. 6.5.2). That is the sum of squares of the hypothesis (Theorem 11.3.2(b)), whose F statistic is Eq. 17.1.1 by Proposition 17.1.1(d). ■

Part (b) says that the extra sum of squares of $\mathbf{X}_2$ tests whether the residual of the true cell means, after the terms already fitted and weighted by the counts, is orthogonal to the new term. Unless $\mathbf{D}$ is a multiple of the identity, the counts enter the hypothesis. That is the root of every difference between the types.

17.2.2 The complete list for two factors

Let the $a \times b$ layout have all $n_{ij} \geq 1$, with row totals $n_{i.}$, column totals $n_{.j}$ and $n = \sum_{ij} n_{ij}$. Besides the weighted row means $\bar{\mu}_i^w$ of Section 17.1, write

$$\bar{\mu}_{.j}^w = \frac{1}{n_{.j}} \sum_i n_{ij} \mu_{ij}, \quad \bar{\mu}^w = \frac{1}{n} \sum_{i,j} n_{ij} \mu_{ij}$$

for the weighted column means and the weighted grand mean. As in Chapter 9, $\text{SS}(B \mid \mu, A)$ denotes the extra sum of squares of the columns of B given the intercept and A .

Theorem 17.2.2 — The cell-mean hypotheses of the types of sums of squares

In the two-way layout with all cells occupied:

- (a) $SS(A \mid \mu)$, the Type I sum of squares of A entered first, addresses $\bar{\mu}_1^w = \cdots = \bar{\mu}_a^w$;
- (b) $SS(B \mid \mu, A)$, which is both the Type I sum of squares of B entered second and the Type II sum of squares of B , addresses

$$\sum_i n_{ij} (\mu_{ij} - \bar{\mu}_i^w) = 0 \quad \text{for } j = 1, \dots, b; \quad (17.2.1)$$

- (c) $SS(A \mid \mu, B)$, the Type II sum of squares of A , addresses

$$\sum_j n_{ij} (\mu_{ij} - \bar{\mu}_{.j}^w) = 0 \quad \text{for } i = 1, \dots, a; \quad (17.2.2)$$

- (d) the Type III sum of squares of A addresses $\bar{\mu}_{1.} = \cdots = \bar{\mu}_{a.}$;
- (e) $SS(AB \mid \mu, A, B)$, the interaction entry of every type, addresses additivity: $\mu_{ij} - \mu_{il} - \mu_{kj} + \mu_{kl} = 0$ for all i, k, j, l .

The hypotheses have $a - 1$, $b - 1$, $a - 1$, $a - 1$ and $(a - 1)(b - 1)$ degrees of freedom, and each sum of squares is the sum of squares Eq. 17.1.1 of its hypothesis. The statements for B follow by exchanging the factors.

Proof. Parts (a) and (d) are Theorem 9.3.2(a) and (b). By Lemma 17.2.1(c), each sum of squares is the sum of squares of the hypothesis given by Lemma 17.2.1(b), and it remains to identify that hypothesis and count its degrees of freedom.

- (b) Take $\mathbf{X}_1 = [\mathbf{1}, \mathbf{Z}_A]$ and $\mathbf{X}_2 = \mathbf{Z}_B$. The columns of $\mathbf{X}_1$ span the vectors that are constant within rows, so $\mathbf{P}_1$ replaces each entry of a vector by the average of its row. Applied to $\mathbf{W}\boldsymbol{\mu}$, this gives $\bar{\mu}_i^w$ in row i . The entry j of $\mathbf{Z}_B^\top (\mathbf{I} - \mathbf{P}_1) \mathbf{W}\boldsymbol{\mu}$ sums $\mu_{ij} - \bar{\mu}_i^w$ over the observations in column j , which is the left side of Eq. 17.2.1. Part (c) is the same argument with the factors exchanged.

For part (e), the projection is $\mathbf{Q} = \mathbf{M} - \mathbf{P}_{A+B}$, where $\mathbf{P}_{A+B}$ projects onto the additive model space, so $\mathbf{QW}\boldsymbol{\mu} = \mathbf{0}$ iff $\mathbf{W}\boldsymbol{\mu}$ lies in that space, that is, iff $\mu_{ij} = \alpha_i + \beta_j$ for some α, β . Additive tables have vanishing tetrads. Conversely, if all tetrads vanish, then $\mu_{ij} = \mu_{i1} + \mu_{1j} - \mu_{11}$, which is additive.

Degrees of freedom. A complete layout is connected, so the additive model matrix has rank $a + b - 1$ (Theorem 8.6.1(a)). The degrees of freedom of the extra sums of squares are therefore $a - 1$ for (a), $(a + b - 1) - a = b - 1$ for (b), $a - 1$ for (c) and $ab - (a + b - 1)$ for (e). In each case this is $\text{rank}(\mathbf{Q})$, the number of independent linear restrictions that the hypothesis places on $\boldsymbol{\mu}$. ■

In the Type II hypothesis Eq. 17.2.2, row i is compared cell by cell with the weighted means $\bar{\mu}_{.j}^w$ of its columns, with the row's own counts as weights. The a equations sum to zero (Exercise (B1)). With two rows the hypothesis is $\sum_j h_j (\mu_{1j} - \mu_{2j}) = 0$ with $h_j = n_{1j}n_{2j}/n_{.j}$ (Exercise (B2)), which favours columns where *both* rows are well replicated. That is the most precise comparison when the row difference is the same in every column. When it is not, the weights are set by the design rather than by anyone's question.

Under additivity, $\mu_{ij} = \alpha_i + \beta_j$, the hypotheses separate cleanly. The Type II and Type III

Type I, variety first				Type II				Type III			
V1	+0.35	+0.20	+0.10	V1	+0.22	+0.21	+0.13	V1	+0.22	+0.22	+0.22
V2	-0.08	-0.14	-0.11	V2	-0.13	-0.13	-0.05	V2	-0.11	-0.11	-0.11
V3	-0.05	-0.08	-0.19	V3	-0.09	-0.08	-0.08	V3	-0.11	-0.11	-0.11
	S1	S2	S3		S1	S2	S3		S1	S2	S3

Figure 17.2.1: Coefficients on the cell means of the first equation of each variety hypothesis in [Example \(Three varieties at three sites\)](#) (Type II divided by $n_{1\cdot}$).

hypotheses both reduce to $\alpha_1 = \dots = \alpha_a$: Type III because unweighted row means are $\alpha_i + \bar{\beta}$, and Type II by [Theorem 9.3.2\(d\)](#). The Type I hypothesis becomes

$$\alpha_i + \sum_j \frac{n_{ij}}{n_{i\cdot}} \beta_j \text{ the same for all } i,$$

which involves the column effects unless the counts are proportional ([Theorem 9.4.3](#)). A factor entered first is credited with the effects of the factors it is confounded with.

In [Figure 17.2.1](#) the Type I coefficients (V1's weighted mean minus the weighted grand mean) do not sum to zero within columns, so that hypothesis compares sites as well as varieties. The Type II and Type III tables have zero column sums and compare varieties within sites. Type II gives site j the weight $n_{1j}(n_{\cdot j} - n_{1j})/n_{\cdot j}$, which is large only where V1 and the other varieties are both well replicated. Type III weights the sites equally.

17.2.3 Why Type III needs contrast codings

[Definition 9.3.2](#) defines Type III through sum-to-zero coding, and [Theorem 9.3.2\(c\)](#) showed that reference coding gives a different hypothesis. The next result settles which codings give Type III and why.

Proposition 17.2.3 — Which coding a last-in sum of squares depends on

In the two-way layout with all cells occupied, code A by an $a \times (a - 1)$ coding matrix $\mathbf{C}_A$ and B by a $b \times (b - 1)$ coding matrix $\mathbf{C}_B$, with $[\mathbf{1}_a, \mathbf{C}_A]$ and $[\mathbf{1}_b, \mathbf{C}_B]$ nonsingular ([Definition 8.5.1](#)). Let the interaction columns be the products of the coded columns of A and B , and let $\mathbf{w} \neq \mathbf{0}$ span the line $\mathcal{C}(\mathbf{C}_B)^\perp \subseteq \mathbb{R}^b$. Then the partial sum of squares of the columns of A , with the intercept, B and the interaction in the model, addresses

$$\sum_j w_j \mu_{ij} \text{ is the same for all } i. \quad (17.2.3)$$

The hypothesis depends neither on $\mathbf{C}_A$ nor on the counts. It is the Type III hypothesis

$\bar{\mu}_{1\cdot} = \cdots = \bar{\mu}_{a\cdot}$ iff every column of $\mathbf{C}_B$ sums to zero.

Proof. Put $\mathbf{K}_A = [\mathbf{1}_a, \mathbf{C}_A]$ and $\mathbf{K}_B = [\mathbf{1}_b, \mathbf{C}_B]$. For an observation in cell (i, j) , the product of the k th coded column of A and the l th coded column of B takes the value $(\mathbf{C}_A)_{ik}(\mathbf{C}_B)_{jl}$, the entry in row (i, j) of the corresponding column of $\mathbf{C}_A \otimes \mathbf{C}_B$. So the full model matrix is $\mathbf{W}$ times the columns of $\mathbf{K}_A \otimes \mathbf{K}_B$, namely $\mathbf{1}_a \otimes \mathbf{1}_b$, $\mathbf{1}_a \otimes \mathbf{C}_B$, $\mathbf{C}_A \otimes \mathbf{1}_b$ and $\mathbf{C}_A \otimes \mathbf{C}_B$. The matrix $\mathbf{K}_A \otimes \mathbf{K}_B$ is nonsingular (Proposition 1.10.1(b)), so the full model space is $\mathcal{C}(\mathbf{W})$ and its ab columns are linearly independent. Deleting the $a - 1$ columns $\mathbf{C}_A \otimes \mathbf{1}_b$ leaves the reduced model $\mathbf{WF}$ with

$$\mathbf{F} = [\mathbf{1}_a \otimes \mathbf{1}_b, \mathbf{1}_a \otimes \mathbf{C}_B, \mathbf{C}_A \otimes \mathbf{C}_B], \quad \text{rank}(\mathbf{F}) = ab - (a - 1).$$

Let $\mathcal{V} = \{\boldsymbol{\mu} : (\mathbf{u} \otimes \mathbf{w})^\top \boldsymbol{\mu} = 0 \text{ for all } \mathbf{u} \in \mathbf{1}_a^\perp\}$. Each column of $\mathbf{F}$ lies in $\mathcal{V}$: by the mixed-product rule, $(\mathbf{u}^\top \otimes \mathbf{w}^\top)(\mathbf{1}_a \otimes \mathbf{v}) = (\mathbf{u}^\top \mathbf{1}_a)(\mathbf{w}^\top \mathbf{v}) = 0$ for any $\mathbf{v}$, and $(\mathbf{u}^\top \otimes \mathbf{w}^\top)(\mathbf{C}_A \otimes \mathbf{C}_B) = (\mathbf{u}^\top \mathbf{C}_A) \otimes (\mathbf{w}^\top \mathbf{C}_B) = \mathbf{0}$ because $\mathbf{w} \perp \mathcal{C}(\mathbf{C}_B)$. The functionals $\mathbf{u} \otimes \mathbf{w}$, $\mathbf{u} \in \mathbf{1}_a^\perp$, form a space of dimension $a - 1$, since $\mathbf{u} \mapsto \mathbf{u} \otimes \mathbf{w}$ is injective. So $\dim \mathcal{V} = ab - (a - 1) = \text{rank}(\mathbf{F})$, and $\mathcal{C}(\mathbf{F}) = \mathcal{V}$. The partial sum of squares is the drop in residual sum of squares from $\mathcal{C}(\mathbf{WF})$ to $\mathcal{C}(\mathbf{W})$, so it addresses the hypothesis $\boldsymbol{\mu} \in \mathcal{V}$. Now $(\mathbf{u} \otimes \mathbf{w})^\top \boldsymbol{\mu} = \sum_i u_i \sum_j w_j \mu_{ij}$ vanishes for every contrast $\mathbf{u}$ iff $\sum_j w_j \mu_{ij}$ does not depend on i , which is Eq. 17.2.3. Finally, $\mathbf{w} \propto \mathbf{1}_b$ iff $\mathbf{1}_b \perp \mathcal{C}(\mathbf{C}_B)$, that is, iff $\mathbf{1}_b^\top \mathbf{C}_B = \mathbf{0}$. ■

Sum-to-zero, Helmert and orthogonal polynomial codings of B all give the Type III sum of squares for A , whatever coding A receives. Reference coding of B at level r gives $\mathbf{w} = \mathbf{e}_r$ and the simple effect of Theorem 9.3.2(c). With more factors (Exercise (C2)), the last-in sum of squares of a main effect is the Type III one when every *other* factor is coded by contrasts. In statsmodels, write $\mathcal{C}(\mathbf{x}, \text{Sum})$ for every factor.

17.2.4 The variety trial, five ways

Example. (Five tables for one data set)

The table has the layout of Example (Party, education and political self-placement) in Chapter 9, and the listing computes its entries the same way, as squared lengths of projections. For the trial of Example (Three varieties at three sites):

Term	df	Type I, variety first	Type I, site first	Type II	Type III	reference coding
variety	2	0.571	6.184	6.184	4.958	3.601
site	2	31.175	25.562	31.175	27.634	7.456
interaction	4	2.146	2.146	2.146	2.146	2.146
residual	28	8.781	8.781	8.781	8.781	8.781

Only the Type I columns add up to the model sum of squares 33.892; the Type II and Type III entries add up to 39.506 and 34.738. The verdicts on varieties differ. Entered first, $F = 0.91$ and $p = 0.414$: the raw averages 6.423, 6.583 and 6.275 mix each variety with the sites it was grown at. After sites (Type II), $F = 9.86$ and $p = 0.001$. Type III gives $F = 7.90$ and $p = 0.002$, the test of [Example \(Three varieties at three sites\)](#). The last column compares the varieties at S1 only ($F = 5.74$, $p = 0.008$).

The script checks every entry against statsmodels' `anova_lm` (types 1, 2 and 3, with sum-to-zero and Helmert coding for type 3), and recovers each entry from the matrix **L** of its part of [Theorem 17.2.2](#). It also confirms [Proposition 17.2.3](#): reference coding of the varieties with contrast coding of the sites reproduces 4.958, and a random coding of the sites gives the sum of squares of [Eq. 17.2.3](#).

```
import numpy as np
import pandas as pd
counts = np.array([[7, 4, 2],          # rows: varieties V1-V3; columns: sites S1-S3
                  [3, 5, 4],
                  [2, 3, 7]])
true_means = np.array([[5.8, 7.2, 7.6],

17.2.5 Choosing a sum of squares

The advice of [Section 9.3](#) stands: decide the hypothesis first, use Type I only when the order of entry is part of the question, and without interaction prefer Type II. The cell-mean hypotheses sharpen it in three ways.

1. *Test the interaction first.* It is the same in every type and tests additivity ([Theorem 17.2.2\(e\)](#)).

Under additivity Type II and Type III test the same hypothesis, and Type II is never less powerful ([Exercise \(C1\)](#)).

2. *If the factors interact*, the weights of a main-effect hypothesis decide the answer. Choose weights that describe a population (equal weights give Type III), or report simple effects within each column with multiplicity-adjusted intervals ([Chapter 13](#)).
3. *Report the hypothesis, not the type*. Anyone can read $\mathbf{L}\boldsymbol{\mu} = \mathbf{0}$, and [Eq. 17.1.1](#) tests it. With empty cells this is the only safe course ([Section 17.4](#)).

17.2.6 Exercises

17.2.6.1 A. Check your understanding

Exercise A1.

In a 2×2 layout with counts $n_{11} = 6$, $n_{12} = 2$, $n_{21} = 1$, $n_{22} = 3$, write the hypothesis of the Type I sum of squares of A entered first as one linear equation in the four cell means. Show that for the additive table $\mu_{ij} = \beta_j$, in which A has no effect, the hypothesis holds only if $\beta_1 = \beta_2$. In particular it fails for $\beta_1 = 0$, $\beta_2 = 1$.

17.2.6.2 B. Practice

Exercise B1.

Show that the left sides of the a equations [Eq. 17.2.2](#) add up to zero for every table $\boldsymbol{\mu}$. Show also that, for a connected design, the equations have rank exactly $a - 1$. *Hint:* count degrees of freedom.

Solution. Summing over i gives

$$\sum_{ij} n_{ij} \mu_{ij} - \sum_j n_{.j} \bar{\mu}_{.j}^w = \sum_{ij} n_{ij} \mu_{ij} - \sum_j \sum_i n_{ij} \mu_{ij} = 0.$$

So at most $a - 1$ of the equations are independent. By [Lemma 17.2.1\(b\)](#) the equations are $\mathbf{Z}_A^\top (\mathbf{I} - \mathbf{P}_B) \mathbf{W} \boldsymbol{\mu} = \mathbf{0}$, where $\mathbf{P}_B$ projects onto $\mathcal{C}([\mathbf{1}, \mathbf{Z}_B])$. The number of independent restrictions they impose on $\boldsymbol{\mu}$ is the rank of the projection onto $\mathcal{C}((\mathbf{I} - \mathbf{P}_B) \mathbf{Z}_A)$, which is $\text{rank}[\mathbf{1}, \mathbf{Z}_A, \mathbf{Z}_B] - \text{rank}[\mathbf{1}, \mathbf{Z}_B] = (a + b - 1) - b = a - 1$ for a connected design ([Theorem 8.6.1\(a\)](#)).

Exercise B2.

Show that when $a = 2$, the Type II hypothesis [Eq. 17.2.2](#) for A is the single equation $\sum_j h_j (\mu_{1j} - \mu_{2j}) = 0$ with $h_j = n_{1j} n_{2j} / (n_{1j} + n_{2j})$. Show that σ^2 / h_j is the variance of $\bar{y}_{1j} - \bar{y}_{2j}$, and conclude that under additivity the Type II hypothesis compares the rows with inverse-variance weights.

Solution. The first equation is

$$\sum_j n_{1j} (\mu_{1j} - (n_{1j} \mu_{1j} + n_{2j} \mu_{2j}) / n_{.j}) = \sum_j (n_{1j} n_{2j} / n_{.j}) (\mu_{1j} - \mu_{2j}),$$

and the second is its negative (Exercise B1). The variance of $\bar{y}_{1j} - \bar{y}_{2j}$ is $\sigma^2(1/n_{1j} + 1/n_{2j}) = \sigma^2 n_{\cdot j} / (n_{1j} n_{2j}) = \sigma^2 / h_j$. If the difference $\delta = \mu_{1j} - \mu_{2j}$ is the same in every column, the most precise combination of the column differences weights them in proportion to h_j , and the hypothesis says that this combination is zero.

Exercise B3.

Suppose the counts are proportional, $n_{ij} = n_{i\cdot} n_{\cdot j} / n$. Show that the hypotheses of Theorem 17.2.2(a) and (c) coincide, and that both say that the row means weighted by the column shares $n_{\cdot j} / n$ are equal. Why does this agree with Theorem 9.4.3?

Solution. With proportional counts, $n_{ij} / n_{i\cdot} = n_{\cdot j} / n =: \pi_j$ for every i , so $\bar{\mu}_i^w = \sum_j \pi_j \mu_{ij}$. The left side of Eq. 17.2.2 is $n_{i\cdot} \sum_j \pi_j (\mu_{ij} - \bar{\mu}_{\cdot j}^w) = n_{i\cdot} (\bar{\mu}_i^w - \sum_j \pi_j \bar{\mu}_{\cdot j}^w)$, and $\sum_j \pi_j \bar{\mu}_{\cdot j}^w = \bar{\mu}^w$. So (c) says $\bar{\mu}_i^w = \bar{\mu}^w$ for all i , which is (a). In Theorem 9.4.3 the centred factor spaces are orthogonal, so $\text{SS}(A \mid \mu, B) = \text{SS}(A \mid \mu)$ for every data set. Two sums of squares that agree for every $\mathbf{y}$ must address the same hypothesis.

Exercise B4.

Use Proposition 17.2.3 to find the hypothesis of the last-in sum of squares of A when B (with $b = 3$) is coded by (a) the Helmert columns $(-1, 1, 0)^\top, (-1, -1, 2)^\top$; (b) the orthogonal polynomial columns $(-1, 0, 1)^\top, (1, -2, 1)^\top$; (c) the columns $(1, 0, 0)^\top, (0, 0, 1)^\top$, reference coding with level 2 as reference; (d) the columns $(1, 0, 0)^\top, (0, 1, 0)^\top$ plus $\frac{1}{2}(1, 1, 1)^\top$ added to both.

17.2.6.3 C. Going deeper

Exercise C1.

Suppose the cell means are additive. Let $\mathbf{P}_{\text{II}} = \mathbf{P}_{A+B} - \mathbf{P}_B$ and let $\mathbf{P}_{\text{III}}$ be the projection of the Type III sum of squares of A . Both have rank $a-1$, and both are used with the cell-means error mean square. Show that the noncentrality parameters satisfy $\|\mathbf{P}_{\text{II}} \mathbf{W}\boldsymbol{\mu}\|^2 \geq \|\mathbf{P}_{\text{III}} \mathbf{W}\boldsymbol{\mu}\|^2$, so that the Type II test is at least as powerful. *Hint:* both are squared distances from $\mathbf{W}\boldsymbol{\mu}$ to a subspace.

Solution. Write $\mathbf{v} = \mathbf{W}\boldsymbol{\mu}$, which lies in the additive space $\mathcal{C}(\mathbf{P}_{A+B})$. Then $\mathbf{P}_{\text{II}} \mathbf{v} = \mathbf{v} - \mathbf{P}_B \mathbf{v}$, so $\|\mathbf{P}_{\text{II}} \mathbf{v}\|^2$ is the squared distance from $\mathbf{v}$ to $\mathcal{C}([\mathbf{1}, \mathbf{Z}_B])$. Also $\mathbf{P}_{\text{III}} = \mathbf{M} - \mathbf{P}_R$, where $\mathbf{P}_R$ projects onto the reduced space $\mathcal{C}([\mathbf{1}, \mathbf{C}_B\text{-columns, interaction columns}])$, and $\mathbf{M}\mathbf{v} = \mathbf{v}$. So $\|\mathbf{P}_{\text{III}} \mathbf{v}\|^2$ is the squared distance from $\mathbf{v}$ to $\mathcal{C}(\mathbf{P}_R)$. This space contains $\mathcal{C}([\mathbf{1}, \mathbf{Z}_B])$, and the distance to a larger subspace is smaller. The two F statistics have the same degrees of freedom, and the power of an F test increases with its noncentrality (Theorem 11.5.1).

Exercise C2.

In an $a \times b \times d$ layout, where C has d levels and all cells are occupied, code the factors by $\mathbf{C}_A, \mathbf{C}_B, \mathbf{C}_C$, and let the model contain all main effects and all two- and three-factor interactions, formed as products of coded columns. Show that the last-in sum of squares

of the columns of A addresses equality over i of $\sum_{j,k} v_j w_k \mu_{ijk}$, where $\mathbf{v}$ spans $\mathcal{C}(\mathbf{C}_B)^\perp$ and $\mathbf{w}$ spans $\mathcal{C}(\mathbf{C}_C)^\perp$. When is this the unweighted hypothesis $\bar{\mu}_{1..} = \cdots = \bar{\mu}_{a..}$?

17.3 Constrained models

The cell-means model assumes nothing about the table of means. Smaller models, such as the additive model or a three-way model without the three-factor interaction, are the cell-means model with linear constraints $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$. This section fits and tests them with the restricted least squares of Section 11.3, and shows that main-effect hypotheses can merge once the constraints hold.

17.3.1 Estimation and tests under constraints

Theorem 17.3.1 — Constrained cell-means models

In the cell-means model of Definition 17.1.1, let $\mathbf{R}$ be a $g \times p$ matrix of rank g , and let the columns of the $p \times (p - g)$ matrix $\mathbf{K}$ form a basis of $\mathcal{N}(\mathbf{R})$. Assume that $\mathbf{WK}$ has full column rank $p - g$. The **constrained model** is $E(\mathbf{Y}) = \mathbf{W}\boldsymbol{\mu}$ with $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$.

- (a) The constrained model is the full-rank linear model $E(\mathbf{Y}) = \mathbf{WK}\boldsymbol{\theta}$, with $\boldsymbol{\mu} = \mathbf{K}\boldsymbol{\theta}$. Every cell mean, including the means of empty cells, is estimable in it. The least squares estimate is

$$\hat{\boldsymbol{\mu}}_{\mathbf{R}} = \mathbf{V}_{\mathbf{R}}\mathbf{D}\bar{\mathbf{y}}, \quad \mathbf{V}_{\mathbf{R}} = \mathbf{K}(\mathbf{K}^\top \mathbf{D}\mathbf{K})^{-1}\mathbf{K}^\top, \quad \text{Cov}(\hat{\boldsymbol{\mu}}_{\mathbf{R}}) = \sigma^2 \mathbf{V}_{\mathbf{R}}, \quad (17.3.1)$$

and its residual sum of squares $\text{SSE}_{\mathbf{R}}$ has $n - p + g$ degrees of freedom.

- (b) If every cell is occupied, then $\mathbf{V}_{\mathbf{R}} = \mathbf{D}^{-1} - \mathbf{D}^{-1}\mathbf{R}^\top(\mathbf{R}\mathbf{D}^{-1}\mathbf{R}^\top)^{-1}\mathbf{R}\mathbf{D}^{-1}$, so $\hat{\boldsymbol{\mu}}_{\mathbf{R}} = \bar{\mathbf{y}} - \mathbf{D}^{-1}\mathbf{R}^\top(\mathbf{R}\mathbf{D}^{-1}\mathbf{R}^\top)^{-1}\mathbf{R}\bar{\mathbf{y}}$, and $\text{SSE}_{\mathbf{R}} - \text{SSE} = (\mathbf{R}\bar{\mathbf{y}})^\top(\mathbf{R}\mathbf{D}^{-1}\mathbf{R}^\top)^{-1}\mathbf{R}\bar{\mathbf{y}}$ is the sum of squares, on g degrees of freedom, of the hypothesis $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$ in the unconstrained model.
- (c) Under normality, for an $\ell \times p$ matrix $\mathbf{L}$ with $q = \text{rank}(\mathbf{L}\mathbf{K}) \geq 1$, the F statistic for $H : \mathbf{L}\boldsymbol{\mu} = \mathbf{0}$ within the constrained model is

$$F = \frac{(\mathbf{L}\hat{\boldsymbol{\mu}}_{\mathbf{R}})^\top(\mathbf{L}\mathbf{V}_{\mathbf{R}}\mathbf{L}^\top)^{-1}\mathbf{L}\hat{\boldsymbol{\mu}}_{\mathbf{R}}}{q s_{\mathbf{R}}^2}, \quad s_{\mathbf{R}}^2 = \frac{\text{SSE}_{\mathbf{R}}}{n - p + g}, \quad (17.3.2)$$

for any generalized inverse. It has the $F(q, n - p + g, \gamma)$ distribution with $\gamma = (\mathbf{L}\boldsymbol{\mu})^\top(\mathbf{L}\mathbf{V}_{\mathbf{R}}\mathbf{L}^\top)^{-1}\mathbf{L}\boldsymbol{\mu}/\sigma^2$.

- (d) Within the constrained model, $\mathbf{L}_1\boldsymbol{\mu} = \mathbf{0}$ and $\mathbf{L}_2\boldsymbol{\mu} = \mathbf{0}$ are the same hypothesis iff $\mathbf{L}_1\mathbf{K}$ and $\mathbf{L}_2\mathbf{K}$ have the same row space, and then their F statistics coincide.

Proof.

- (a) A table satisfies $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$ iff $\boldsymbol{\mu} = \mathbf{K}\boldsymbol{\theta}$ for a unique $\boldsymbol{\theta}$, so the constrained model is the linear model with model matrix $\mathbf{WK}$, of full column rank by assumption. Every coordinate of $\boldsymbol{\theta}$ is then estimable, and so is every linear function of $\boldsymbol{\mu} = \mathbf{K}\boldsymbol{\theta}$.

Since $(\mathbf{W}\mathbf{K})^\top \mathbf{W}\mathbf{K} = \mathbf{K}^\top \mathbf{D}\mathbf{K}$ and $\mathbf{W}^\top \mathbf{y} = \mathbf{D}\bar{\mathbf{y}}$, the least squares estimate is $\hat{\boldsymbol{\theta}} = (\mathbf{K}^\top \mathbf{D}\mathbf{K})^{-1} \mathbf{K}^\top \mathbf{D}\bar{\mathbf{y}}$, with covariance $\sigma^2(\mathbf{K}^\top \mathbf{D}\mathbf{K})^{-1}$ (Theorem 5.5.1). Multiplying by $\mathbf{K}$ gives Eq. 17.3.1. The model matrix has rank $p - g$, which gives the degrees of freedom.

- (b) With every cell occupied, $\mathbf{W}$ has full column rank, $\mathbf{D}^{-1}$ is the inverse of $\mathbf{W}^\top \mathbf{W}$, and $\bar{\mathbf{y}}$ is the unrestricted estimate. The constrained model is the reduced model of the testable hypothesis $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$ in the unconstrained one. So Proposition 11.3.3(a) and (b), with $\boldsymbol{\Lambda}^\top = \mathbf{R}$ and $\mathbf{G} = \mathbf{D}^{-1}$, give the displayed formula for $\hat{\boldsymbol{\mu}}_{\mathbf{R}}$ and $\text{SSE}_{\mathbf{R}} = \text{SSE} + (\mathbf{R}\bar{\mathbf{y}})^\top (\mathbf{R}\mathbf{D}^{-1}\mathbf{R}^\top)^{-1} \mathbf{R}\bar{\mathbf{y}}$, the sum of squares Eq. 17.1.1 of the hypothesis. For the covariance, let $\mathbf{V}'$ be the right side of the claimed identity. On vectors $\mathbf{D}\mathbf{K}\mathbf{a}$ both matrices give $\mathbf{K}\mathbf{a}$, because $\mathbf{R}\mathbf{K} = \mathbf{0}$. On vectors $\mathbf{R}^\top \mathbf{b}$ both give $\mathbf{0}$, because $\mathbf{K}^\top \mathbf{R}^\top = \mathbf{0}$ and $\mathbf{V}'\mathbf{R}^\top \mathbf{b} = \mathbf{D}^{-1}\mathbf{R}^\top \mathbf{b} - \mathbf{D}^{-1}\mathbf{R}^\top \mathbf{b}$. These vectors span $\mathbb{R}^p$: the spaces $\mathcal{C}(\mathbf{D}\mathbf{K})$ and $\mathcal{C}(\mathbf{R}^\top)$ have dimensions $p - g$ and g , and if $\mathbf{D}\mathbf{K}\mathbf{a} = \mathbf{R}^\top \mathbf{b}$, then $\mathbf{a}^\top \mathbf{K}^\top \mathbf{D}\mathbf{K}\mathbf{a} = (\mathbf{R}\mathbf{K}\mathbf{a})^\top \mathbf{b} = 0$, so $\mathbf{K}\mathbf{a} = \mathbf{0}$ because $\mathbf{D}$ is positive definite. Two matrices that agree on a spanning set are equal.
- (c) In the full-rank model $\mathbf{W}\mathbf{K}\boldsymbol{\theta}$ the hypothesis is $\mathbf{L}\mathbf{K}\boldsymbol{\theta} = \mathbf{0}$, which is testable. Theorem 11.3.2 with $\boldsymbol{\Lambda}^\top = \mathbf{L}\mathbf{K}$ and $\mathbf{G} = (\mathbf{K}^\top \mathbf{D}\mathbf{K})^{-1}$ gives the statistic, since $\mathbf{L}\mathbf{K}\hat{\boldsymbol{\theta}} = \mathbf{L}\hat{\boldsymbol{\mu}}_{\mathbf{R}}$ and $\mathbf{L}\mathbf{K}(\mathbf{K}^\top \mathbf{D}\mathbf{K})^{-1} \mathbf{K}^\top \mathbf{L}^\top = \mathbf{L}\mathbf{V}_{\mathbf{R}}\mathbf{L}^\top$.
- (d) Within the model, $\mathbf{L}\boldsymbol{\mu} = \mathbf{0}$ iff $\boldsymbol{\theta} \in \mathcal{N}(\mathbf{L}\mathbf{K})$, and two matrices have the same null space iff they have the same row space. The hypotheses then have the same reduced model, and by Theorem 11.3.2(b) the same F statistic.

■

Part (d) is the new phenomenon: hypotheses that differ in the cell-means model can coincide once the constraints hold. Part (b) pulls the cell averages onto the constraint set along the directions $\mathbf{D}^{-1}\mathbf{R}^\top$. The rank assumption on $\mathbf{W}\mathbf{K}$ holds whenever every cell is occupied; with empty cells it is a real condition (Exercise (C2)).

17.3.2 The additive model

Take $\mathbf{R} = \mathbf{C}_a^\top \otimes \mathbf{C}_b^\top$, the interaction hypothesis matrix of Eq. 17.1.2, with $g = (a - 1)(b - 1)$. Its null space is the space of additive tables $\mu_{ij} = \alpha_i + \beta_j$ (Section 17.1), so the constrained model is the additive model Eq. 8.6.1 written in cell means.

Corollary 17.3.2 — Main effects in the additive model

In the two-way layout with all cells occupied, let $\mathbf{R} = \mathbf{C}_a^\top \otimes \mathbf{C}_b^\top$. Then:

- (a) $\hat{\boldsymbol{\mu}}_{\mathbf{R}}$ is the table of fitted cell means of the additive model, and $\text{SSE}_{\mathbf{R}} - \text{SSE} = \text{SS}(AB \mid \mu, A, B)$;
- (b) for any weights $\mathbf{w} \in \mathbb{R}^b$ with $\sum_j w_j \neq 0$, the hypothesis that $\sum_j w_j \mu_{ij}$ is the same for all i is, within the additive model, the hypothesis $\alpha_1 = \cdots = \alpha_a$. Its sum of squares is $\text{SS}(A \mid \mu, B)$, whatever $\mathbf{w}$;
- (c) weights that differ from row to row do not have this property: the hypothesis that $\sum_j w_{ij} \mu_{ij}$ is the same for all i depends on the column effects unless $\sum_j w_{ij} \beta_j$ does not depend on i .

Proof.

- (a) The constrained mean vectors $\mathbf{W}\boldsymbol{\mu}$ with $\boldsymbol{\mu}$ additive form $\mathcal{C}([\mathbf{1}, \mathbf{Z}_A, \mathbf{Z}_B])$, so the constrained fit is the additive fit. The difference of residual sums of squares is then $SS(AB \mid \mu, A, B)$ by definition. (b) For an additive table, $\sum_j w_j \mu_{ij} = (\sum_j w_j) \alpha_i + \sum_j w_j \beta_j$, which is the same for all i iff the α_i are equal. So all these hypotheses define the same subspace of the constrained model, and by [Theorem 17.3.1\(d\)](#) the same test. Taking $\mathbf{w} = \mathbf{e}_1$ shows that the subspace is $\{\mu_{ij} = \beta_j\}$, the model with B only, and the drop in residual sum of squares from it to the additive model is $SS(A \mid \mu, B)$. (c) Now $\sum_j w_{ij} \mu_{ij} = (\sum_j w_{ij}) \alpha_i + \sum_j w_{ij} \beta_j$, and the second term varies with i in general.

■

So once additivity is accepted, the argument about types disappears for the main effects: any common weighting, and even a single column, gives the comparison $\alpha_i - \alpha_k$, tested by the Type II sum of squares (and by Type III, which coincides with it there). Only the count-weighted means of Type I stay contaminated, by part (c). The usual summaries after an additive fit are the **least squares means** (estimated marginal means), the unweighted row means of $\hat{\boldsymbol{\mu}}_{\mathbf{R}}$, with standard errors from $\mathbf{V}_{\mathbf{R}}$.

Example. (The variety trial under additivity)

In [Example \(Five tables for one data set\)](#) the interaction sum of squares 2.146 gave $F = 1.71$ on 4 and 28 degrees of freedom, $p = 0.176$. Suppose we accept additivity. The constrained fit [Eq. 17.3.1](#) gives the table of fitted means

	S1	S2	S3
V1	5.56	7.17	7.95
V2	5.11	6.73	7.51
V3	4.48	6.09	6.87

with $SSE_{\mathbf{R}} = 10.927$ on $37 - 9 + 4 = 32$ degrees of freedom and $s_{\mathbf{R}}^2 = 0.3415$. The fitted mean of V1 at S3 is 7.95, although its two plots averaged 7.45: additivity carries V1's advantage at S1 and S2 over to S3. The test of equal unweighted variety means, [Eq. 17.3.2](#), gives 6.184, the Type II sum of squares, with $F = 9.06$ on 2 and 32 degrees of freedom, $p = 0.00076$. The script checks that site weights 0.5, 0.3, 0.2, and the column S1 alone, give the same 6.184 ([Corollary 17.3.2\(b\)](#)), while each variety's own count weights give 0.571, the Type I value. The least squares means are 6.894, 6.449 and 5.811 (standard errors 0.169, 0.170, 0.178), and V1 exceeds V2 by 0.445 (standard error 0.243).

The generating means had a small interaction: V1's advantage over V2 is 0.8 at S1, 0.7 at S2 and 0.1 at S3, and the test on 4 and 28 degrees of freedom has little power to detect it. A non-significant interaction test is not evidence of additivity.

In the listing the constraint matrix is called **G**. The script checks the fit, the identity of [Theorem 17.3.1\(b\)](#) and the tests against statsmodels.

17.3.3 Several factors: choosing among constrained models

With three or more factors the useful constrained models are the hierarchical ones, named by their highest interactions. In an $a \times b \times d$ layout, where C has d levels, $[AB][C]$ contains the AB interaction, the main effect of C , and everything below them. The model $[AB][AC][BC]$ sets the $(a-1)(b-1)(d-1)$ contrasts $\mathbf{C}_a^\top \otimes \mathbf{C}_b^\top \otimes \mathbf{C}_d^\top$ to zero. Unbalanced data make these models non-orthogonal, so we remove one term at a time, judging each step by its drop in residual sum of squares over the error mean square of the full model.

Example. (Simplifying a three-factor curing study)

A (synthetic) study of a resin coating measured hardness after curing at three temperatures (T), with two hardeners (H) and resin from three suppliers (S). The 18 cells received one to three panels each, 37 in all, so the full model $[THS]$ leaves 19 error degrees of freedom, with mean square 0.408. The backward path:

Step	From	To	Term removed	df	SS	F	p
1	$[THS]$	$[TH][TS][HS]$	THS	4	1.137	0.70	0.6036
2	$[TH][TS][HS]$	$[TH][HS]$	TS	4	1.845	1.13	0.3719
3	$[TH][HS]$	$[TH][S]$	HS	2	4.132	5.06	0.0173
4	$[TH][HS]$	$[T][HS]$	TH	2	13.716	16.81	0.0001
5	$[TH][HS]$	$[HS]$	T and TH	4	19.100	11.70	0.0001

Steps 1 and 2 cost little. Step 1 is the test of the constraints $\mathbf{G}_3\boldsymbol{\mu} = \mathbf{0}$ with $\mathbf{G}_3 = \mathbf{C}_3^\top \otimes \mathbf{C}_2^\top \otimes \mathbf{C}_3^\top$, and the script recovers its sum of squares from the cell means through [Theorem 17.3.1\(b\)](#). Steps 3 and 4 show that neither interaction with the hardener can go, so the path stops at $[TH][HS]$. In that model the effect of temperature under a given hardener is the same for all three suppliers, so whether temperature matters at all is a single question inside the model, answered by step 5.

```
import statsmodels.formula.api as smf
rng3 = np.random.default_rng(31)
levels = [(i, j, k) for i in range(3) for j in range(2) for k in range(3)]
n3 = rng3.integers(1, 4, size=len(levels)) # 1 to 3 runs per cell

def true_hardness(i, j, k):
    """Temperature i, hardener j, supplier k: hardener interacts with both, nothing else does."""
    return (40 + [0, 1.0, 2.0][i] + 1.5 * j + [0, 0.5, -0.5][k]
            + j * [0, -1.0, -2.0][i] + j * [0, 1.2, -0.8][k])

cure = pd.DataFrame([(f"t{i + 1}", f"h{j + 1}", f"s{k + 1}", true_hardness(i, j, k)
                      + rng3.normal(0, 0.7))
```

```

        for (i, j, k), r in zip(levels, n3) for _ in range(r)],
        columns=["temp", "hardener", "supplier", "y"])

def fit(formula):
    f = smf.ols(formula, cure).fit()
    return f.ssr, int(f.df_resid)

sse_full, df_full = fit("y ~ temp * hardener * supplier")
mse_full = sse_full / df_full
path = [("THS", "[TH] [TS] [HS]", "y ~ temp * hardener * supplier", "y ~ (temp +
    hardener + supplier) ** 2"),
        ("TH [TS] [HS]", "[TH] [HS]", "y ~ (temp + hardener + supplier) ** 2", "y ~
    temp * hardener + hardener * supplier"),
        ("TH [HS]", "[TH] [S]", "y ~ temp * hardener + hardener * supplier", "y ~
    temp * hardener + supplier"),
        ("TH [HS]", "[T] [HS]", "y ~ temp * hardener + hardener * supplier", "y ~
    temp + hardener * supplier"),
        ("TH [HS]", "[HS]", "y ~ temp * hardener + hardener * supplier", "y ~
    hardener * supplier")]
steps = []
for big, small, f_big, f_small in path:
    (s1, d1), (s0, d0) = fit(f_big), fit(f_small)
    F = (s0 - s1) / (d0 - d1) / mse_full
    steps.append((big, small, d0 - d1, s0 - s1, F, stats.f.sf(F, d0 - d1, df_full)))
print(f"{big:13s} -> {small:13s} df = {d0 - d1}  SS = {s0 - s1:6.3f}  F = {F:5.2
f}  p = {steps[-1][5]:.4f}")

```

Such comparisons can look contradictory: a factor may matter alone but not after another. That is the unbalanced analogue of collinearity, and it should be reported as such, not resolved by choosing a type of sum of squares.

17.3.4 Exercises

17.3.4.1 A. Check your understanding

Exercise A1.

In an $a \times b \times d$ layout with every cell occupied and n observations, how many constraints define the model $[AB][AC][BC]$, and how many error degrees of freedom does it have? Check your answer against step 1 of [Example \(Simplifying a three-factor curing study\)](#).

17.3.4.2 B. Practice

Exercise B1.

For a 2×2 layout with all cells occupied, take $\mathbf{R} = (1, -1, -1, 1)$. Use [Theorem 17.3.1\(b\)](#) to show that the additive fit is $\hat{\mu}_{ij} = \bar{y}_{ij} - (-1)^{i+j} \hat{\delta} / (n_{ij}H)$, where $\hat{\delta} = \bar{y}_{11} - \bar{y}_{12} - \bar{y}_{21} + \bar{y}_{22}$ and $H = \sum_{ij} 1/n_{ij}$. Which cells move most?

Solution. Here $\mathbf{R}\bar{\mathbf{y}} = \hat{\delta}$ and $\mathbf{R}\mathbf{D}^{-1}\mathbf{R}^\top = H$, so $\hat{\boldsymbol{\mu}}_{\mathbf{R}} = \bar{\mathbf{y}} - \mathbf{D}^{-1}\mathbf{R}^\top \hat{\delta} / H$. The (i, j) entry of $\mathbf{D}^{-1}\mathbf{R}^\top$ is $(-1)^{i+j} / n_{ij}$. Each cell average moves by $\hat{\delta} / (n_{ij}H)$ in the direction that removes the interaction, so the least replicated cells move most. The four moves remove

$\hat{\delta}$ exactly: $\sum_{ij} (-1)^{i+j} \cdot (-1)^{i+j} \hat{\delta} / (n_{ij} H) = \hat{\delta}$.

Exercise B2.

In a 2×3 layout with every cell occupied, impose only $\mu_{11} - \mu_{12} - \mu_{21} + \mu_{22} = 0$. Describe the constrained model in words. How many degrees of freedom does its residual have, and what does the F test of the remaining interaction contrast within it test?

Exercise B3.

In the additive model with all cells occupied, show that the least squares means satisfy $\hat{\mu}_{i\cdot} - \hat{\mu}_{k\cdot} = \hat{\alpha}_i - \hat{\alpha}_k$ for any solution of the normal equations, and that the same difference is obtained if the fitted table is averaged over j with any fixed weights summing to one. Why does the choice of weights still matter for the least squares means themselves?

Solution. The fitted table is $\hat{\mu}_{ij} = \hat{m} + \hat{\alpha}_i + \hat{\beta}_j$, unique as a table (Theorem 6.4.2). Averaging over j with weights w_j summing to one gives $\hat{m} + \hat{\alpha}_i + \sum_j w_j \hat{\beta}_j$, and the last term does not depend on i . So the differences are $\hat{\alpha}_i - \hat{\alpha}_k$, an estimable function whose value does not depend on the solution chosen. The means themselves contain $\sum_j w_j \hat{\beta}_j$, which does depend on the weights. They are levels, not comparisons, and a level is a mean over some population of columns.

17.3.4.3 C. Going deeper

Exercise C1.

The *method of unweighted means* estimates $\alpha_1 - \alpha_2$ in a $2 \times b$ additive layout by $b^{-1} \sum_j (\bar{y}_{1j} - \bar{y}_{2j})$, as if every cell had the same count. Show that the least squares estimate is $\sum_j h_j (\bar{y}_{1j} - \bar{y}_{2j}) / \sum_j h_j$ with $h_j = n_{1j} n_{2j} / n_{\cdot j}$. Deduce that both are unbiased under additivity, and that the least squares estimate has the smaller variance unless all h_j are equal.

Solution. Under additivity each $\bar{y}_{1j} - \bar{y}_{2j}$ is unbiased for $\delta = \alpha_1 - \alpha_2$, with variance σ^2/h_j (Exercise (B2)), and the b differences are independent. Any weighted average with weights summing to one is unbiased. Its variance $\sigma^2 \sum_j v_j^2 / h_j$ is minimized, by the Cauchy-Schwarz argument of Proposition 17.1.2, at $v_j \propto h_j$. The minimum variance is $\sigma^2 / \sum_j h_j$. The least squares estimate is the best linear unbiased estimator (Theorem 7.2.1), and it is a linear function of the cell averages, which are sufficient here. So it is the h -weighted average. The unweighted average has $v_j = 1/b$, and it is optimal only if all h_j are equal.

Exercise C2.

Allow empty cells. Show that **WK** in Theorem 17.3.1 has full column rank iff no nonzero table satisfying $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$ vanishes on every occupied cell. Deduce that for the additive constraints this holds iff the design graph of Theorem 8.6.1 is connected.

Solution. $\mathbf{WK}\boldsymbol{\theta} = \mathbf{0}$ iff the table $\mathbf{K}\boldsymbol{\theta}$ vanishes on every occupied cell, since the rows of $\mathbf{W}$ pick out the occupied cells. The columns of $\mathbf{K}$ are independent, so $\mathbf{WK}$ has a nonzero null vector iff some nonzero table satisfying the constraints vanishes on O . For additive tables $\alpha_i + \beta_j$, vanishing on O means $\alpha_i = -\beta_j$ for every occupied (i, j) . As in the proof of [Theorem 8.6.1](#), this forces $\alpha_i = t_C$ and $\beta_j = -t_C$ on each component C of the design graph. The table is nonzero iff the t_C are not all equal, which is possible iff there are at least two components.

17.4 Empty cells and estimability

Some combinations of levels are never observed, or are impossible. An empty cell's mean does not appear in the distribution of the data, so no unconstrained analysis can estimate it ([Proposition 17.1.1\(b\)](#)). This section works out what survives, building on connectedness ([Theorem 8.6.1](#)) and the estimability of interaction contrasts ([Proposition 8.6.2](#)).

Throughout, the two-way layout has occupied cells O , with $m = |O|$, every row and every column contains at least one occupied cell, and c is the number of connected components of the design graph of [Theorem 8.6.1](#). A row is **complete** if none of its cells is empty.

17.4.1 What remains estimable

Theorem 17.4.1 — Estimability and tests with empty cells

In the two-way layout described above:

- (a) In the cell-means model, $\sum_i u_i \sum_j w_j \mu_{ij}$ is estimable iff $u_i w_j = 0$ for every empty cell (i, j) . In particular the unweighted mean $\bar{\mu}_i$ is estimable iff row i is complete.
- (b) The estimable interaction contrasts, the tables (d_{ij}) with zero row and column sums and $d_{ij} = 0$ on every empty cell ([Proposition 8.6.2\(c\)](#)), form a space of dimension $m - a - b + c$. The interaction sum of squares $\text{SS}(AB \mid \mu, A, B)$ has $m - a - b + c$ degrees of freedom. It addresses the hypothesis that all these contrasts vanish, which holds iff the occupied cell means are additive: $\mu_{ij} = \alpha_i + \beta_j$ for all $(i, j) \in O$ and some α, β .
- (c) If the design is connected, the additive model estimates every cell mean, including those of empty cells, and under additivity $\text{SS}(A \mid \mu, B)$ addresses $\alpha_1 = \cdots = \alpha_a$, with $a - 1$ degrees of freedom.
- (d) Code both factors by contrasts and form the interaction columns as products. If at least one row is incomplete and k rows are complete, the last-in sum of squares of A addresses equality of the unweighted means of the complete rows, and it has $\max(k - 1, 0)$ degrees of freedom.

Proof.

- (a) The coefficient of μ_{ij} is $u_i w_j$, and [Proposition 17.1.1\(b\)](#) applies. For $\bar{\mu}_i$ the coefficients are $1/b$ on row i and zero elsewhere.
- (b) Let $T : \mathbb{R}^O \rightarrow \mathbb{R}^a \times \mathbb{R}^b$ send a table $(d_{ij})_{(i,j) \in O}$ to its row sums and column sums.

The estimable interaction contrasts form $\mathcal{N}(T)$. The transpose sends $(\mathbf{u}, \mathbf{v})$ to the table $(u_i + v_j)_{(i,j) \in O}$. As in the proof of [Theorem 8.6.1](#), $u_i + v_j = 0$ on O forces $u_i = t_C$ and $v_j = -t_C$ on each component C , with arbitrary t_C . So $\mathcal{N}(T^\top)$ has dimension c , $\text{rank}(T) = a + b - c$, and $\dim \mathcal{N}(T) = m - a - b + c$. The tables $(u_i + v_j)_{(i,j) \in O}$ are exactly the occupied parts of additive tables. They form $\mathcal{C}(T^\top)$, whose orthogonal complement in $\mathbb{R}^O$ is $\mathcal{N}(T)$. So the occupied cell means are additive iff they are orthogonal to every estimable interaction contrast, that is, iff all those contrasts vanish. The interaction sum of squares is $\mathbf{y}^\top (\mathbf{M} - \mathbf{P}_{A+B}) \mathbf{y}$, which addresses the hypothesis that $\mathbf{W}\boldsymbol{\mu}$ lies in the additive model space, that is, that the occupied cell means are additive. Its degrees of freedom are $m - (a + b - c)$ by [Proposition 17.1.1\(a\)](#) and [Theorem 8.6.1\(a\)](#).

- (c) The first claim is [Theorem 8.6.1\(c\)](#). For the second, let $\mu_{ij} = \alpha_i + \beta_j$. Then $(\mathbf{P}_{A+B} - \mathbf{P}_B)\mathbf{W}\boldsymbol{\mu} = \mathbf{0}$ iff $\mathbf{W}\boldsymbol{\mu} \in \mathcal{C}([\mathbf{1}, \mathbf{Z}_B])$, that is, iff $\alpha_i + \beta_j = \beta'_j$ on O for some β' . Then $\alpha_i + (\beta_j - \beta'_j) = 0$ on O , and in a connected design this forces all α_i to be equal, as in (b). Conversely, equal α_i give such a β' . The degrees of freedom are $\text{rank}[\mathbf{1}, \mathbf{Z}_A, \mathbf{Z}_B] - \text{rank}[\mathbf{1}, \mathbf{Z}_B] = (a + b - 1) - b$.
- (d) As in the proof of [Proposition 17.2.3](#), the full model matrix is $\mathbf{W}$ times the ab independent columns of $\mathbf{K}_A \otimes \mathbf{K}_B$, so its column space is $\mathcal{C}(\mathbf{W})$. The reduced model is $\mathbf{W}\mathbf{F}$. The argument in that proof does not use the counts, and with $\mathbf{w} = \mathbf{1}$ it shows that $\mathcal{C}(\mathbf{F})$ is the space $\mathcal{V}$ of tables with equal unweighted row means. Hence the reduced mean vectors are $\{\mathbf{W}\boldsymbol{\mu} : \boldsymbol{\mu} \in \mathcal{V}\}$: the tables of occupied cell means that can be completed, by choosing values in the empty cells, to a table with equal unweighted row means. Suppose the complete rows share a common unweighted mean t , with t arbitrary if there are none. Each incomplete row can then be given the mean t by choosing the value in one of its empty cells, so the occupied means can be completed. Conversely, a completion cannot change the means of complete rows. So the hypothesis is equality of the unweighted means of the complete rows. It consists of the $k - 1$ restrictions $\bar{\mu}_i = \bar{\mu}_{i_0}$, for the complete rows $i \neq i_0$, which are independent because they involve disjoint sets of cells, and of none if $k \leq 1$. The last-in sum of squares is the drop in residual sum of squares from the reduced model to $\mathcal{C}(\mathbf{W})$, so it addresses this hypothesis ([Eq. 6.5.2](#)), and its degrees of freedom are the number of independent restrictions. ■

In part (b), a table with zero row and column sums on the edges of the design graph is a *circulation*. The simplest ones run around cycles with alternating signs. A four-cycle is the familiar tetrad $\mu_{ij} - \mu_{il} - \mu_{kj} + \mu_{kl}$; longer cycles give contrasts on six or more cells that survive when every tetrad through them is broken. The number $m - a - b + c$ counts the independent cycles ([Exercise \(C1\)](#)).

Part (d) is the result to remember about Type III. With empty cells it ignores every incomplete row, and it may test nothing at all: an empty cell can hold whatever value makes its row's unweighted mean agree, and such means are not estimable, by (a).

17.4.2 An example with two combinations never grown

Figure 17.4.1: Design graph of [Example \(The variety trial with two empty cells\)](#) (dashed: empty cells). The blue and orange tetrads share the purple edge V2–S2.

Example. (The variety trial with two empty cells)

Suppose that in the trial of [Example \(Three varieties at three sites\)](#) V1 had never been grown at S3, nor V3 at S1. That leaves $n = 33$ plots in $m = 7$ cells, with 26 error degrees of freedom and error mean square 0.3096. The design graph ([Figure 17.4.1](#)) is connected, so the estimable interaction contrasts have dimension $7 - 3 - 3 + 1 = 2$, spanned by two tetrads. The interaction sum of squares is 1.218, $F = 1.97$, $p = 0.160$, and the script checks that the tetrads give the same value through [Eq. 17.1.1](#). The six-cell contrast around V1–S1–V2–S3–V3–S2–V1 is the difference of the tetrads ([Exercise \(B3\)](#)).

The unweighted means of V1 and V3 are no longer estimable. V1 and V2 share S1 and S2, and the difference of their averages there is 0.603 (standard error 0.268). The additive model is still identified. Its Type II sum of squares for varieties is 5.766 on 2 degrees of freedom, and it fills the empty cells with 8.32 for V1 at S3 and 4.20 for V3 at S1. The first exceeds every observed cell mean: V1's advantage at S1 and S2 is carried to a site where V1 was never grown, although in the generating means it had nearly vanished there (the true mean is 7.6).

The “Type III” sum of squares for varieties is 0 on 0 degrees of freedom: V2 is the only complete row ([Theorem 17.4.1\(d\)](#)). If only V1 at S3 is removed, it is 2.027 on 1 degree of freedom, the sum of squares of $\bar{\mu}_{2.} = \bar{\mu}_{3.}$, for every ordering of the levels.

17.4.3 How software behaves

A program fitting the rank-deficient effects model picks one coefficient vector and computes its sums of squares from it. The script fits the data of [Example \(The variety trial with two empty cells\)](#) with statsmodels 0.15 under three namings of the levels. It warns that the design is rank-deficient and prints tables anyway. The Type I interaction appears on 4 degrees of freedom instead of 2, with sums of squares 3.96, 2.15 and 2.05 instead of 1.218. The Type II interaction entries are 23.46, 53.21 and 3.17, and the Type III variety entries 9.43, 41.10 and 34.25 on 2 degrees of freedom, where there is nothing to test. The projections give the same answers under every naming, as they must. SAS's "Type IV" sums of squares for empty cells build hypotheses from the occupied cells in a way that depends on the order of the levels (Goodnight 1980). Whatever the program, check that the printed degrees of freedom equal the rank of the

projection, and write down the hypothesis.

17.4.4 Recommended practice

1. *Tabulate the counts first*, draw the design graph and count its components. Rows in different components cannot be compared, even under additivity ([Theorem 8.6.1\(b\)](#)).
2. *Ask why the cells are empty*. Cells lost at random fit the theory above. Impossible combinations have no mean, and a main effect averaged over them is fiction. Combinations avoided *because* they were expected to do badly bias every additive fill-in, and no analysis of the observed cells can detect it.
3. *Test the interaction on its $m-a-b+c$ degrees of freedom*. If there are few cycles, additivity is barely checked.
4. *If additivity is credible*, use the additive model and $SS(A \mid \mu, B)$, and flag least squares means that involve empty cells as extrapolations.
5. *If not*, ask estimable questions of the cell means: simple effects, comparisons over shared columns, or a complete sub-table, and state which cells each comparison uses. Do not report a Type III or Type IV table without identifying its hypotheses.

One can also impose just enough interaction constraints to identify the empty cells ([Section 17.3](#)). The resulting estimates are then set by constraints the data cannot test ([Exercise \(B4\)](#)), and should be presented as assumptions.

17.4.5 Exercises

17.4.5.1 A. Check your understanding

Exercise A1.

A 3×4 layout has every cell occupied except $(1, 4)$, $(2, 1)$ and $(3, 1)$. Find m , the number of components of the design graph, the degrees of freedom of the interaction, and the tetrads that are estimable.

Exercise A2.

In [Example \(The variety trial with two empty cells\)](#), which comparisons between V1 and V3 are estimable in the cell-means model? Why is the V1–V2 comparison over S1 and S2 estimable when neither unweighted mean is?

17.4.5.2 B. Practice

Exercise B1.

In a 2×2 layout with cell $(2, 2)$ empty, show that the additive model estimates μ_{22} by $\bar{y}_{21} + \bar{y}_{12} - \bar{y}_{11}$, and find its variance. Show that the last-in sum of squares of A with sum-to-zero coding is identically zero. Compare with [Exercise \(B4\)](#).

Solution. With three occupied cells and a connected graph, the additive model has $1 + 2 + 2 - 1 = 3 = m$ free parameters. Its fitted values are the three cell averages, since $\text{SS}(AB \mid \mu, A, B)$ has $3 - 2 - 2 + 1 = 0$ degrees of freedom. Additivity gives $\mu_{22} = \mu_{21} + \mu_{12} - \mu_{11}$, estimated by $\bar{y}_{21} + \bar{y}_{12} - \bar{y}_{11}$ with variance $\sigma^2(1/n_{21} + 1/n_{12} + 1/n_{11})$. Row 1 is the only complete row, so [Theorem 17.4.1\(d\)](#) with $k = 1$ gives zero degrees of freedom, and the sum of squares vanishes for every data set. Directly, the reduced model with columns **1**, the B column and the product column already has rank 3 on the three occupied cells.

Exercise B2.

Take the 4×5 design of [Example \(Two islands\)](#), with occupied cells $(1, 1), (1, 2), (2, 2), (2, 3), (3, 4), (4, 4), (4, 5)$. Find the degrees of freedom of the interaction and the Type II sum of squares of A . Which comparisons of rows can the additive model make?

Exercise B3.

In [Example \(The variety trial with two empty cells\)](#), show that the six-cell contrast $\mu_{11} - \mu_{12} - \mu_{21} + \mu_{23} + \mu_{32} - \mu_{33}$ has zero row and column sums and vanishes on the empty cells. Write it as a combination of the two tetrads, and trace the cycle it corresponds to in [Figure 17.4.1](#).

Solution. Row sums: $1 - 1 = 0$, $-1 + 1 = 0$, $1 - 1 = 0$. Column sums: $1 - 1 = 0$ for S1, $-1 + 1 = 0$ for S2, $1 - 1 = 0$ for S3. It has no coefficient on $(1, 3)$ or $(3, 1)$. With $T_1 = \mu_{11} - \mu_{12} - \mu_{21} + \mu_{22}$ and $T_2 = \mu_{22} - \mu_{23} - \mu_{32} + \mu_{33}$, the contrast is $T_1 - T_2$, because μ_{22} cancels. The cycle is V1–S1–V2–S3–V3–S2–V1. It uses every occupied cell except V2–S2, the edge the two tetrads share.

Exercise B4.

In a 2×3 layout with only cell $(2, 3)$ empty, impose the single constraint $\mu_{12} - \mu_{13} - \mu_{22} + \mu_{23} = 0$. Show that every cell mean becomes estimable and find the estimate of μ_{23} . Can the constraint be tested?

Solution. The constraint gives $\mu_{23} = \mu_{22} + \mu_{13} - \mu_{12}$, so any table satisfying it that vanishes on the occupied cells vanishes everywhere, and [Exercise \(C2\)](#) gives identifiability. The five occupied cell means are unrestricted, so their estimates remain the cell averages, and $\hat{\mu}_{23} = \bar{y}_{22} + \bar{y}_{13} - \bar{y}_{12}$. The constraint involves the empty cell with a nonzero coefficient, so it is not estimable in the cell-means model and cannot be tested ([Proposition 11.3.1](#)). The fit is the same whether it holds or not. It only decides what we say about μ_{23} .

17.4.5.3 C. Going deeper

Exercise C1.

Let F be a spanning forest of the design graph, with $a + b - c$ edges. Show that each occupied cell e not in F closes a unique cycle in $F \cup \{e\}$, and that the alternating-

sign contrast $d^{(e)}$ of that cycle is an estimable interaction contrast. Show that the $m - a - b + c$ contrasts $d^{(e)}$ are linearly independent and hence form a basis of the space in [Theorem 17.4.1\(b\)](#).

Solution. Adding an edge $e = (i, j)$ to a forest joins two vertices of the same tree (the graph and the forest have the same components), so it closes exactly one cycle, the tree path from i to j followed by e . A cycle in a bipartite graph has even length and alternates between row and column vertices. Giving its edges alternating signs ± 1 makes the two edges at each vertex cancel, so the row and column sums vanish, and the table is supported on occupied cells. The contrast $d^{(e)}$ is the only one of the family with a nonzero entry at e , because the other cycles use only forest edges and their own extra edge. So in any vanishing linear combination the coefficient of $d^{(e)}$ is zero, for each e . There are $m - (a + b - c)$ of them, the dimension of the space, so they form a basis.

Exercise C2.

In the trial with only V1 at S3 removed, what does the “Type III” sum of squares for sites test, and on how many degrees of freedom? Verify your answer by modifying the listing.

17.5 Summary and Notes

17.5.1 Summary

Idea.

1. The cell-means model is the one-way layout on the occupied cells. Any hypothesis $\mathbf{L}\boldsymbol{\mu} = \mathbf{d}$ on occupied cells is tested by [Eq. 17.1.1](#) ([Definition 17.1.1](#), [Proposition 17.1.1](#)).
2. Count-weighted marginal means are the most precise, but they estimate the mixture the design happened to produce. Choose the target before the weights ([Proposition 17.1.2](#)).
3. An extra sum of squares tests whether the count-weighted residual of the true cell means, after the terms already fitted, is orthogonal to the new term ([Lemma 17.2.1](#)). This gives the hypotheses of all the types ([Theorem 17.2.2](#)).
4. The last-in sum of squares of a main effect depends on the coding of the *other* factors. It is the Type III sum of squares exactly when they are coded by contrasts ([Proposition 17.2.3](#)).
5. Constrained models are cell-means models with $\mathbf{R}\boldsymbol{\mu} = \mathbf{0}$, fitted and tested by restricted least squares ([Theorem 17.3.1](#)). Under additivity every common weighting of the row means gives the Type II test ([Corollary 17.3.2](#)).
6. With empty cells, the interaction has $m - a - b + c$ degrees of freedom, one per independent cycle of the design graph, and the “Type III” sum of squares compares only the complete rows ([Theorem 17.4.1](#)).

17.5.2 Notes and sources

Cell means. Analysing unbalanced data through cell means goes back to Yates (1934), whose weighted squares of means test hypotheses about unweighted means. Speed, Hocking and Hackney (1978) identified the cell-mean hypotheses of the sums of squares computed by the programs of their day, and Hocking (1985) and Searle (1987) give book-length treatments. Rencher and Schaalje (2008, chapter 15) presents unconstrained and constrained cell-means models and empty cells, and was the main source for this chapter’s coverage. Christensen (2020, sections 7.5–7.6) treats unbalanced layouts as a problem of comparing models, an emphasis reflected in [Section 17.3](#).

Types of sums of squares. The Type I, II and III terminology comes from statistical software. Nelder (1977) argued from the marginality of model terms that main effects should not be tested in the presence of their interactions, and Nelder and Lane (1995) restated the case. Langsrud (2003) argued for Type II on grounds of power, which [Exercise \(C1\)](#) makes precise. The hypothesis formulas of [Theorem 17.2.2\(b\)](#) and (c) are classical. Christensen (2020, section 7.5) states them for the two-way layout with interaction, and [Lemma 17.2.1](#) is our route to them. The characterization of the coding dependence in [Proposition 17.2.3](#), stated through the orthogonal complement of the other factor’s coding columns, is this book’s formulation of the familiar advice to use sum-to-zero contrasts.

Empty cells. Goodnight (1980) described the construction of the hypotheses behind SAS’s Type IV sums of squares for designs with empty cells, and noted that they are not unique. Milliken and Johnson (2009) discuss the analysis of two-way layouts with missing cells at length, with an emphasis on estimable questions and on identifying the hypotheses that software tests. The reading of estimable interaction contrasts as the cycle space of the design graph ([Theorem 17.4.1\(b\)](#)) uses the standard fact that a graph with m edges, v vertices and c components has $m - v + c$ independent cycles. The description of the Type III hypothesis with empty cells in [Theorem 17.4.1\(d\)](#) and the software comparison of [Section 17.4](#) are this book’s.

Data. The variety trial and the curing study are synthetic, generated by the scripts in `code/ch17/` with fixed seeds, so that the true cell means are known.

Chapter 18

Analysis of Covariance and Designed Experiments

An experiment is designed before any response is measured. The experimenter decides which units receive which treatment, which nuisance variation to remove by grouping units into blocks, and which extra measurements to take on each unit before treatment begins. Each decision shows up in the linear model: blocks as additional factors, extra measurements as covariates, and the randomization as the reason the error assumptions are believable. This chapter works through the standard designed structures with the projection tools of Parts II and III. Analysis of covariance turns out to be the Frisch–Waugh–Lovell theorem applied to a factor model. Adjusted means are estimable functions with a correction term. The test of parallel slopes compares nested subspaces. Randomized blocks, Latin squares and balanced incomplete blocks are layouts whose balance makes the projections simple. A lost observation is handled exactly by least squares on the observations that remain, and the classical ways of filling in the gap are shortcuts to the same answer.

What you need. [Chapter 6](#) (nested projections, [Theorem 6.5.1](#), and the Frisch–Waugh–Lovell theorem, [Theorem 6.6.2](#)), [Chapter 8](#) (estimability, and the parallel and separate lines models of [Section 8.6](#)), [Chapter 9](#) (extra sums of squares and orthogonal designs), [Chapter 11](#) and [Chapter 13](#) (F tests and simultaneous inference), [Chapter 12](#) (t intervals, prediction intervals and the Working–Hotelling band), and, from this part, [Chapter 15](#) and [Chapter 16](#) (the one-way and additive two-way layouts) and [Chapter 17](#) (cell means and least squares means in unbalanced layouts).

18.1 Analysis of covariance as a projection problem

In many experiments something about each unit is known before the treatments are applied: a pretest score, the weight of an animal at the start of a feeding trial, the yield of a plot in the previous season, a patient's blood pressure at enrolment. Such a measurement is a **covariate**. If it predicts the response, much of the variation that the one-way analysis (Chapter 15) calls error is not error at all. Part of it is the covariate at work, and it can be removed.

The **analysis of covariance** (ANCOVA) adds covariates to a factor model. Section 8.6 treated one factor and one covariate (Proposition 8.6.3). This section states the result for any design part, rank deficient or not, and any number of covariates, and then asks what a covariate does in a randomized experiment.

18.1.1 The model

Write the mean of the response as the sum of a *design part* and a *covariate part*,

$$E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}_n. \quad (18.1.1)$$

Here $\mathbf{X}$ is $n \times p$ with rank r , built from the indicator columns of the treatment factor and of any blocking factors. It is usually overparameterized. The $n \times q$ matrix $\mathbf{Z}$ holds the covariate values, and $\boldsymbol{\gamma} \in \mathbb{R}^q$ their coefficients. Let $\mathbf{M}$ be the orthogonal projection onto $\mathcal{C}(\mathbf{X})$. Everything below is written with the three matrices

$$\mathbf{E}_{zz} = \mathbf{Z}^\top (\mathbf{I} - \mathbf{M}) \mathbf{Z}, \quad \mathbf{E}_{zy} = \mathbf{Z}^\top (\mathbf{I} - \mathbf{M}) \mathbf{y}, \quad E_{yy} = \mathbf{y}^\top (\mathbf{I} - \mathbf{M}) \mathbf{y}. \quad (18.1.2)$$

The letter E stands for *error* or *within*: in the one-way layout $(\mathbf{I} - \mathbf{M})\mathbf{y}$ holds the deviations from the group means (Example (The one-way layout)), so these are within-group sums of squares and products. We assume throughout that

$$\text{rank}[\mathbf{X}, \mathbf{Z}] = \text{rank}(\mathbf{X}) + q, \quad \text{equivalently} \quad (\mathbf{I} - \mathbf{M})\mathbf{Z} \text{ has full column rank } q. \quad (18.1.3)$$

The two forms are equivalent by Lemma 9.2.1, since $\mathcal{C}([\mathbf{X}, \mathbf{Z}]) = \mathcal{C}(\mathbf{X}) \oplus \mathcal{C}((\mathbf{I} - \mathbf{M})\mathbf{Z})$. The condition fails exactly when some combination of the covariates lies in the design space. With one factor and one covariate, it fails when the covariate is constant within every group. Then the covariate cannot be separated from the group effects (Exercise (B1)).

18.1.2 The main theorem

Theorem 18.1.1 — Analysis of covariance

Assume Eq. 18.1.1 and Eq. 18.1.3. Let $\mathbf{M}_W$ be the orthogonal projection onto $\mathcal{C}([\mathbf{X}, \mathbf{Z}])$.

- (a) $\mathbf{M}_W = \mathbf{M} + (\mathbf{I} - \mathbf{M})\mathbf{Z}\mathbf{E}_{zz}^{-1}\mathbf{Z}^\top(\mathbf{I} - \mathbf{M})$, and the two terms are orthogonal projections

with orthogonal ranges.

- (b) $\boldsymbol{\gamma}$ is estimable, with the unique least squares estimate $\hat{\boldsymbol{\gamma}} = \mathbf{E}_{zz}^{-1}\mathbf{E}_{zy}$.
 (c) A function $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ is estimable in Eq. 18.1.1 iff it is estimable in the model $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ without covariates. If $\boldsymbol{\lambda} = \mathbf{X}^\top \boldsymbol{\rho}$, its least squares estimate is

$$\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} = \boldsymbol{\rho}^\top \mathbf{M}(\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}), \quad (18.1.4)$$

so the fitted design part is $\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{M}(\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}})$: the covariance-adjusted response $\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}$ analysed by the formulas of the model without covariates.

- (d) The residual sum of squares is

$$\text{SSE} = E_{yy} - \mathbf{E}_{zy}^\top \mathbf{E}_{zz}^{-1} \mathbf{E}_{zy}, \quad (18.1.5)$$

on $n - r - q$ degrees of freedom.

- (e) $\text{Cov}(\hat{\boldsymbol{\gamma}}) = \sigma^2 \mathbf{E}_{zz}^{-1}$, $\text{Cov}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\gamma}}) = -\sigma^2 \boldsymbol{\rho}^\top \mathbf{M} \mathbf{Z} \mathbf{E}_{zz}^{-1}$, and

$$\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}) = \sigma^2 (\boldsymbol{\rho}^\top \mathbf{M} \boldsymbol{\rho} + \boldsymbol{\rho}^\top \mathbf{M} \mathbf{Z} \mathbf{E}_{zz}^{-1} \mathbf{Z}^\top \mathbf{M} \boldsymbol{\rho}). \quad (18.1.6)$$

- (f) Let $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with rank $r_0 < r$ and projection $\mathbf{M}_0$, and define $\mathbf{T}_{zz}, \mathbf{T}_{zy}, T_{yy}$ as in Eq. 18.1.2 with $\mathbf{M}_0$ in place of $\mathbf{M}$. Then Eq. 18.1.3 holds for $\mathbf{X}_0$ as well, and the hypothesis that the design part of the mean lies in $\mathcal{C}(\mathbf{X}_0)$, with $\boldsymbol{\gamma}$ unrestricted, has the **adjusted sum of squares**

$$\text{SS}_H = (T_{yy} - \mathbf{T}_{zy}^\top \mathbf{T}_{zz}^{-1} \mathbf{T}_{zy}) - (E_{yy} - \mathbf{E}_{zy}^\top \mathbf{E}_{zz}^{-1} \mathbf{E}_{zy}) \quad (18.1.7)$$

on $r - r_0$ degrees of freedom. If $\mathbf{Y}$ is normal,

$$F = \frac{\text{SS}_H / (r - r_0)}{\text{SSE} / (n - r - q)} \sim F(r - r_0, n - r - q, \gamma),$$

where the noncentrality γ , a scalar not to be confused with the coefficient vector $\boldsymbol{\gamma}$, is given by $\sigma^2 \gamma$ equal to the squared distance from $\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$ to $\mathcal{C}([\mathbf{X}_0, \mathbf{Z}])$.

Proof.

- (a) By Lemma 9.2.1, $\mathcal{C}([\mathbf{X}, \mathbf{Z}]) = \mathcal{C}(\mathbf{X}) \oplus \mathcal{C}(\tilde{\mathbf{Z}})$ with $\tilde{\mathbf{Z}} = (\mathbf{I} - \mathbf{M})\mathbf{Z}$, and the summands are orthogonal. $\tilde{\mathbf{Z}}$ has full column rank by Eq. 18.1.3, so its projection is $\tilde{\mathbf{Z}}(\tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}})^{-1} \tilde{\mathbf{Z}}^\top$ (Theorem 6.3.6), and $\tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}} = \mathbf{E}_{zz}$ because $\mathbf{I} - \mathbf{M}$ is symmetric and idempotent. Theorem 6.3.7 adds the two projections.
 (b) and (c). Put $\hat{\boldsymbol{\gamma}} = \mathbf{E}_{zz}^{-1} \mathbf{E}_{zy}$. By (a),

$$\mathbf{M}_W \mathbf{y} = \mathbf{M} \mathbf{y} + (\mathbf{I} - \mathbf{M}) \mathbf{Z} \hat{\boldsymbol{\gamma}} = \mathbf{M}(\mathbf{y} - \mathbf{Z} \hat{\boldsymbol{\gamma}}) + \mathbf{Z} \hat{\boldsymbol{\gamma}}.$$

The first term lies in $\mathcal{C}(\mathbf{X})$, so it equals $\mathbf{X}\mathbf{b}$ for some $\mathbf{b}$, and $(\mathbf{b}, \hat{\boldsymbol{\gamma}})$ is a least squares estimate (Theorem 6.4.1). If $(\mathbf{b}', \boldsymbol{\gamma}')$ is another one, then $\mathbf{X}(\mathbf{b} - \mathbf{b}') = \mathbf{Z}(\boldsymbol{\gamma}' - \hat{\boldsymbol{\gamma}})$. Applying $\mathbf{I} - \mathbf{M}$ gives $\tilde{\mathbf{Z}}(\boldsymbol{\gamma}' - \hat{\boldsymbol{\gamma}}) = \mathbf{0}$, and so $\boldsymbol{\gamma}' = \hat{\boldsymbol{\gamma}}$. The coefficient vector of the covariates is therefore the same in every least squares estimate, and so $\boldsymbol{\gamma}$ is estimable (Theorem 8.3.1(g)). The same argument shows that $\mathbf{X}\hat{\boldsymbol{\beta}} = \mathbf{M}(\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}})$ for every least squares estimate.

For estimability of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$: in the covariance model this function has coefficient vector $(\boldsymbol{\lambda}^\top, \mathbf{0}^\top)$, which is estimable iff $\mathbf{a}^\top [\mathbf{X}, \mathbf{Z}] = (\boldsymbol{\lambda}^\top, \mathbf{0}^\top)$ for some $\mathbf{a}$ (Theorem 8.2.2). Such

an $\mathbf{a}$ gives $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$. Conversely, if $\boldsymbol{\lambda} = \mathbf{X}^\top \boldsymbol{\rho}$, put

$$\mathbf{a} = \mathbf{M}\boldsymbol{\rho} - \tilde{\mathbf{Z}}\mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\mathbf{M}\boldsymbol{\rho}.$$

Then $\mathbf{a}^\top\mathbf{X} = \boldsymbol{\rho}^\top\mathbf{M}\mathbf{X} - \boldsymbol{\rho}^\top\mathbf{M}\mathbf{Z}\mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\mathbf{X} = \boldsymbol{\lambda}^\top$, because $\tilde{\mathbf{Z}}^\top\mathbf{X} = \mathbf{Z}^\top(\mathbf{I} - \mathbf{M})\mathbf{X} = \mathbf{0}$, and $\mathbf{a}^\top\mathbf{Z} = \boldsymbol{\rho}^\top\mathbf{M}\mathbf{Z} - \boldsymbol{\rho}^\top\mathbf{M}\mathbf{Z}\mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\mathbf{Z} = \mathbf{0}^\top$, because $\tilde{\mathbf{Z}}^\top\mathbf{Z} = \mathbf{E}_{zz}$. So $\boldsymbol{\lambda}^\top\boldsymbol{\beta}$ is estimable. Since $\mathbf{a}$ lies in $\mathcal{C}([\mathbf{X}, \mathbf{Z}])$, its least squares estimate is $\mathbf{a}^\top\mathbf{M}_W\mathbf{y} = \mathbf{a}^\top\mathbf{y}$ (Proposition 8.3.2(a)):

$$\mathbf{a}^\top\mathbf{y} = \boldsymbol{\rho}^\top\mathbf{M}\mathbf{y} - \boldsymbol{\rho}^\top\mathbf{M}\mathbf{Z}\mathbf{E}_{zz}^{-1}\mathbf{E}_{zy} = \boldsymbol{\rho}^\top\mathbf{M}(\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}).$$

- (d) $\text{SSE} = \|(\mathbf{I} - \mathbf{M}_W)\mathbf{y}\|^2 = \mathbf{y}^\top(\mathbf{I} - \mathbf{M})\mathbf{y} - \mathbf{y}^\top\tilde{\mathbf{Z}}\mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\mathbf{y}$ by (a), and $\tilde{\mathbf{Z}}^\top\mathbf{y} = \mathbf{E}_{zy}$. The rank of $\mathbf{M}_W$ is $r + q$.
- (e) $\hat{\boldsymbol{\gamma}} = \mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\mathbf{Y}$ has covariance $\sigma^2\mathbf{E}_{zz}^{-1}\tilde{\mathbf{Z}}^\top\tilde{\mathbf{Z}}\mathbf{E}_{zz}^{-1} = \sigma^2\mathbf{E}_{zz}^{-1}$. The estimate of $\boldsymbol{\lambda}^\top\boldsymbol{\beta}$ is $\mathbf{a}^\top\mathbf{Y}$, and $\mathbf{M}\boldsymbol{\rho}$ is orthogonal to $\tilde{\mathbf{Z}}$. So $\text{Var}(\mathbf{a}^\top\mathbf{Y}) = \sigma^2\|\mathbf{a}\|^2$ is the sum of the two squared lengths in Eq. 18.1.6, and $\text{Cov}(\mathbf{a}^\top\mathbf{Y}, \hat{\boldsymbol{\gamma}}) = \sigma^2\mathbf{a}^\top\tilde{\mathbf{Z}}\mathbf{E}_{zz}^{-1} = -\sigma^2\boldsymbol{\rho}^\top\mathbf{M}\mathbf{Z}\mathbf{E}_{zz}^{-1}$.
- (f) If $(\mathbf{I} - \mathbf{M}_0)\mathbf{Z}\mathbf{c} = \mathbf{0}$, then $\mathbf{Z}\mathbf{c} \in \mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$, so $(\mathbf{I} - \mathbf{M})\mathbf{Z}\mathbf{c} = \mathbf{0}$ and $\mathbf{c} = \mathbf{0}$. So Eq. 18.1.3 holds for $\mathbf{X}_0$, and (d) applied to $[\mathbf{X}_0, \mathbf{Z}]$ gives the first bracket in Eq. 18.1.7 as the residual sum of squares of the reduced model. The rank of the reduced model is $r_0 + q$, and $\mathcal{C}([\mathbf{X}_0, \mathbf{Z}]) \subseteq \mathcal{C}([\mathbf{X}, \mathbf{Z}])$. The distribution is Theorem 11.1.1. ■

The proof is the Frisch–Waugh–Lovell theorem (Theorem 6.6.2) with the covariates as the residualized columns, stated through $\mathbf{M}$ so that the design part may be rank deficient.

Idea. Analysis of covariance is two ordinary analyses joined by one projection. The within-group regression of $\mathbf{y}$ on the covariates gives $\hat{\boldsymbol{\gamma}}$, and the analysis of variance of the adjusted response $\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}$ gives the treatment estimates. Their variances Eq. 18.1.6 carry an extra term for the uncertainty in $\hat{\boldsymbol{\gamma}}$. Tests must compare models, as in Eq. 18.1.7: the between-groups sum of squares of the adjusted response is not the numerator of any F statistic, because the reduced model must be allowed to re-estimate $\boldsymbol{\gamma}$.

18.1.3 The one-way layout with one covariate

For a single factor with g levels and a single covariate x , the matrices of Eq. 18.1.2 are scalars:

$$E_{xx} = \sum_k \sum_{i \in k} (x_i - \bar{x}_k)^2, \quad E_{xy} = \sum_k \sum_{i \in k} (x_i - \bar{x}_k)(y_i - \bar{y}_k),$$

and E_{yy} is the within-groups sum of squares of y . With $\mathbf{X}_0 = \mathbf{1}$, the T quantities are the same sums around the grand means. Theorem 18.1.1 gives:

- (i) slope $\hat{\beta} = E_{xy}/E_{xx}$;
- (ii) $\text{SSE} = E_{yy} - E_{xy}^2/E_{xx}$ on $n - g - 1$ degrees of freedom;
- (iii) adjusted treatment sum of squares $\text{SS}_{\text{trt}} = (T_{yy} - T_{xy}^2/T_{xx}) - (E_{yy} - E_{xy}^2/E_{xx})$ on $g - 1$ degrees of freedom;
- (iv) level means adjusted to a common covariate value, $\bar{y}_k - \hat{\beta}(\bar{x}_k - x_0)$, which differ by $(\bar{y}_k - \bar{y}_l) - \hat{\beta}(\bar{x}_k - \bar{x}_l)$, as in Proposition 8.6.3;
- (v) the test of $\beta = 0$, with sum of squares E_{xy}^2/E_{xx} on one degree of freedom (Corollary 9.2.3).

Example. (Four study formats with a pretest)

In a synthetic randomized experiment, $n = 40$ students are assigned at random, ten to each of four study formats for an introductory statistics unit. A pretest score x is recorded before the assignment, and the response y is the score on the final examination. The data were generated from a parallel lines model. Randomization balanced the pretest only on average: the four groups have pretest means 62.1, 57.2, 59.9 and 60.5, and final means 72.86, 75.15, 69.09 and 78.09. Figure 18.1.1 shows the data, and the sums of squares and products are:

	xx	xy	yy	df
between formats	124.9	-31.4	432.94	3
within formats	3643.9	3159.2	4146.41	36
total	3768.8	3127.8	4579.35	39

Without the covariate, the one-way analysis has error mean square $4146.41/36 = 115.2$ and treatment $F = 1.25$ on 3 and 36 degrees of freedom ($p = 0.305$). There is no evidence that the formats differ.

With the covariate, the within-groups slope is $\hat{\beta} = 3159.2/3643.9 = 0.8670$ points on the final per point on the pretest. The residual sum of squares falls to

$$\text{SSE} = 4146.41 - 2738.94 = 1407.47$$

on 35 degrees of freedom, so the error mean square falls from 115.2 to 40.2. The residual standard deviation falls from 10.73 to 6.34. The reduced model, one line for all forty students, has residual sum of squares $4579.35 - 2595.83 = 1983.52$. The adjusted treatment sum of squares is therefore $1983.52 - 1407.47 = 576.05$, and

$$F = \frac{576.05/3}{1407.47/35} = 4.77$$

on 3 and 35 degrees of freedom, with $p = 0.0068$: clear differences between the formats. The test of $\beta = 0$ has $F = 68.1$. The adjusted treatment sum of squares, 576.05, is even *larger* than the unadjusted 432.94: format 2 had the weakest students on entry and still finished second, and adjustment gives it credit for that.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(84)
g, m = 4, 10                                # four formats, ten students
    each
n = g * m
group = rng.permutation(np.repeat(np.arange(g), m)) # the randomization
x = np.round(rng.normal(60, 10, n))             # pretest, measured before
    assignment
mu_true = np.array([70.0, 74.0, 71.0, 77.0])
y = np.round(mu_true[group] + 0.8 * (x - 60) + rng.normal(0, 6, n), 1)

Z = np.eye(g)[group]                         # indicator matrix of the
    formats
n_k = Z.sum(axis=0)
```

Figure 18.1.1: The tutoring experiment: final score against pretest score for the four formats, with the fitted parallel lines of the covariance model. Open symbols mark the raw group means $(\bar{x}_k, \bar{y}_k)$, and filled symbols on the dotted vertical line mark the adjusted means at the overall pretest mean $\bar{x}$. The lines of formats 2 (dashed, drawn on top) and 4 almost coincide.

```
x_bar, y_bar = Z.T @ x / n_k, Z.T @ y / n_k           # group means

def within(v):
    """(I - M) v: deviations from the group means (M projects onto C(Z))."""
    return v - (Z.T @ v / n_k)[group]

E_xx, E_xy, E_yy = within(x) @ within(x), within(x) @ within(y), within(y) @ within(
    y)
beta = E_xy / E_xx                                   # slope from within-group
            variation only
sse = E_yy - E_xy ** 2 / E_xx                        # ANCOVA residual sum of
            squares
nu = n - g - 1

T_xx = np.sum((x - x.mean()) ** 2)                   # the same with I - MO, MO =
            mean only

            squares
F_adj = (ss_trt / (g - 1)) / (sse / nu)
F_unadj = ((T_yy - E_yy) / (g - 1)) / (E_yy / (n - g))
print(f"slope {beta:.4f}; SSE: ANOVA {E_yy:.2f} on {n - g} df, ANCOVA {sse:.2f} on
      {nu} df")
print(f"treatments: unadjusted F = {F_unadj:.2f} (p = {stats.f.sf(F_unadj, g - 1, n
      - g):.3f}),"
      f" adjusted F = {F_adj:.2f} (p = {stats.f.sf(F_adj, g - 1, nu):.4f})")
```

18.1.4 What a covariate does in a randomized experiment

In a randomized experiment the groups differ on the covariate only by chance. Adjustment still helps, for two reasons.

Precision. The error variance of the covariance model is the variance of y given x , which is smaller whenever the two are correlated. The price is the estimated slope, which adds the second term in [Eq. 18.1.6](#). The next result balances gain against price when the covariate is random, as it is in practice.

Proposition 18.1.2 — The precision of adjustment

Consider a one-way layout with g groups of m units, $N = gm$. Suppose the covariate is measured before randomization, so that the x_i are independent $N(\xi, \tau^2)$ whatever their group, and that given all the x 's the y_i are independent and normal, with $E(y_i | x_i) = \mu_k + \beta x_i$ for unit i in group k and $\text{Var}(y_i | x_i) = \sigma^2$. Let ρ be the within-group correlation of x and y . For two groups $k \neq l$, the unadjusted estimate $\bar{y}_k - \bar{y}_l$ and the adjusted estimate $(\bar{y}_k - \bar{y}_l) - \hat{\beta}(\bar{x}_k - \bar{x}_l)$ are both unbiased for $\mu_k - \mu_l$. If $N - g > 2$,

$$\frac{\text{Var}(\text{adjusted})}{\text{Var}(\text{unadjusted})} = (1 - \rho^2) \left(1 + \frac{1}{N - g - 2} \right). \quad (18.1.8)$$

Proof. Write $\bar{y}_k = \mu_k + \beta \bar{x}_k + \bar{\varepsilon}_k$, where $\varepsilon_i = y_i - \mu_k - \beta x_i$ has mean zero and variance σ^2 and is independent of all the x 's. Unconditionally $\bar{y}_k - \bar{y}_l$ has mean $\mu_k - \mu_l$, because $E \bar{x}_k = E \bar{x}_l$, and variance $(2/m)(\beta^2 \tau^2 + \sigma^2)$. The within-group variance of y is $\beta^2 \tau^2 + \sigma^2$, and $\sigma^2 = (1 - \rho^2)(\beta^2 \tau^2 + \sigma^2)$.

Given all the x 's, the covariance model holds with fixed covariates. By [Theorem 18.1.1\(e\)](#), with $\mathbf{p}$ the difference of the two scaled group indicators (so $\mathbf{M}\mathbf{p} = \mathbf{p}$ and $\mathbf{p}^\top \mathbf{Z} = \bar{x}_k - \bar{x}_l$), the adjusted estimate is conditionally unbiased with conditional variance $\sigma^2 \{2/m + (\bar{x}_k - \bar{x}_l)^2 / E_{xx}\}$. Its unconditional mean is therefore $\mu_k - \mu_l$, and its unconditional variance is the mean of the conditional variance. The group means of x are independent of the within-group sum of squares E_{xx} ([Corollary 4.4.5](#), applied group by group), with $\bar{x}_k - \bar{x}_l \sim N(0, 2\tau^2/m)$ and $E_{xx}/\tau^2 \sim \chi^2(N - g)$. For $V \sim \chi^2(\nu)$ with $\nu > 2$, $E(1/V) = 1/(\nu - 2)$ ([Exercise \(B1\)](#)). Hence

$$E \frac{(\bar{x}_k - \bar{x}_l)^2}{E_{xx}} = \frac{2\tau^2}{m} \cdot \frac{1}{\tau^2(N - g - 2)}, \quad \text{Var}(\text{adjusted}) = \frac{2\sigma^2}{m} \left(1 + \frac{1}{N - g - 2} \right).$$

Dividing by the unadjusted variance gives [Eq. 18.1.8](#). ■

The factor $1 - \rho^2$ is what adjustment would achieve if the slope were known. The factor $1 + 1/(N - g - 2)$ is the cost of estimating it. For the design of [Example \(Four study formats with a pretest\)](#) the cost is 1.0294. Adjustment pays whenever $\rho^2 > 1/(N - g - 1)$, that is, when $|\rho|$ exceeds 0.169. At $\rho = 0.8$, the correlation used to generate the tutoring data, the adjusted comparison has 0.371 of the variance of the unadjusted one (simulation: 0.372; [Figure 18.1.2](#)). Without the covariate the experiment would need almost three times as many students.

Figure 18.1.2: Variance of the adjusted difference of two group means relative to the unadjusted difference, for four groups of ten, as a function of the within-group correlation between covariate and response. The curve is Eq. 18.1.8, and the points are simulated from 100000 experiments each. The dashed curve is the ratio when the slope is known.

Chance imbalance. Randomization makes $\bar{y}_k - \bar{y}_l$ unbiased *over repetitions of the experiment*. In the experiment actually run, the proof above shows that, given the covariates,

$$E(\bar{y}_k - \bar{y}_l \mid x\text{'s}) = \mu_k - \mu_l + \beta(\bar{x}_k - \bar{x}_l),$$

which is *not* $\mu_k - \mu_l$ unless the covariate means agree. Once the pretests are known, the raw difference has an error of predictable sign. In [Example \(Four study formats with a pretest\)](#), format 1 started 4.9 points ahead of format 2 on the pretest, which predicts $0.8670 \times 4.9 \approx 4.25$ points of the final difference. The raw difference between formats 1 and 2 is -2.29 , and the conditionally unbiased adjusted difference is $-2.29 - 4.25 = -6.54$.

All this assumes the covariate was chosen in advance. Choosing, after seeing the data, the covariates that make the effect look best is a form of multiple testing, which is why trial protocols name their covariates beforehand.

Remark (Random covariates). The theorem ([Theorem 18.1.1](#)) treats $\mathbf{Z}$ as fixed. If, given random covariates, the model holds with normal errors, every F test and t interval of the theorem keeps its level unconditionally ([Theorem 14.1.2](#), applied after reparameterizing the design part to full rank, which changes neither the tests nor the estimable functions). Only the power depends on the covariate values that occur.

18.1.5 Adjusting for a covariate that the treatment affects

Warning. A covariate must not be affected by the treatment. If it is measured after assignment and the treatment changes it, adjusting for it removes the part of the treatment effect that acts through the covariate, and the adjusted comparison no longer estimates the effect of assigning the treatment.

If hours of study were used as a covariate, a format that works *by* getting students to study more would be compared with the others at equal hours of study, which removes the very thing

it does. In a synthetic randomized experiment with two arms of 100, let the treatment raise a post-assignment variable w by 2 units and let $E(y) = \theta T + 0.75w$ with direct effect $\theta = 1$. The effect of assigning the treatment is $1 + 0.75 \times 2 = 2.50$. Over 20000 replications, the unadjusted difference of means averages 2.500, and the coefficient of the treatment after adjustment for w averages 1.000, the direct effect, which is not what a decision about the treatment needs.

```
import numpy as np

rng = np.random.default_rng(2025)
n, reps = 200, 20_000
theta, delta, gamma = 1.0, 2.0, 0.75          # direct effect; T -> w; w ->
y                                              # effect of assigning
total = theta + gamma * delta
treatment
est_unadj, est_adj = np.empty(reps), np.empty(reps)
for r in range(reps):
    T = rng.permutation(np.repeat([0.0, 1.0], n // 2)) # randomized assignment
    w = rng.normal(size=n) + delta * T                 # measured after treatment
    y = theta * T + gamma * w + rng.normal(size=n)
    X = np.column_stack([np.ones(n), T, w])
    est_unadj[r] = y[T == 1].mean() - y[T == 0].mean()
    est_adj[r] = np.linalg.lstsq(X, y, rcond=None)[0][1]
print(f"total effect {total:.2f}: unadjusted mean {est_unadj.mean():.3f}, "
      f" adjusted for w mean {est_adj.mean():.3f}")
```

Chapter 25 develops the language for this in observational data: mediators, on the causal path from treatment to response, must not be adjusted for when the total effect is wanted. In a randomized experiment the safe rule is simple: *adjust only for variables fixed before randomization*. By Proposition 18.1.2 this costs little even when the covariate turns out to be useless. A test of whether the groups are “balanced” on such a covariate is pointless, since its null hypothesis is true by construction. What matters is whether the covariate predicts the response.

18.1.6 Exercises

18.1.6.1 A. Check your understanding

Exercise A1.

In the one-way layout with one covariate, suppose x is constant within each group. Show that Eq. 18.1.3 fails, and describe the set of least squares estimates of β . Is the adjusted difference of two group means estimable?

Solution. If $x_i = c_k$ for every unit in group k , then $\mathbf{x}$ is a combination of the group indicators, so $\mathbf{x} \in \mathcal{C}(\mathbf{X})$, $(\mathbf{I} - \mathbf{M})\mathbf{x} = \mathbf{0}$, and Eq. 18.1.3 fails. The mean of group k is $\theta_k = \mu_k + \beta c_k$, and only the θ_k are estimable. Every value of β belongs to some least squares estimate: for any b , the group parameters $\bar{y}_k - bc_k$ together with b reproduce the fitted group means. The adjusted difference $\mu_k - \mu_l = (\theta_k - \theta_l) - \beta(c_k - c_l)$ is therefore estimable iff $c_k = c_l$. The data cannot separate a covariate that varies only between groups from the group effects.

Exercise A2.

From the numbers in [Example \(Four study formats with a pretest\)](#), compute the F statistic for $\beta = 0$ and check that its square root is the t statistic $\hat{\beta}/(s/\sqrt{E_{xx}})$.

18.1.6.2 B. Practice**Exercise B1.**

Let $V \sim \chi^2(\nu)$ with $\nu > 2$. Show that $E(1/V) = 1/(\nu - 2)$, and that $E(1/V) = \infty$ for $\nu \leq 2$.

Solution. The density of V is $f_\nu(v) = v^{\nu/2-1}e^{-v/2}/\{2^{\nu/2}\Gamma(\nu/2)\}$. Then

$$E(1/V) = \int_0^\infty \frac{v^{\nu/2-2}e^{-v/2}}{2^{\nu/2}\Gamma(\nu/2)} dv = \frac{2^{\nu/2-1}\Gamma(\nu/2-1)}{2^{\nu/2}\Gamma(\nu/2)} = \frac{1}{2(\nu/2-1)} = \frac{1}{\nu-2},$$

using $\Gamma(s+1) = s\Gamma(s)$. The integral converges at 0 iff $\nu/2 - 2 > -1$, that is, iff $\nu > 2$.

Exercise B2.

In the one-way layout with one covariate, write $B_{xx} = T_{xx} - E_{xx}$, and similarly B_{xy} and B_{yy} , for the between-groups sums of squares and products. Show that the adjusted treatment sum of squares equals

$$B_{yy} - \left(\frac{T_{xy}^2}{T_{xx}} - \frac{E_{xy}^2}{E_{xx}} \right),$$

and deduce that it exceeds B_{yy} iff $E_{xy}^2/E_{xx} > T_{xy}^2/T_{xx}$. Show that this happens in [Example \(Four study formats with a pretest\)](#), and explain it in terms of B_{xy} .

Solution. The formula is [Eq. 18.1.7](#) with $T_{yy} - E_{yy} = B_{yy}$. In the example $E_{xy}^2/E_{xx} = 2738.94$ and $T_{xy}^2/T_{xx} = 2595.83$, so the adjusted sum of squares is larger, by 143.11. The total regression uses both the within-group and the between-group variation of x . Here the between-group cross-product $B_{xy} = -31.4$ is negative: across the four formats, higher pretest means go with *lower* final means, the opposite of the within-group relationship. The single line for all students therefore explains less than the within-group lines do, and the difference is attributed to the formats.

Exercise B3.

In the one-way layout with q covariates, use [Eq. 18.1.6](#) to show that the adjusted difference $(\bar{y}_k - \bar{y}_l) - (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}_l)^\top \hat{\boldsymbol{\gamma}}$ has variance $\sigma^2\{1/n_k + 1/n_l + (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}_l)^\top \mathbf{E}_{zz}^{-1}(\bar{\mathbf{z}}_k - \bar{\mathbf{z}}_l)\}$.

18.1.6.3 C. Going deeper**Exercise C1.**

In the one-way covariance model, show that replacing x by $a + cx$ with $c \neq 0$ leaves the

fitted values, SSE, the adjusted treatment sum of squares and the adjusted differences unchanged. Then replace x by $x + d_k$ on group k , with group-specific constants d_k . Show that $\hat{\beta}$ and SSE are unchanged but the adjusted differences and the adjusted treatment sum of squares change. Explain why a covariate recorded with a group-specific calibration error is dangerous.

18.2 Adjusted treatment means

A covariance analysis is usually reported as a table of treatment means “adjusted” for the covariate. The raw mean $\bar{y}_k$ estimates the mean response of treatment k at whatever covariate values its units happened to have; the adjusted mean estimates it at a covariate value common to all treatments. This section defines adjusted means, gives their standard errors, and shows how to compare them.

18.2.1 Definition

Take the one-way covariance model with g groups of sizes $n_1, \dots, n_g$ and q covariates,

$$E(y_i) = \mu_k + \mathbf{z}_{(i)}^\top \boldsymbol{\gamma} \quad \text{for unit } i \text{ in group } k, \quad (18.2.1)$$

where $\mathbf{z}_{(i)} \in \mathbb{R}^q$ is the covariate vector of unit i , and write $\bar{\mathbf{z}}_k$ for the mean covariate vector of group k and $\bar{\mathbf{z}}$ for the overall mean. We assume [Eq. 18.1.3](#), and write $\mathbf{E}_{zz}$ and $\hat{\boldsymbol{\gamma}}$ as in [Theorem 18.1.1](#).

Definition 18.2.1 — Adjusted treatment means

For a fixed covariate vector $\mathbf{z}_0 \in \mathbb{R}^q$, the **adjusted mean** of treatment k at $\mathbf{z}_0$ is $\mu_k + \mathbf{z}_0^\top \boldsymbol{\gamma}$, the mean response of a unit with covariate $\mathbf{z}_0$ under treatment k . Its estimate is

$$\hat{\mu}_k(\mathbf{z}_0) = \bar{y}_k - (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \hat{\boldsymbol{\gamma}}. \quad (18.2.2)$$

When no value is named, $\mathbf{z}_0 = \bar{\mathbf{z}}$, the overall mean of the covariates, and $\hat{\mu}_k(\bar{\mathbf{z}})$ is called simply the adjusted mean of treatment k .

The fitted line (or plane) of treatment k passes through $(\bar{\mathbf{z}}_k, \bar{y}_k)$ with slope $\hat{\boldsymbol{\gamma}}$; the adjusted mean is its height at $\mathbf{z}_0$. In [Figure 18.1.1](#) the filled symbols on the dashed line are the adjusted means.

The adjusted mean is estimable: $\mu_k + \mathbf{z}_0^\top \boldsymbol{\gamma}$ is the sum of $\mu_k + \bar{\mathbf{z}}_k^\top \boldsymbol{\gamma}$, the mean of the fitted values of group k , and $(\mathbf{z}_0 - \bar{\mathbf{z}}_k)^\top \boldsymbol{\gamma}$, a multiple of the estimable $\boldsymbol{\gamma}$ ([Theorem 18.1.1\(b\)](#)). By [Theorem 18.1.1\(c\)](#) with $\boldsymbol{\rho}$ the scaled indicator of group k , the least squares estimate of μ_k is $\bar{y}_k - \bar{\mathbf{z}}_k^\top \hat{\boldsymbol{\gamma}}$, which gives [Eq. 18.2.2](#).

18.2.2 Standard errors

Proposition 18.2.1 — Moments of adjusted means

In the model Eq. 18.2.1 with $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, and for a fixed $\mathbf{z}_0$:

- (a) $\bar{y}_1, \dots, \bar{y}_g$ are uncorrelated with $\hat{\gamma}$, and

$$\text{Var}(\hat{\mu}_k(\mathbf{z}_0)) = \sigma^2 \left(\frac{1}{n_k} + (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \mathbf{E}_{zz}^{-1} (\bar{\mathbf{z}}_k - \mathbf{z}_0) \right); \quad (18.2.3)$$

- (b) for $k \neq l$, $\text{Cov}(\hat{\mu}_k(\mathbf{z}_0), \hat{\mu}_l(\mathbf{z}_0)) = \sigma^2 (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \mathbf{E}_{zz}^{-1} (\bar{\mathbf{z}}_l - \mathbf{z}_0)$;

- (c) for a contrast $\psi = \sum_k c_k \mu_k$, the estimate $\hat{\psi} = \sum_k c_k \hat{\mu}_k(\mathbf{z}_0) = \sum_k c_k \bar{y}_k - \bar{\mathbf{z}}_c^\top \hat{\gamma}$, with $\bar{\mathbf{z}}_c = \sum_k c_k \bar{\mathbf{z}}_k$, does not depend on $\mathbf{z}_0$, and

$$\text{Var}(\hat{\psi}) = \sigma^2 \left(\sum_k \frac{c_k^2}{n_k} + \bar{\mathbf{z}}_c^\top \mathbf{E}_{zz}^{-1} \bar{\mathbf{z}}_c \right); \quad (18.2.4)$$

- (d) with $\mathbf{z}_0 = \bar{\mathbf{z}}$, the weighted average of the adjusted means is the grand mean: $\sum_k n_k \hat{\mu}_k(\bar{\mathbf{z}}) = \sum_i y_i$.

Proof. Let $\mathbf{M}$ project onto the span of the group indicators. The group mean $\bar{y}_k$ is $\mathbf{u}_k^\top \mathbf{Y}$ with $\mathbf{u}_k$ the indicator of group k divided by n_k , a vector in $\mathcal{C}(\mathbf{M})$. The estimate $\hat{\gamma} = \mathbf{E}_{zz}^{-1} \mathbf{Z}^\top (\mathbf{I} - \mathbf{M}) \mathbf{Y}$ is a linear function of $(\mathbf{I} - \mathbf{M}) \mathbf{Y}$. Hence $\text{Cov}(\bar{y}_k, \hat{\gamma}) = \sigma^2 \mathbf{u}_k^\top (\mathbf{I} - \mathbf{M}) \mathbf{Z} \mathbf{E}_{zz}^{-1} = \mathbf{0}$, since $(\mathbf{I} - \mathbf{M}) \mathbf{u}_k = \mathbf{0}$. Then (a) and (b) follow from $\text{Var}(\bar{y}_k) = \sigma^2/n_k$, $\text{Cov}(\bar{y}_k, \bar{y}_l) = 0$ and $\text{Cov}(\hat{\gamma}) = \sigma^2 \mathbf{E}_{zz}^{-1}$ (Theorem 18.1.1(e)). For (c), $\sum_k c_k = 0$ removes $\mathbf{z}_0$, and the variance follows in the same way. For (d), $\sum_k n_k \hat{\mu}_k(\bar{\mathbf{z}}) = \sum_k n_k \bar{y}_k - (\sum_k n_k \bar{\mathbf{z}}_k - n \bar{\mathbf{z}})^\top \hat{\gamma}$, and the bracket is zero. ■

Adjusted means are correlated, because their errors share $\hat{\gamma}$. Their variances grow with the distance of $\bar{\mathbf{z}}_k$ from $\mathbf{z}_0$: an adjusted mean is a prediction from the treatment's line, and for a group whose covariate values barely overlap the others' it rests on extrapolation, as in Section 12.3. Differences do not depend on $\mathbf{z}_0$; only the common level and the individual standard errors do. The overall mean $\bar{\mathbf{z}}$ keeps the adjusted means on the scale of the data (d) and minimizes $\sum_k n_k \text{Var}(\hat{\mu}_k(\mathbf{z}_0))$ (Exercise B1), but any stated value, such as a clinically meaningful baseline, is legitimate.

18.2.3 Comparing adjusted means

Pairwise differences are contrasts, so Eq. 18.2.4 gives

$$\text{se}(\hat{\mu}_k - \hat{\mu}_l) = s \sqrt{\frac{1}{n_k} + \frac{1}{n_l} + (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}_l)^\top \mathbf{E}_{zz}^{-1} (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}_l)}, \quad s^2 = \frac{\text{SSE}}{n - g - q}, \quad (18.2.5)$$

and a single comparison uses the t interval of Theorem 12.1.1 with $n - g - q$ degrees of freedom. For simultaneous comparisons the correlations matter.

- (i) *Scheffé*. The adjusted treatment F test of Theorem 18.1.1(f) is a test of $\mu_1 = \dots = \mu_g$, a $(g - 1)$ -dimensional space of estimable contrasts. By Theorem 13.2.2, the intervals

- $\hat{\psi} \pm \sqrt{(g-1)F_\alpha(g-1, n-g-q)} \text{se}(\hat{\psi})$ have simultaneous coverage exactly $1 - \alpha$ over *all* contrasts ψ . Some interval excludes zero iff the adjusted F test rejects ([Corollary 13.2.3](#)).
- (ii) *Bonferroni*. For a planned list of m comparisons, t intervals at level α/m have coverage at least $1 - \alpha$ whatever the correlations ([Theorem 13.4.1](#)).
 - (iii) *Tukey-type intervals*. The half-width $(q_\alpha(g, n-g-q)/\sqrt{2}) \text{se}(\hat{\mu}_k - \hat{\mu}_l)$ copies the Tukey–Kramer rule [Eq. 13.3.3](#). It is exact when the covariate means are equal and the groups balanced ([Exercise \(C1\)](#)). Otherwise its coverage is only approximately $1 - \alpha$: Hayter’s theorem covers unequal group sizes in the one-way layout, but not the correlations that the covariate introduces. When the covariate means are close, as they usually are after randomization, the departure is small ([Exercise \(C2\)](#) asks you to measure it). When they are far apart, use Scheffé’s intervals, or compute the exact multiplier for the given correlation matrix by simulation, as [Section 13.3](#) did for Tukey–Kramer.

Example. (Adjusted means for the four formats)

In [Example \(Four study formats with a pretest\)](#), the overall pretest mean is $\bar{x} = 59.92$. Format 2 had pretest mean 57.2, so its adjusted mean is

$$75.15 - 0.8670(57.2 - 59.92) = 75.15 + 2.36 = 77.51.$$

The four adjusted means are 70.97, 77.51, 69.11 and 77.59, averaging to the grand mean 73.80, with standard errors 2.02, 2.03, 2.01 and 2.01. These barely differ, because the pretest means are close to $\bar{x}$ compared with the within-group standard deviation of the pretest, 10.06.

The six pairwise comparisons, with $s = 6.34$ on 35 degrees of freedom, are as follows. The Tukey-type multiplier is $q_{0.05}(4, 35)/\sqrt{2} = 2.697$, and Scheffé’s is $\sqrt{3F_{0.05}(3, 35)} = 2.936$.

formats	raw difference	adjusted difference	se	Tukey-type half-width	Scheffé half-width
1 2	−2.29	−6.54	2.88	7.77	8.46
1 3	3.77	1.86	2.85	7.67	8.36
1 4	−5.23	−6.62	2.84	7.66	8.34
2 3	6.06	8.40	2.85	7.69	8.37
2 4	−2.94	−0.08	2.86	7.71	8.39
3 4	−9.00	−8.48	2.84	7.65	8.33

Both methods declare formats 2 and 4 better than format 3 and resolve nothing else, although the 2 3 comparison clears Scheffé’s bound by only 0.03. Without the covariate the standard error of a difference would be $10.73\sqrt{2/10} = 4.80$. The raw difference between formats 3 and 4, −9.00, would then have had a Tukey half-width near 13, and nothing would have been resolved.

Adjustment moved comparisons in both directions: format 2’s advantage over format 1 grew from 2.29 to 6.54, while format 4’s lead over format 3 shrank from 9.00 to 8.48.

```

18.2.4 Adjusted means in other designs

For any design part, the adjusted version at $\mathbf{z}_0$ of an estimable $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$, such as a treatment mean averaged over blocks, is $\boldsymbol{\lambda}^\top \boldsymbol{\beta} + \mathbf{z}_0^\top \boldsymbol{\gamma}$, estimated by $\boldsymbol{\rho}^\top \mathbf{M}(\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}) + \mathbf{z}_0^\top \hat{\boldsymbol{\gamma}}$ with variance from [Theorem 18.1.1\(e\)](#). Software calls these **least squares means**. In unbalanced multi-way data the choice of $\boldsymbol{\lambda}$, equal or count-proportional weights over cells, matters as much as $\mathbf{z}_0$ ([Chapter 17](#), [Theorem 17.2.2](#)); it is safest to write the intended function of the cell means ([Definition 17.1.1](#)) explicitly.

Remark (The adjusted mean is not a prediction interval). The standard error [Eq. 18.2.3](#) describes the uncertainty about the *mean* response of treatment k at $\mathbf{z}_0$. A new unit

with covariate $\mathbf{z}_0$ given treatment k will vary around that mean with variance σ^2 as well. Its prediction interval uses $s\sqrt{1 + 1/n_k + (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \mathbf{E}_{zz}^{-1}(\bar{\mathbf{z}}_k - \mathbf{z}_0)}$, as in [Theorem 12.3.1](#).

18.2.5 Exercises

18.2.5.1 A. Check your understanding

Exercise A1.

From the numbers in [Example \(Four study formats with a pretest\)](#), compute the adjusted means of formats 1 and 3 by hand and check them against the values in [Example \(Adjusted means for the four formats\)](#).

Exercise A2.

Software that fits the model $E(y) = \mu_k + \beta x$ reports $\hat{\mu}_k$, the adjusted mean at $x_0 = 0$. For a pretest scored from 0 to 100, what does this number describe? Show that its standard error can be far larger than that of the adjusted mean at $\bar{x}$, although both give the same differences.

18.2.5.2 B. Practice

Exercise B1.

Show that $\sum_k n_k \text{Var}(\hat{\mu}_k(\mathbf{z}_0))$ is minimized over $\mathbf{z}_0$ by $\mathbf{z}_0 = \bar{\mathbf{z}}$.

Solution. By [Eq. 18.2.3](#), the sum is $\sigma^2(g + \sum_k n_k (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \mathbf{E}_{zz}^{-1}(\bar{\mathbf{z}}_k - \mathbf{z}_0))$. Writing $\bar{\mathbf{z}}_k - \mathbf{z}_0 = (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}) + (\bar{\mathbf{z}} - \mathbf{z}_0)$ and using $\sum_k n_k (\bar{\mathbf{z}}_k - \bar{\mathbf{z}}) = \mathbf{0}$, the cross terms vanish and the sum becomes

$$\sigma^2 \left(g + \sum_k n_k (\bar{\mathbf{z}}_k - \bar{\mathbf{z}})^\top \mathbf{E}_{zz}^{-1}(\bar{\mathbf{z}}_k - \bar{\mathbf{z}}) + n(\bar{\mathbf{z}} - \mathbf{z}_0)^\top \mathbf{E}_{zz}^{-1}(\bar{\mathbf{z}} - \mathbf{z}_0) \right).$$

The last term is nonnegative, and zero iff $\mathbf{z}_0 = \bar{\mathbf{z}}$, because $\mathbf{E}_{zz}$ is positive definite.

Exercise B2.

A common alternative to covariance adjustment analyses the *change* $y - x$. Show that this is the covariance model with β fixed at 1. Using [Proposition 18.1.2](#)'s setting with τ^2 the variance of x , find the variance of the difference of mean changes between two groups, and show that it exceeds the variance of the adjusted difference (ignoring the $1/(N - g - 2)$ term) unless $\beta = 1$.

Solution. The mean change in group k is $\bar{y}_k - \bar{x}_k = \mu_k + (\beta - 1)\bar{x}_k + \bar{\varepsilon}_k$. The difference of two groups has variance $(2/m)\{(\beta - 1)^2\tau^2 + \sigma^2\}$. The adjusted difference, with the slope known, has variance $2\sigma^2/m$. The change-score analysis is therefore worse by $(2/m)(\beta - 1)^2\tau^2$, which is zero only when $\beta = 1$. It beats the unadjusted analysis, which

has $(\beta - 1)^2$ replaced by β^2 , only if $\beta > 1/2$. Covariance adjustment estimates the slope rather than assuming one.

18.2.5.3 C. Going deeper

Exercise C1.

Suppose all groups have size m and the covariate means $\bar{\mathbf{z}}_1, \dots, \bar{\mathbf{z}}_g$ are equal. Show that the adjusted differences $\hat{\mu}_k - \hat{\mu}_l$ are the raw differences $\bar{y}_k - \bar{y}_l$, that these are independent of s^2 from the covariance model, and that the Tukey intervals built from s and $q_\alpha(g, n - g - q)$ have simultaneous coverage exactly $1 - \alpha$.

Solution. With equal covariate means, $\bar{\mathbf{z}}_c = \sum_k c_k \bar{\mathbf{z}}_k = \mathbf{0}$ for every contrast, so the adjusted contrast equals the raw one and has variance $\sigma^2 \sum_k c_k^2 / m$ by Eq. 18.2.4. The group means are functions of $\mathbf{M}\mathbf{Y}$. The residual vector $(\mathbf{I} - \mathbf{M}_W)\mathbf{Y}$ is orthogonal to $\mathcal{C}(\mathbf{M}_W) \supseteq \mathcal{C}(\mathbf{M})$, so under normality s^2 is independent of $\bar{y}_1, \dots, \bar{y}_g$ (Theorem 4.4.4), and $(n - g - q)s^2/\sigma^2 \sim \chi^2(n - g - q)$. The means are independent normal with common variance σ^2/m . The maximum of $|(\bar{y}_k - \bar{y}_l) - (\mu_k - \mu_l)|/(s/\sqrt{m})$ therefore has the studentized range distribution with parameters g and $n - g - q$, and the proof of Theorem 13.3.2 applies unchanged.

Exercise C2.

For four groups of ten and one covariate, simulate the simultaneous coverage of the Tukey-type intervals of Example (Adjusted means for the four formats) when the covariate means are held at (62, 57, 60, 61) and when they are held at (70, 50, 60, 60), with the within-group covariate variation as in the example. How far from 0.95 is the coverage in each case?

18.3 Heterogeneous slopes

The covariance model of Section 18.1 assumes a common slope, so each treatment comparison is a vertical shift between parallel lines, one number. If the slopes differ, the treatment effect depends on the covariate, and “the” adjusted difference no longer exists. This section tests parallelism and says what to report when it fails.

18.3.1 The separate lines model and the test of parallelism

Keep one factor with g levels and one covariate, and allow each level its own line:

$$E(y_i) = \mu_k + \beta_k x_i \quad \text{for unit } i \text{ in group } k.$$

This is the separate lines model Eq. 8.6.4 of Section 8.6. The parallel lines model is the special case $\beta_1 = \dots = \beta_g$. For group k write

$$E_{xx,k} = \sum_{i \in k} (x_i - \bar{x}_k)^2, \quad E_{xy,k} = \sum_{i \in k} (x_i - \bar{x}_k)(y_i - \bar{y}_k),$$

so that the pooled within-group quantities of Section 18.1 are $E_{xx} = \sum_k E_{xx,k}$ and $E_{xy} = \sum_k E_{xy,k}$.

Theorem 18.3.1 — The test of parallel slopes

Assume x varies within every group, so that every $E_{xx,k} > 0$, and $n > 2g$.

- (a) In the separate lines model, $\hat{\beta}_k = E_{xy,k}/E_{xx,k}$, these estimates are uncorrelated with variances $\sigma^2/E_{xx,k}$, and the residual sum of squares is

$$\text{SSE}_{\text{sep}} = \sum_k \left(E_{yy,k} - \frac{E_{xy,k}^2}{E_{xx,k}} \right)$$

on $n - 2g$ degrees of freedom.

- (b) The pooled slope of the parallel lines model is the weighted mean $\hat{\beta} = \sum_k E_{xx,k} \hat{\beta}_k / \sum_k E_{xx,k}$, and the extra sum of squares for the separate slopes is

$$\text{SS}_{\text{slopes}} = \sum_k E_{xx,k} (\hat{\beta}_k - \hat{\beta})^2 = \sum_k \frac{E_{xy,k}^2}{E_{xx,k}} - \frac{E_{xy}^2}{E_{xx}} \quad (18.3.1)$$

on $g - 1$ degrees of freedom.

- (c) If $\mathbf{Y}$ is normal,

$$F = \frac{\text{SS}_{\text{slopes}}/(g-1)}{\text{SSE}_{\text{sep}}/(n-2g)} \sim F(g-1, n-2g, \gamma),$$

with

$$\gamma = \frac{1}{\sigma^2} \sum_k E_{xx,k} (\beta_k - \bar{\beta})^2,$$

where $\bar{\beta} = \sum_k E_{xx,k} \beta_k / \sum_k E_{xx,k}$. The test that rejects for large F is the F test of parallelism.

Proof. Let $\mathbf{M}$ project onto the span of the group indicators, and let $\mathbf{w}_k$ be the vector that equals $x_i - \bar{x}_k$ for units of group k and zero elsewhere. The k th slope column of the separate lines model is $\mathbf{x}$ restricted to group k , and its residual after projection onto $\mathcal{C}(\mathbf{M})$ is $\mathbf{w}_k$. By Lemma 9.2.1 the separate lines model space is $\mathcal{C}(\mathbf{M}) \oplus \text{span}\{\mathbf{w}_1, \dots, \mathbf{w}_g\}$, and the parallel lines space is $\mathcal{C}(\mathbf{M}) \oplus \text{span}\{\mathbf{w}\}$ with $\mathbf{w} = \sum_k \mathbf{w}_k = (\mathbf{I} - \mathbf{M})\mathbf{x}$. The vectors $\mathbf{w}_k$ have disjoint supports, so they are mutually orthogonal, with $\|\mathbf{w}_k\|^2 = E_{xx,k}$ and $\mathbf{w}_k^\top \mathbf{y} = E_{xy,k}$.

- (a) The projection of $\mathbf{y}$ onto $\text{span}\{\mathbf{w}_k\}$ is $\sum_k (E_{xy,k}/E_{xx,k})\mathbf{w}_k$. Reading off the coefficient of the k th slope column gives $\hat{\beta}_k$, which is $\mathbf{w}_k^\top \mathbf{y} / \|\mathbf{w}_k\|^2$. Hence $\text{Cov}(\hat{\beta}_k, \hat{\beta}_l) = \sigma^2 \mathbf{w}_k^\top \mathbf{w}_l / (E_{xx,k} E_{xx,l})$, which is $\sigma^2/E_{xx,k}$ for $k = l$ and zero otherwise. The residual sum of squares is $\|(\mathbf{I} - \mathbf{M})\mathbf{y}\|^2 - \sum_k E_{xy,k}^2/E_{xx,k}$, and $\|(\mathbf{I} - \mathbf{M})\mathbf{y}\|^2 = \sum_k E_{yy,k}$. The model has rank $2g$.

- (b) The pooled slope is $\mathbf{w}^\top \mathbf{y} / \|\mathbf{w}\|^2 = E_{xy} / E_{xx}$, and $E_{xy} = \sum_k E_{xx,k} \hat{\beta}_k$. By [Theorem 6.5.1](#) the extra sum of squares is the squared length of the projection onto the orthogonal complement of $\mathbf{w}$ in $\text{span}\{\mathbf{w}_k\}$, which equals $\sum_k E_{xy,k}^2 / E_{xx,k} - E_{xy}^2 / E_{xx}$. Writing $E_{xy,k} = E_{xx,k} \hat{\beta}_k$ and expanding $\sum_k E_{xx,k} (\hat{\beta}_k - \hat{\beta})^2 = \sum_k E_{xx,k} \hat{\beta}_k^2 - \hat{\beta}^2 E_{xx}$ gives the first form.
- (c) By [Theorem 11.1.1](#), with $\sigma^2 \gamma$ equal to the extra sum of squares evaluated at the mean vector. The mean vector has $\mathbf{w}_k^\top \boldsymbol{\mu} = \beta_k E_{xx,k}$, because $\mathbf{w}_k$ is orthogonal to the group indicators. Substituting into (b) with $\hat{\beta}_k$ replaced by β_k gives γ .

■

The test is a weighted test of homogeneity of g independent slope estimates, with weights equal to their precisions $E_{xx,k} / \sigma^2$.

Example. (Parallelism in the tutoring experiment)

For the four formats of [Example \(Four study formats with a pretest\)](#), the separate slopes are 0.703, 0.823, 1.035 and 0.992, and their weighted mean is the pooled slope 0.8670. The separate lines model has residual sum of squares 1347.47 on 32 degrees of freedom, against 1407.47 on 35 for parallel lines. The test gives $F = 0.47$ on 3 and 32 degrees of freedom, $p = 0.70$, and the covariance analysis stands.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(84)
g, m = 4, 10                                # four formats, ten students
    each
n = g * m
group = rng.permutation(np.repeat(np.arange(g), m)) # the randomization
x = np.round(rng.normal(60, 10, n))           # pretest, measured before
    assignment
mu_true = np.array([70.0, 74.0, 71.0, 77.0])
y = np.round(mu_true[group] + 0.8 * (x - 60) + rng.normal(0, 6, n), 1)
Z = np.eye(g)[group]                         # indicator matrix of the
    formats
n_k = Z.sum(axis=0)

def within(v):
    """(I - M) v: deviations from the group means (M projects onto C(Z))."""
    return v - (Z.T @ v / n_k)[group]

E_xx, E_xy, E_yy = within(x) @ within(x), within(x) @ within(y), within(y) @ within(
    y)
sse = E_yy - E_xy ** 2 / E_xx                 # ANCOVA residual sum of
    squares
X_sep = np.column_stack([Z, Z * x[:, None]]) # a separate line for each
    format
E_xx_k = np.array([within(x)[group == k] @ within(x)[group == k] for k in range(g)])
E_xy_k = np.array([within(x)[group == k] @ within(y)[group == k] for k in range(g)])
slopes = E_xy_k / E_xx_k
sse_sep = sse - (np.sum(E_xy_k ** 2 / E_xx_k) - E_xy ** 2 / E_xx)
F_par = ((sse - sse_sep) / (g - 1)) / (sse_sep / (n - 2 * g))
print("separate slopes", slopes.round(3),
```

```
f" F = {F_par:.2f}, p = {stats.f.sf(F_par, g - 1, n - 2 * g):.3f}"
```

With ten students per group the test has little power, so the case for parallel lines rests mostly on the science. When a treatment is meant to help some units more than others, such as a remedial programme aimed at weak students, the separate lines model should be the starting point rather than a check.

18.3.2 When the slopes differ

If the slopes differ, the difference between treatments k and l at covariate value x is the line

$$\delta(x) = (\mu_k - \mu_l) + (\beta_k - \beta_l)x,$$

estimated by $\hat{\delta}(x) = (\hat{\mu}_k - \hat{\mu}_l) + (\hat{\beta}_k - \hat{\beta}_l)x$. The two lines are independent simple regressions, so by [Corollary 5.5.4](#)

$$\text{Var}(\hat{\delta}(x)) = \sigma^2 v(x), \quad v(x) = \frac{1}{n_k} + \frac{(x - \bar{x}_k)^2}{E_{xx,k}} + \frac{1}{n_l} + \frac{(x - \bar{x}_l)^2}{E_{xx,l}}. \quad (18.3.2)$$

Honest reports include:

- (i) Report $\hat{\delta}(x)$ with its standard error at a few covariate values chosen for their meaning, for instance the quartiles of x , or a clinical threshold. Each is a t interval ([Theorem 12.1.1](#)) with $n - 2g$ degrees of freedom.
- (ii) Draw $\hat{\delta}(x)$ as a function with a confidence band. The pointwise band uses $t_{n-2g, \alpha/2}$. A band that covers the whole line $\delta(\cdot)$ with probability exactly $1 - \alpha$ replaces this multiplier by $\sqrt{2F_\alpha(2, n - 2g)}$, because $\{\delta(x) : x \in \mathbb{R}\}$ lies in a two-dimensional space of estimable functions. This is the argument of [Theorem 13.2.2](#), as used for the Working–Hotelling band ([Theorem 12.4.1](#)).
- (iii) Give the set of covariate values at which the treatments differ significantly. This is the **Johnson–Neyman region** ([Proposition 18.3.2](#) below).

Reporting $\hat{\delta}(\bar{x})$ alone as *the* treatment effect hides the slope, which is the whole point.

Remark (The average effect in a randomized experiment). There is one exception. In a randomized experiment, δ at the population mean of the covariate is the *average* treatment effect, because δ is linear. Its estimate $\hat{\delta}(\bar{x})$ is the treatment coefficient in the regression with a treatment-by-covariate interaction and the covariate centred at $\bar{x}$ ([Exercise \(C1\)](#)). This “interacted” adjustment is asymptotically never less precise than the unadjusted difference, even when the model is wrong. [Chapter 25](#) returns to it ([Theorem 25.6.2](#)).

18.3.3 The Johnson–Neyman region

Proposition 18.3.2 — Johnson–Neyman region

In the separate lines model with normal errors, let $s^2 = \text{SSE}_{\text{sep}}/(n - 2g)$ and fix a multiplier $c > 0$. Write $\Delta_\mu = \hat{\mu}_k - \hat{\mu}_l$ and $\Delta_\beta = \hat{\beta}_k - \hat{\beta}_l$. The set of x with $|\hat{\delta}(x)| >$

$cs\sqrt{v(x)}$ is $\{x : Ax^2 + Bx + C > 0\}$, where

$$A = \Delta_\beta^2 - c^2 s^2 \left(\frac{1}{E_{xx,k}} + \frac{1}{E_{xx,l}} \right), \quad B = 2\Delta_\mu \Delta_\beta + 2c^2 s^2 \left(\frac{\bar{x}_k}{E_{xx,k}} + \frac{\bar{x}_l}{E_{xx,l}} \right),$$

$$C = \Delta_\mu^2 - c^2 s^2 \left(\frac{1}{n_k} + \frac{1}{n_l} + \frac{\bar{x}_k^2}{E_{xx,k}} + \frac{\bar{x}_l^2}{E_{xx,l}} \right).$$

If $A > 0$, which happens iff the t test of $\beta_k = \beta_l$ with multiplier c rejects, the region is the whole line with at most an interval removed: δ is significantly positive on one side and significantly negative on the other. If $A < 0$, the region is a bounded interval or empty. With $c = t_{n-2g, \alpha/2}$ each point of the region is significant at level α . With $c = \sqrt{2F_\alpha(2, n-2g)}$ the statement “ $\delta(x) \neq 0$ for every x in the region” holds with probability at least $1 - \alpha$.

Proof. Square both sides of $|\hat{\delta}(x)| > cs\sqrt{v(x)}$ and expand $\hat{\delta}(x)^2 = \Delta_\mu^2 + 2\Delta_\mu \Delta_\beta x + \Delta_\beta^2 x^2$ and $v(x)$ from Eq. 18.3.2 as polynomials in x . Collecting terms gives $Ax^2 + Bx + C$. The coefficient A is positive iff $\Delta_\beta^2 / \{s^2(1/E_{xx,k} + 1/E_{xx,l})\} > c^2$, which is the squared t statistic for $\beta_k - \beta_l$ exceeding c^2 . A quadratic with $A > 0$ is positive outside the interval between its real roots (everywhere if it has none), and with $A < 0$ it is positive between its real roots (nowhere if it has none). The last statement follows from the simultaneous band of item (ii) above: on the event that the band covers $\delta(\cdot)$ everywhere, $\delta(x)$ cannot be zero at any point where the band excludes zero. ■

Example. (Two versions of a reading programme)

In a second synthetic randomized experiment, 48 children with baseline reading fluency between 42 and 118 words per minute are assigned, 24 each, to the current and a new version of a reading programme. The response is the gain in fluency. The new version was designed for weak readers, and the fitted lines of Figure 18.3.1(a) show why that matters. The slope is 0.0156 for the current version and -0.1615 for the new one. The test of parallelism has $F = 11.2$ on 1 and 44 degrees of freedom, $p = 0.0017$. The pooled slope of the parallel lines model would be -0.0638 , a compromise that describes neither group.

The estimated lines cross at $x = 107.7$. At a baseline of 60 words per minute the new version adds 8.46 words per minute (standard error 1.56). At 100 it adds 1.37 (standard error 1.46), which is not significant. With $c = t_{44, 0.025}$, the Johnson–Neyman region (Proposition 18.3.2) is $x < 93.5$ together with $x > 152.0$. The second part lies far beyond the largest baseline in the data, and it is an artefact of extending two fitted lines. The useful conclusion is that the new version is better for children who start below about 93 words per minute, which covers 33 of the 48 children in the study. With the simultaneous multiplier $\sqrt{2F_{0.05}(2, 44)}$, the region shrinks slightly, to $x < 90.8$ (and $x > 195.6$).

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(31)
n_per = 24
```

Figure 18.3.1: The reading programme. (a) Gain against baseline fluency with the separate least squares lines. (b) The estimated difference $\hat{\delta}(x)$ (new minus current) with a pointwise 95% band (dashed) and a simultaneous 95% band (shaded). The dotted line marks the lower end of the Johnson–Neyman region, $x = 93.5$; to its left the difference is significantly positive.

```

arm = rng.permutation(np.repeat([0, 1], n_per))      # 0 = current version, 1 = new
version
x = np.round(rng.uniform(40, 120, 2 * n_per))      # baseline fluency
y = np.where(arm == 0, 14 + 0.06 * x, 36 - 0.16 * x) + rng.normal(0, 4, 2 * n_per)
y = np.round(y, 1)
n = len(y)

def line(k):
    """Least squares line within arm k, and the arm's summaries."""
    xs, ys = x[arm == k], y[arm == k]
    Sxx = np.sum((xs - xs.mean()) ** 2)
    b = np.sum((xs - xs.mean()) * (ys - ys.mean())) / Sxx
    a = ys.mean() - b * xs.mean()
    sse = np.sum((ys - a - b * xs) ** 2)
    return a, b, xs.mean(), Sxx, len(xs), sse

(a0, b0, xb0, S0, n0, e0), (a1, b1, xb1, S1, n1, e1) = line(0), line(1)
nu = n - 4
s2 = (e0 + e1) / nu                                # separate-lines model

def significant_region(crit2):
    """Roots of  $d(x)^2 - crit2 * s2 * v(x) = 0$ , a quadratic in  $x$ ."""
    A = (b1 - b0) ** 2 - crit2 * s2 * (1 / S0 + 1 / S1)
    B = 2 * (a1 - a0) * (b1 - b0) + 2 * crit2 * s2 * (xb0 / S0 + xb1 / S1)
    C = (a1 - a0) ** 2 - crit2 * s2 * (1 / n0 + 1 / n1 + xb0 ** 2 / S0 + xb1 ** 2 / S1)
    return np.sort(np.roots([A, B, C]).real)

t2 = stats.t.ppf(0.975, nu) ** 2                    # pointwise, 5% level
w2 = 2 * stats.f.ppf(0.95, 2, nu)                  # simultaneous over all x (
    Scheffe,  $q = 2$ )
x_cross = -(a1 - a0) / (b1 - b0)
print(f"lines cross at x = {x_cross:.1f}")
print("pointwise 5% region: difference significant outside", significant_region(t2).
    round(1))

```

```
print("simultaneous region: difference significant outside", significant_region(w2).
      round(1))
```

The region is only as good as the linearity of each line, it extrapolates outside the data, and it marks significance, not practical importance: with enough data every value except the crossing point becomes significant.

18.3.4 Several covariates, several factors

With q covariates, the test of a common γ against $\gamma_1, \dots, \gamma_g$ has $(g-1)q$ and $n - g(q+1)$ degrees of freedom. With two factors, slope terms can be built term by term like the means model of [Chapter 16](#). Each such test compares nested column spaces ([Theorem 11.1.1](#)).

18.3.5 Exercises

18.3.5.1 A. Check your understanding

Exercise A1.

For $g = 2$, show that [Eq. 18.3.1](#) reduces to $SS_{\text{slopes}} = \frac{E_{xx,1}E_{xx,2}}{E_{xx,1} + E_{xx,2}} (\hat{\beta}_1 - \hat{\beta}_2)^2$, and that the F statistic is the square of the two-sample t statistic for the difference of slopes.

Exercise A2.

In [Example \(Two versions of a reading programme\)](#), the estimated lines cross at $x = 107.7$. Explain why the Johnson–Neyman region never contains the crossing point, whatever the multiplier.

18.3.5.2 B. Practice

Exercise B1.

Give a numerical example of two groups for which $A < 0$ and the Johnson–Neyman region of [Proposition 18.3.2](#) is a bounded interval. Interpret the region.

Exercise B2.

In the tutoring experiment, suppose the true slopes were 0.8, 0.8, 0.8, 1.2 and $\sigma = 6$. Using the $E_{xx,k}$ of the example (their sum is 3643.9; take them equal for the calculation), compute the noncentrality of the test of parallelism and its power at level 0.05 ([Theorem 11.5.1](#)).

Exercise B3.

Prove the claim in item (ii): with $c = \sqrt{2F_\alpha(2, n-2g)}$, the band $\hat{\delta}(x) \pm cs\sqrt{v(x)}$

contains $\delta(x)$ for all x simultaneously with probability at least $1 - \alpha$. Is the probability exactly $1 - \alpha$?

Solution. The functions $\delta(x) = \lambda_x^\top \beta$ for $x \in \mathbb{R}$ have λ_x in a two-dimensional space $\mathcal{L}$ spanned by the coefficient vectors of $\mu_k - \mu_l$ and $\beta_k - \beta_l$, both estimable. By [Theorem 13.2.2\(b\)](#) with $q = 2$, with probability exactly $1 - \alpha$ every $\lambda \in \mathcal{L}$ satisfies $|\lambda^\top \hat{\beta} - \lambda^\top \beta| \leq c \text{se}(\lambda^\top \hat{\beta})$. The functions λ_x form a subset of $\mathcal{L}$, so the probability for them is at least $1 - \alpha$. It is in fact exactly $1 - \alpha$. In the coordinates $(\mu_k - \mu_l, \beta_k - \beta_l)$ we have $\lambda_x = (1, x)$, and the studentized ratio $(\lambda^\top \hat{\beta} - \lambda^\top \beta)^2 / \text{se}(\lambda^\top \hat{\beta})^2$ is unchanged when λ is rescaled and is continuous on $\mathcal{L} \setminus \{0\}$. Every direction of $\mathcal{L}$ except that of $(0, 1)$ is the direction of some λ_x , and $\lambda_x / \|\lambda_x\| \rightarrow \pm(0, 1)$ as $x \rightarrow \pm\infty$. So the supremum of the ratio over $x \in \mathbb{R}$ equals its supremum over $\mathcal{L} \setminus \{0\}$, and the two events coincide. This is the argument of [Theorem 12.4.1\(b\)](#) for a single line.

18.3.5.3 C. Going deeper

Exercise C1.

In a two-group randomized experiment, show that the treatment coefficient in the least squares fit of y on $1, T, x - \bar{x}$ and $T(x - \bar{x})$, where $\bar{x}$ is the overall mean, equals $(\bar{y}_1 - \hat{\beta}_1(\bar{x}_1 - \bar{x})) - (\bar{y}_0 - \hat{\beta}_0(\bar{x}_0 - \bar{x}))$, with $\hat{\beta}_k$ the within-group slopes. Compare with the adjusted difference of the parallel lines model.

Solution. The model with an interaction is the separate lines model, so its fitted lines are the two within-group least squares lines, $\bar{y}_k + \hat{\beta}_k(x - \bar{x}_k)$. In the given parameterization the line for group k is $(\beta_0 + \beta_T T) + (\beta_x + \beta_{Tx} T)(x - \bar{x})$, so the coefficient of T is the difference of the two lines at $x = \bar{x}$, which is the stated expression. The parallel lines model replaces both $\hat{\beta}_k$ by the pooled slope. The two estimates agree when the slopes are equal or when $\bar{x}_0 = \bar{x}_1 = \bar{x}$.

18.4 Randomized complete blocks

A covariate removes nuisance variation by regression. **Blocking** removes it by design: similar units (plots in one part of a field, animals from one litter, strips cut from one board) are grouped into blocks, and treatments are compared *within* blocks. This section analyses the randomized complete block design, explains how randomization justifies its model, and measures what blocking gains.

18.4.1 The design and its model

Definition 18.4.1 — Randomized complete block design

There are t treatments and b blocks of t units each. In every block, the t treatments are assigned to the t units by a random permutation, chosen uniformly and independently for different blocks. The response of the unit in block j that received treatment i is

written y_{ij} .

The usual model is the additive two-way model with one observation per cell,

$$y_{ij} = \mu + \tau_i + \beta_j + \varepsilon_{ij}, \quad \varepsilon_{ij} \stackrel{\text{iid}}{\sim} N(0, \sigma^2), \quad (18.4.1)$$

with treatment effects τ_i and block effects β_j . Its geometry is [Example \(Additive two-factor model, one observation per cell\)](#) and its analysis of variance is that of [Theorem 16.1.2](#); we restate it in the form the design needs.

Theorem 18.4.1 — Analysis of the randomized complete block design

Assume [Eq. 18.4.1](#) with $t, b \geq 2$. Let $\bar{y}_{i\cdot}$, $\bar{y}_{\cdot j}$ and $\bar{y}_{\cdot\cdot}$ be the treatment, block and grand means.

- (a) The sums of squares

$$\begin{aligned} SS_T &= b \sum_i (\bar{y}_{i\cdot} - \bar{y}_{\cdot\cdot})^2, & SS_B &= t \sum_j (\bar{y}_{\cdot j} - \bar{y}_{\cdot\cdot})^2, \\ SSE &= \sum_{i,j} (y_{ij} - \bar{y}_{i\cdot} - \bar{y}_{\cdot j} + \bar{y}_{\cdot\cdot})^2 \end{aligned}$$

are squared lengths of projections onto mutually orthogonal subspaces of dimensions $t-1$, $b-1$ and $(t-1)(b-1)$, and with the correction for the mean they add up to $\sum_{i,j} y_{ij}^2$.

- (b) A function $\sum_i c_i \tau_i$ is estimable iff $\sum_i c_i = 0$. Its least squares estimate is $\sum_i c_i \bar{y}_{i\cdot}$, and

$$\sum_i c_i \bar{y}_{i\cdot} = \sum_i c_i \tau_i + \sum_i c_i \bar{\varepsilon}_i.$$

identically, whatever the block effects. Its variance is $\sigma^2 \sum_i c_i^2 / b$.

- (c) The treatment F statistic satisfies

$$F_T = \frac{SS_T / (t-1)}{SSE / ((t-1)(b-1))} \sim F(t-1, (t-1)(b-1), \gamma),$$

with

$$\gamma = \frac{b}{\sigma^2} \sum_i (\tau_i - \bar{\tau})^2.$$

- (d) $E(SS_B / (b-1)) = \sigma^2 + t \sum_j (\beta_j - \bar{\beta})^2 / (b-1)$, and $E(SSE / ((t-1)(b-1))) = \sigma^2$.

Proof. Model [Eq. 18.4.1](#) is the additive two-way model of [Theorem 16.1.2](#) with factor A the treatments, factor B the blocks, $a = t$ and $m = 1$, so that $n - a - b + 1 = (t-1)(b-1)$. Parts (a), (b) and (c) are [Theorem 16.1.2](#)(a), (b) and (c), with (e) for the form of the residual space. The only new statement is the identity in (b): averaging [Eq. 18.4.1](#) over j gives $\bar{y}_{i\cdot} = \mu + \tau_i + \bar{\beta} + \bar{\varepsilon}_i$, and $\sum_i c_i (\mu + \bar{\beta}) = 0$ for a contrast. Part (d) is [Theorem 9.6.1](#) applied to the decomposition in (a); the block projection sends the mean vector to the

vector with entries $\beta_j - \bar{\beta}$, whose squared length is $t \sum_j (\beta_j - \bar{\beta})^2$.

■

Part (b) is the reason to block. However large the block effects, they cancel exactly from every treatment comparison and from the error mean square, which estimates the variation *within* blocks. The between-block variation moves into its own line, SS_B . A test of blocks is rarely of interest, since blocks were chosen because they differ; a large MS_B measures what blocking achieved ([Proposition 18.4.4](#) below).

Any block-by-treatment interaction is absorbed into the error, and without replication within cells it cannot be separated from it. Tukey's one-degree-of-freedom test ([Theorem 16.1.2\(f\)](#)) checks for its most common form. If treatment differences genuinely vary between blocks, the comparisons refer to the average over the blocks used.

18.4.2 Randomization as the justification of the model

The units of an experiment are not a sample from a normal population; they are the boards or patients at hand. What the experimenter controls is the randomization, and it alone supports much of the analysis. Give each unit u a fixed value ξ_u , and assume **unit–treatment additivity**: unit u responds to treatment i with $\xi_u + \tau_i$. The only probability below is that of the randomization.

Proposition 18.4.2 — Randomization moments of the block analysis

Let the units of block j have values $\xi_{j1}, \dots, \xi_{jt}$, with mean $\bar{\xi}_j$ and $W_j = \sum_s (\xi_{js} - \bar{\xi}_j)^2$, and put

$$S_W^2 = \frac{1}{b(t-1)} \sum_j W_j,$$

the average within-block variance of the unit values. Under unit–treatment additivity and the randomization of [Definition 18.4.1](#):

- (a) every contrast estimate $\sum_i c_i \bar{y}_i$ has randomization mean $\sum_i c_i \tau_i$ and randomization variance $S_W^2 \sum_i c_i^2 / b$;
- (b) $E(\text{SSE} / ((t-1)(b-1))) = S_W^2$;
- (c) $E(\text{SS}_T / (t-1)) = S_W^2 + b \sum_i (\tau_i - \bar{\tau})^2 / (t-1)$.

So the error mean square is unbiased for the variance that the model attributes to σ^2 , and when the treatments have no effect the treatment and error mean squares have the same expectation.

Proof. Let $\pi_j(i)$ be the unit of block j that receives treatment i , and $w_{ij} = \xi_{j\pi_j(i)} - \bar{\xi}_j$. Then $y_{ij} = \bar{\xi}_j + \tau_i + w_{ij}$. For fixed j , the vector $(w_{1j}, \dots, w_{tj})$ is a uniformly random permutation of the deviations $\xi_{js} - \bar{\xi}_j$, which sum to zero. Hence $E w_{ij} = 0$, $E w_{ij}^2 = W_j / t$, and, since $\sum_k w_{kj} = 0$, $E w_{ij} w_{kj} = -W_j / \{t(t-1)\}$ for $i \neq k$. Different blocks are independent.

- (a) $\sum_i c_i \bar{y}_i = \sum_i c_i \tau_i + b^{-1} \sum_j \sum_i c_i w_{ij}$, because $\sum_i c_i = 0$ removes the $\bar{\xi}_j$. The mean follows. For the variance,

$$\text{Var}\left(\sum_i c_i w_{ij}\right) = \frac{W_j}{t} \sum_i c_i^2 - \frac{W_j}{t(t-1)} \sum_{i \neq k} c_i c_k = \frac{W_j}{t-1} \sum_i c_i^2,$$

since $\sum_{i \neq k} c_i c_k = (\sum_i c_i)^2 - \sum_i c_i^2 = -\sum_i c_i^2$. Summing over the independent blocks and dividing by b^2 gives $S_W^2 \sum_i c_i^2 / b$.

- (b) The block means are $\bar{y}_{.j} = \bar{\xi}_j + \bar{\tau}$, and the treatment means are $\bar{y}_i = \bar{\xi} + \tau_i + \bar{w}_{i.}$, with $\bar{\xi} = b^{-1} \sum_j \bar{\xi}_j$. So the residual is $w_{ij} - \bar{w}_{i.}$, and

$$\text{SSE} = \sum_{i,j} w_{ij}^2 - b \sum_i \bar{w}_{i.}^2.$$

The first sum is $\sum_j W_j$ for every randomization. By independence across blocks, $E \bar{w}_{i.}^2 = b^{-2} \sum_j E w_{ij}^2 = b^{-2} \sum_j W_j / t$, so $E(b \sum_i \bar{w}_{i.}^2) = b^{-1} \sum_j W_j$. Hence $E(\text{SSE}) = (1 - 1/b) \sum_j W_j = (t-1)(b-1)S_W^2$.

- (c) $\text{SS}_T = b \sum_i (\tau_i - \bar{\tau} + \bar{w}_{i.})^2$, using $\sum_i \bar{w}_{i.} = 0$. The cross terms have mean zero, and $E(b \sum_i \bar{w}_{i.}^2) = (t-1)S_W^2$ by the computation in (b).

■

Independent measurement errors of variance σ_e^2 add σ_e^2 to every expectation. The proposition does not make F_T exactly F -distributed, but it shows that the estimates and their estimated variances are unbiased because of the randomization, whatever made the units differ. A systematic assignment could line treatments up with the ξ 's, and then neither statement would hold.

Randomization tests. Under the *sharp* null hypothesis that every unit would respond the same under every treatment, the responses are fixed and only the labels are random. The proportion of the $(t!)^b$ equally likely randomizations giving an F_T at least as large as the observed one is an exact p -value, estimated by sampling randomizations when there are too many. [Chapter 23](#) develops permutation tests for linear models.

18.4.3 An example

Example. (Five wood adhesives on six boards)

In a synthetic experiment, five adhesives are compared for the shear strength of glued joints. Timber varies from board to board, so each of six boards is cut into five strips, assigned to the adhesives by a random permutation. The strengths (MPa) are:

adhesive	board 1	board 2	board 3	board 4	board 5	board 6
1	7.89	8.42	8.55	8.30	9.26	9.15
2	8.68	8.69	8.73	8.62	9.72	9.51
3	9.13	9.28	9.81	9.43	10.30	9.41
4	8.48	8.60	8.46	8.95	9.42	9.02
5	8.90	9.17	9.79	9.57	10.24	9.09

The analysis of variance is:

source	df	sum of squares	mean square	F
adhesives	4	4.106	1.0266	14.88
boards	5	4.068	0.8136	11.79
error	20	1.380	0.0690	
corrected total	29	9.555		

The adhesives differ clearly ($p = 8.6 \times 10^{-6}$). The adhesive means are 8.595, 8.992, 9.560, 8.822 and 9.460, and every difference has standard error $\sqrt{2 \times 0.0690/6} = 0.152$. Tukey's honestly significant difference at level 0.05, $q_{0.05}(5, 20)\sqrt{0.0690/6}$, is 0.454 ([Theorem 13.3.2](#) applies, with the error mean square of the block analysis, as in [Exercise \(B1\)](#)). It separates adhesives 3 and 5 from adhesives 1, 2 and 4: the significant pairs are 1–3, 1–5, 2–3, 2–5, 3–4 and 4–5. Tukey's test for nonadditivity gives $F = 0.07$ ($p = 0.80$), so there is no sign that the adhesive differences depend on the strength of the board.

Of 20000 randomizations sampled from the 2.99×10^{12} possible plans, 1 gave an adhesive F at least as large as 14.88: the randomization p -value is $(1 + 1)/(20000 + 1) = 0.00010$, in line with the normal theory.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(606)

    sst = b * np.sum((tm - gm) ** 2)
    sse = np.sum((yy - tm[:, None] - bm[None, :] + gm) ** 2)
    return (sst / (t - 1)) / (sse / df_err)
```

```

rng_perm = np.random.default_rng(7)
draws = 20_000
F_perm = np.empty(draws)
for r in range(draws):
    # re-randomize: permute the adhesive labels independently within every board
    perm = np.array([rng_perm.permutation(t) for _ in range(b)]).T
    F_perm[r] = f_stat(np.take_along_axis(y, perm, axis=0))
p_rand = (1 + np.sum(F_perm >= F_trt)) / (draws + 1)
print(f"randomization p-value {p_rand:.4f} (F-test p-value {stats.f.sf(F_trt, t -
    1, df_err):.2g})")

```

18.4.4 How much did blocking gain?

Had the adhesives been assigned to the thirty strips completely at random, the completely randomized design (CRD) would have had the board-to-board variation in its error. The block experiment itself can estimate how large that error would have been, using a fact about sampling from a finite population.

Lemma 18.4.3 — Sample variance without replacement

Let $u_1, \dots, u_N$ be fixed numbers with mean $\bar{u}$ and $S^2 = \sum_a (u_a - \bar{u})^2 / (N - 1)$. If $\mathcal{S}$ is a simple random sample of $m \geq 2$ of the indices, drawn without replacement, then

$$E \sum_{a \in \mathcal{S}} (u_a - \bar{u}_{\mathcal{S}})^2 = (m - 1)S^2,$$

where $\bar{u}_{\mathcal{S}}$ is the sample mean.

Proof. For any m numbers, $\sum_a (u_a - \bar{u}_{\mathcal{S}})^2 = \frac{1}{2m} \sum_{a,c} (u_a - u_c)^2$, the sum being over ordered pairs of sample members. The $m(m - 1)$ ordered pairs with $a \neq c$ are each a uniformly random ordered pair of distinct population members. For such a pair, $E(u_a - u_c)^2 = \frac{1}{N(N-1)} \sum_{a \neq c} (u_a - u_c)^2 = \frac{2N \sum_a (u_a - \bar{u})^2}{N(N-1)} = 2S^2$. So the expectation is $\frac{1}{2m} m(m - 1) 2S^2 = (m - 1)S^2$. ■

Proposition 18.4.4 — What a completely randomized design would have given

Let the $N = bt$ units follow Eq. 18.4.1, with fixed block effects β_j , and write $S_{\beta}^2 = t \sum_j (\beta_j - \bar{\beta})^2 / (N - 1)$ for the variance of the block effects over the N units.

- (a) If instead the treatments were assigned to the same units completely at random, b units each, the within-treatment mean square of the resulting one-way analysis would have expectation $\sigma^2 + S_{\beta}^2$, over the errors and the randomization.
- (b) In the block design,

$$\hat{\sigma}_{\text{CR}}^2 = \frac{(b - 1)\text{MS}_B + b(t - 1)\text{MSE}}{bt - 1} \quad (18.4.2)$$

is unbiased for $\sigma^2 + S_\beta^2$.

Proof.

- (a) The b units given treatment i form a simple random sample of the N units. Their responses are $\mu + \tau_i + \beta_{j(u)} + \varepsilon_u$, so the within-treatment sum of squares of treatment i is that of the numbers $\beta_{j(u)} + \varepsilon_u$ over the sample. Given the assignment, the errors contribute $(b-1)\sigma^2$ in expectation, and the cross terms have mean zero. By [Lemma 18.4.3](#) the block effects contribute $(b-1)S_\beta^2$ in expectation over the assignment. Summing over the t treatments and dividing by $t(b-1)$ gives $\sigma^2 + S_\beta^2$.
- (b) By [Theorem 18.4.1](#)(d), $E[(b-1)MS_B] = (b-1)\sigma^2 + t \sum_j (\beta_j - \bar{\beta})^2$ and $E[b(t-1)MSE] = b(t-1)\sigma^2$. The sum has expectation $(bt-1)\sigma^2 + (N-1)S_\beta^2$. ■

The **relative efficiency** $\hat{\sigma}_{CR}^2 / \text{MSE}$ estimates how many units a CRD would need per unit of the block design for the same precision. Some authors multiply it by Fisher's factor $(\nu_B + 1)(\nu_C + 3) / \{(\nu_B + 3)(\nu_C + 1)\}$, with $\nu_B = (t-1)(b-1)$ and $\nu_C = t(b-1)$ the two error degrees of freedom, to allow for estimating σ^2 with fewer degrees of freedom; this is a convention, not a theorem.

For the adhesives,

$$\hat{\sigma}_{CR}^2 = \frac{5 \times 0.8136 + 24 \times 0.0690}{29} = 0.1974,$$

and the relative efficiency is $0.1974/0.0690 = 2.86$ (2.81 with Fisher's factor). Blocking was worth almost three times as many strips; without it the adhesive F would have been about $1.0266/0.1974 = 5.20$.

```
s2_crd = ((b - 1) * ms_blk + b * (t - 1) * ms_err) / (b * t - 1)  # estimated CRD
                                error variance
re = s2_crd / ms_err
nu_b, nu_c = df_err, b * t - t                                     # error df: blocked,
                                completely randomized
re_fisher = re * (nu_b + 1) * (nu_c + 3) / ((nu_b + 3) * (nu_c + 1))
F_crd = ms_trt / s2_crd                                           # what the treatment F would
                                roughly have been
print(f"estimated CRD error variance {s2_crd:.2f} against {ms_err:.2f}:"
      f" relative efficiency {re:.2f} ({re_fisher:.2f} with Fisher's df factor)")
```

Remark (Fixed or random blocks). Treating the boards as a random sample of boards changes nothing about treatment comparisons in a complete block design, since block effects cancel from every contrast ([Theorem 18.4.1](#)(b)). It matters for incomplete blocks ([Section 18.5](#)) and for predicting a new block; [Chapter 32](#) treats such mixed models.

18.4.5 Exercises

18.4.5.1 A. Check your understanding

Exercise A1.

An experiment has $t = 4$ treatments in $b = 8$ blocks. Give the degrees of freedom of the block design's error, and of the error of a completely randomized design with the same 32 units. How large must the relative efficiency (without Fisher's factor) be for blocking to be worthwhile?

Exercise A2.

Verify from the table in [Example \(Five wood adhesives on six boards\)](#) that the treatment mean of adhesive 3 is 9.560, and compute the difference between adhesives 3 and 5 with its standard error. Is it significant by Tukey's criterion?

18.4.5.2 B. Practice**Exercise B1.**

The strips cut from a board differ systematically: strips from the outer edge are stronger. How would you modify the design and analysis to remove this source of variation as well? Which design of the next section does your answer lead to?

Exercise B2.

In [Proposition 18.4.2](#), show that $\text{Cov}(\sum_i c_i \bar{y}_i, \sum_i d_i \bar{y}_i) = S_W^2 \sum_i c_i d_i / b$ for two contrasts. Conclude that orthogonal contrasts are uncorrelated over the randomization, as they are under the normal model.

Solution. As in the proof, $\text{Cov}(\sum_i c_i w_{ij}, \sum_k d_k w_{kj}) = \frac{W_j}{t} \sum_i c_i d_i - \frac{W_j}{t(t-1)} \sum_{i \neq k} c_i d_k$, and $\sum_{i \neq k} c_i d_k = (\sum_i c_i)(\sum_k d_k) - \sum_i c_i d_i = -\sum_i c_i d_i$. So the covariance is $W_j \sum_i c_i d_i / (t-1)$. Summing over blocks and dividing by b^2 gives $S_W^2 \sum_i c_i d_i / b$, which is zero for orthogonal contrasts.

Exercise B3.

Suppose the block effects are random, $\beta_j \stackrel{\text{iid}}{\sim} N(0, \sigma_\beta^2)$, independent of the errors. Show that $E(\hat{\sigma}_{\text{CR}}^2) = \sigma^2 + \sigma_\beta^2 t(b-1)/(bt-1)$, and interpret the factor $t(b-1)/(bt-1)$.

18.4.5.3 C. Going deeper**Exercise C1.**

In [Eq. 18.4.1](#) let the block effects be random, $\beta_j \stackrel{\text{iid}}{\sim} N(0, \sigma_\beta^2)$, independent of the errors. Show that the treatment means $\bar{y}_i$ are equicorrelated, with variance $(\sigma^2 + \sigma_\beta^2)/b$ and covariance σ_β^2/b , while every contrast estimate keeps the distribution given by [Theorem 18.4.1\(b\)](#). Show that $E(\text{MS}_B) = \sigma^2 + t\sigma_\beta^2$, and that $(\text{MS}_B + (t-1)\text{MSE})/(tb)$

is unbiased for $\text{Var}(\bar{y}_{i.})$. Why is $s/\sqrt{b}$ the right scale for comparing treatments but the wrong standard error for a single treatment mean?

Solution. Averaging over blocks, $\bar{y}_{i.} = \mu + \tau_i + \bar{\beta} + \bar{\varepsilon}_{i.}$, where $\bar{\beta} \sim N(0, \sigma_\beta^2/b)$ is common to all treatments and the $\bar{\varepsilon}_{i.}$ are independent $N(0, \sigma^2/b)$ and independent of $\bar{\beta}$. Hence $\text{Var}(\bar{y}_{i.}) = (\sigma^2 + \sigma_\beta^2)/b$ and $\text{Cov}(\bar{y}_{i.}, \bar{y}_{k.}) = \text{Var}(\bar{\beta}) = \sigma_\beta^2/b$ for $i \neq k$. In a contrast $\bar{\beta}$ is multiplied by $\sum_i c_i = 0$, so $\sum_i c_i \bar{y}_{i.} = \sum_i c_i \tau_i + \sum_i c_i \bar{\varepsilon}_{i.}$ exactly as with fixed blocks. The block means are $\bar{y}_{.j} = \mu + \bar{\tau} + \beta_j + \bar{\varepsilon}_{.j}$, and the $\beta_j + \bar{\varepsilon}_{.j}$ are independent with variance $\sigma_\beta^2 + \sigma^2/t$, so $E(\text{SS}_B) = t(b-1)(\sigma_\beta^2 + \sigma^2/t)$ and $E(\text{MS}_B) = \sigma^2 + t\sigma_\beta^2$. The error sum of squares is unchanged, because the residual projection annihilates every vector that is constant within blocks, so $E(\text{MSE}) = \sigma^2$. Then

$$E\left(\frac{\text{MS}_B + (t-1)\text{MSE}}{tb}\right) = \frac{t\sigma^2 + t\sigma_\beta^2}{tb} = \frac{\sigma^2 + \sigma_\beta^2}{b}.$$

A comparison of treatments uses only within-block information, in which $\bar{\beta}$ cancels, so $s/\sqrt{b}$ is its scale and the Tukey intervals of [Exercise \(B1\)](#) remain exact. A single treatment mean is a statement about the population of blocks, and its uncertainty includes the sampling of the b blocks: s^2/b misses the term σ_β^2/b . The estimate above mixes two mean squares with different degrees of freedom, so an interval built on it is only approximately t ; the proper treatment is the subject of [Chapter 32](#) ([Proposition 32.5.1](#)).

18.5 Latin squares and incomplete blocks

A **Latin square** removes two crossed sources of nuisance variation at once. A **balanced incomplete block design** allows blocks smaller than the number of treatments, at a computable price in precision. The Latin square is orthogonal; the incomplete block design is not, and its treatment comparisons are adjusted for blocks exactly as they were adjusted for a covariate in [Section 18.1](#).

18.5.1 Latin squares

Definition 18.5.1 — Latin square design

An $a \times a$ **Latin square** is an arrangement of a symbols in an $a \times a$ array such that each symbol occurs exactly once in each row and exactly once in each column. A **Latin square design** compares a treatments on a^2 units classified by two crossed blocking factors with a levels each (rows and columns). The treatment applied to the unit in row i and column j is the symbol in cell (i, j) of a Latin square chosen at random.

The cyclic square $k(i, j) = i + j$ modulo a exists for every a ; the usual randomization permutes its rows, columns and symbols at random, which makes every unit equally likely to receive every treatment. With $k(i, j)$ the treatment in cell (i, j) , the model is additive in all three classifications:

$$y_{ij} = \mu + \rho_i + \kappa_j + \tau_{k(i,j)} + \varepsilon_{ij}, \quad \varepsilon_{ij} \stackrel{\text{iid}}{\sim} N(0, \sigma^2). \quad (18.5.1)$$

Theorem 18.5.1 — Analysis of the Latin square

Assume Eq. 18.5.1 with $a \geq 3$. Write $\bar{y}_{i\cdot}$, $\bar{y}_{\cdot j}$ and $\bar{y}^{(k)}$ for the means of row i , column j and treatment k , each an average of a observations, and $\bar{y}$ for the grand mean.

- (a) The centred row, column and treatment spaces are mutually orthogonal. So $\mathbf{I}$ is the sum of five mutually orthogonal projections: onto the mean, rows, columns, treatments (ranks 1, $a - 1$, $a - 1$, $a - 1$) and error (rank $(a - 1)(a - 2)$). The corresponding sums of squares are

$$\begin{aligned} SS_R &= a \sum_i (\bar{y}_{i\cdot} - \bar{y})^2, & SS_C &= a \sum_j (\bar{y}_{\cdot j} - \bar{y})^2, \\ SS_T &= a \sum_k (\bar{y}^{(k)} - \bar{y})^2, \end{aligned}$$

$$\text{and } SSE = \sum_{i,j} (y_{ij} - \bar{y}_{i\cdot} - \bar{y}_{\cdot j} - \bar{y}^{(k(i,j))} + 2\bar{y})^2.$$

- (b) Every contrast $\sum_k c_k \tau_k$ is estimable, with least squares estimate $\sum_k c_k \bar{y}^{(k)}$, free of the row and column effects, and variance $\sigma^2 \sum_k c_k^2 / a$.
- (c) The treatment F statistic satisfies

$$F_T = \frac{SS_T / (a - 1)}{SSE / ((a - 1)(a - 2))} \sim F(a - 1, (a - 1)(a - 2), \gamma),$$

with

$$\gamma = \frac{a}{\sigma^2} \sum_k (\tau_k - \bar{\tau})^2.$$

Proof.

- (a) Take any two of the three factors, say rows and treatments. Each treatment occurs exactly once in each row, so the two-way table of counts has every entry 1, with all row and column totals a , and it satisfies the proportional frequencies condition Eq. 9.4.1. By Theorem 9.4.3 the two centred spaces are orthogonal. The same argument applies to rows and columns (each cell once) and to columns and treatments. By Theorem 6.3.7 the projection onto the model space is $\mathbf{P}_0 + (\mathbf{P}_R - \mathbf{P}_0) + (\mathbf{P}_C - \mathbf{P}_0) + (\mathbf{P}_T - \mathbf{P}_0)$, of rank $1 + 3(a - 1)$. The error projection is $\mathbf{I}$ minus this, with rank $a^2 - 3a + 2 = (a - 1)(a - 2)$. Applying the projections to $\mathbf{y}$ gives the stated sums of squares and the residual.
- (b) Treatment k occurs once in each row and once in each column, so averaging Eq. 18.5.1 over its a cells gives $\bar{y}^{(k)} = \mu + \bar{\rho} + \bar{\kappa} + \tau_k + \bar{\varepsilon}^{(k)}$. For a contrast the constant cancels. Estimability follows as in Theorem 18.4.1(b), and by (a) and Theorem 9.4.1 the least squares estimate is the one computed from the treatment means alone. (c) is Corollary 9.6.2.

■

The price is the error: two degrees of freedom for $a = 3$ and six for $a = 4$, so small squares

are often replicated. The error consists of pieces of the row-by-column, row-by-treatment and column-by-treatment interactions, which cannot be told apart ([Exercise \(B2\)](#)). An interaction, such as a treatment working better in some rows, distorts the treatment comparisons: the design is only as good as its additivity assumption.

Example. (Keyboard layouts, typists and sessions)

In a synthetic experiment, five typists each type a standard passage in five sessions, comparing five keyboard layouts. Typists differ greatly, and speed rises with practice. A randomized 5×5 Latin square gives each layout once to each typist and once in each session:

	S1	S2	S3	S4	S5
typist 1	2	3	1	4	5
typist 2	3	5	4	2	1
typist 3	5	1	2	3	4
typist 4	4	2	5	1	3
typist 5	1	4	3	5	2

The analysis of variance of the speeds (words per minute) is:

source	df	sum of squares	mean square	F
typists	4	689.2	172.3	82.7
sessions	4	89.8	22.44	10.8
layouts	4	73.6	18.40	8.83
error	12	24.99	2.083	
corrected total	24	877.6		

The layouts differ ($p = 0.0015$). Their means are 47.06, 50.10, 45.92, 50.30 and 48.94 words per minute, and a difference has standard error $\sqrt{2 \times 2.083/5} = 0.913$.

Had the sessions been ignored, with layouts randomized within typists, the error variance would have been about $(MS_C + (a - 1)MSE)/a$ ([Exercise \(B1\)](#)). Relative to the Latin square this is

$$\frac{22.44 + 4 \times 2.083}{5 \times 2.083} = 2.95.$$

Ignoring the typists instead would have cost a factor of 17.35, and no blocking at all a factor of 16.25.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(62)
a = 5
cyclic = (np.arange(a)[: , None] + np.arange(a)[None, :]) % a      # a standard square
square = cyclic[rng.permutation(a)[:, ], rng.permutation(a)]      # permute rows and
    columns
square = rng.permutation(a)[square]                                  # and relabel the
    layouts
typist = rng.normal(0, 8, a)                                         # typists differ a lot
session = np.array([-3.0, -1.0, 0.0, 1.5, 2.5])                    # practice effect over
    sessions
layout = np.array([0.0, 2.0, -1.0, 3.0, 1.0])
y = np.round(55 + typist[:, None] + session[None, :] + layout[square])
```

```

        + rng.normal(0, 1.5, (a, a)), 1)

grand = y.mean()
row_m, col_m = y.mean(axis=1), y.mean(axis=0)
trt_m = np.array([y[square == k].mean() for k in range(a)])
ss_row = a * np.sum((row_m - grand) ** 2)
ss_col = a * np.sum((col_m - grand) ** 2)
ss_trt = a * np.sum((trt_m - grand) ** 2)
ss_tot = np.sum((y - grand) ** 2)
ss_err = ss_tot - ss_row - ss_col - ss_trt
df_err = (a - 1) * (a - 2)
ms_err = ss_err / df_err
F_trt = ss_trt / (a - 1) / ms_err
print(f"SS rows {ss_row:.1f}, columns {ss_col:.1f}, layouts {ss_trt:.1f}, error {
    ss_err:.2f} on {df_err} df")
print(f"F for layouts = {F_trt:.2f}, p = {stats.f.sf(F_trt, a - 1, df_err):.2g}")
print("layout means", trt_m.round(2), " se of a difference", np.sqrt(2 * ms_err / a)
    .round(3))

```

Because the sessions are ordered in time, a layout may affect speed on the next one. Such **carryover** effects are not in [Eq. 18.5.1](#); *crossover designs*, such as Latin squares balanced for the preceding treatment, are built to estimate them.

18.5.2 Balanced incomplete block designs

Often a block cannot hold every treatment: a taster can judge only a few samples, a batch suffices for only a few runs. With blocks of size $k < t$, treatment comparisons are no longer free of block effects, and the fairest arrangement treats every pair alike.

Definition 18.5.2 — Balanced incomplete block design

A **balanced incomplete block design** (BIBD) with parameters (t, b, r, k, λ) arranges t treatments in b blocks of size $k < t$, so that each block contains k distinct treatments, each treatment appears in r blocks, and each pair of distinct treatments appears together in exactly λ blocks. Its **incidence matrix** is the $t \times b$ matrix $\mathbf{N}$ with $n_{ij} = 1$ if treatment i is in block j and 0 otherwise. Treatments are assigned to the units within each block at random, and the labels of treatments and blocks are randomized as well.

Lemma 18.5.2 — Identities for balanced incomplete block designs

For a BIBD:

- (a) $bk = tr$ and $\lambda(t - 1) = r(k - 1)$;
- (b) $\mathbf{N}\mathbf{N}^\top = (r - \lambda)\mathbf{I}_t + \lambda\mathbf{J}_t$, where $\mathbf{J}_t = \mathbf{1}\mathbf{1}^\top$;
- (c) $r > \lambda$, and $b \geq t$ (**Fisher's inequality**).

Proof.

- (a) Both sides of the first identity count the units. For the second, fix a treatment i .

The r blocks containing it hold $r(k-1)$ other units, and each of the other $t-1$ treatments occurs in exactly λ of these blocks.

- (b) The (i, i') entry of $\mathbf{NN}^\top$ counts the blocks containing both i and i' . It is r on the diagonal and λ off it.
- (c) $k < t$ gives $k-1 < t-1$, so $\lambda = r(k-1)/(t-1) < r$. The matrix in (b) has eigenvalue $r - \lambda + \lambda t$ on $\mathbf{1}$ and $r - \lambda$ on $\mathbf{1}^\perp$, all positive. So $\mathbf{NN}^\top$ is nonsingular, and $t = \text{rank}(\mathbf{NN}^\top) \leq \text{rank}(\mathbf{N}) \leq b$.

■

The model is the additive block model, observed only on the occupied cells:

$$y_{ij} = \mu + \tau_i + \beta_j + \varepsilon_{ij} \quad \text{for the } bk \text{ pairs with } n_{ij} = 1. \quad (18.5.2)$$

Let T_i be the total of the observations on treatment i , B_j the total of block j , and define the **adjusted treatment totals**

$$Q_i = T_i - \frac{1}{k} \sum_j n_{ij} B_j, \quad (18.5.3)$$

treatment i 's total minus the average level of the blocks it happened to be in. Then $\sum_i Q_i = 0$.

Theorem 18.5.3 — Intra-block analysis of a balanced incomplete block design

Assume Eq. 18.5.2 for a BIBD, with $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$.

- (a) $\sum_i c_i \tau_i$ is estimable iff $\sum_i c_i = 0$. Its least squares estimate and variance are

$$\sum_i c_i \hat{\tau}_i = \frac{k}{\lambda t} \sum_i c_i Q_i, \quad \text{Var}\left(\sum_i c_i \hat{\tau}_i\right) = \frac{k}{\lambda t} \sigma^2 \sum_i c_i^2. \quad (18.5.4)$$

- (b) The sum of squares for treatments adjusted for blocks is $\text{SS}_{T|B} = \frac{k}{\lambda t} \sum_i Q_i^2$ on $t-1$ degrees of freedom. The residual sum of squares is $\text{SSE} = \text{SS}_{\text{tot}} - \text{SS}_B - \text{SS}_{T|B}$, where $\text{SS}_B = \sum_j B_j^2/k - (\sum_j B_j)^2/(bk)$ is the unadjusted block sum of squares, on $bk - b - t + 1$ degrees of freedom.
- (c) Under normality,

$$F = \frac{\text{SS}_{T|B}/(t-1)}{\text{SSE}/(bk - b - t + 1)} \sim F(t-1, bk - b - t + 1, \gamma),$$

with

$$\gamma = \frac{\lambda t}{k\sigma^2} \sum_i (\tau_i - \bar{\tau})^2.$$

- (d) A randomized complete block design with r blocks estimates each contrast with variance $\sigma^2 \sum_i c_i^2/r$. The ratio of that variance to Eq. 18.5.4 is the **efficiency**

factor

$$E = \frac{\lambda t}{rk} = \frac{t(k-1)}{(t-1)k} < 1.$$

Proof. Let $\mathbf{X}_B$ be the $n \times b$ indicator matrix of blocks (with the intercept in its span) and $\mathbf{Z}$ the $n \times t$ indicator matrix of treatments, with $n = bk$. Let $\mathbf{M}_B$ project onto $\mathcal{C}(\mathbf{X}_B)$, which replaces every observation by its block mean, and put $\tilde{\mathbf{Z}} = (\mathbf{I} - \mathbf{M}_B)\mathbf{Z}$. By Lemma 9.2.1, $\mathcal{C}([\mathbf{X}_B, \mathbf{Z}]) = \mathcal{C}(\mathbf{X}_B) \oplus \mathcal{C}(\tilde{\mathbf{Z}})$, orthogonally. This is the structure of Theorem 18.1.1 with the treatment indicators in the role of covariates, except that $\tilde{\mathbf{Z}}$ is not of full rank: $\mathbf{Z}\mathbf{1} = \mathbf{1}$ lies in $\mathcal{C}(\mathbf{X}_B)$, so $\tilde{\mathbf{Z}}\mathbf{1} = \mathbf{0}$.

The matrix $\mathbf{C} = \tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}} = \mathbf{Z}^\top \mathbf{Z} - \mathbf{Z}^\top \mathbf{M}_B \mathbf{Z}$ is the *information matrix* of the design. Here $\mathbf{Z}^\top \mathbf{Z} = r\mathbf{I}$, and $\mathbf{Z}^\top \mathbf{M}_B \mathbf{Z} = \mathbf{N}\mathbf{N}^\top/k$, because $\mathbf{Z}^\top \mathbf{X}_B = \mathbf{N}$ and $\mathbf{X}_B^\top \mathbf{X}_B = k\mathbf{I}$. By Lemma 18.5.2(b) and (a),

$$\mathbf{C} = r\mathbf{I} - \frac{(r-\lambda)\mathbf{I} + \lambda\mathbf{J}}{k} = \frac{r(k-1) + \lambda}{k}\mathbf{I} - \frac{\lambda}{k}\mathbf{J} = \frac{\lambda t}{k}\left(\mathbf{I} - \frac{1}{t}\mathbf{J}\right).$$

Also $\tilde{\mathbf{Z}}^\top \mathbf{y} = \mathbf{Z}^\top \mathbf{y} - \mathbf{Z}^\top \mathbf{M}_B \mathbf{y} = \mathbf{Q}$, since $\mathbf{Z}^\top \mathbf{y}$ is the vector of treatment totals and $\mathbf{Z}^\top \mathbf{M}_B \mathbf{y}$ has entries $\sum_j n_{ij} B_j/k$.

- (a) A vector $(\mathbf{0}, \mathbf{c})$, zero on the block and intercept parameters, is estimable iff $\mathbf{c}^\top = \mathbf{a}^\top \mathbf{Z}$ for some $\mathbf{a}$ with $\mathbf{a}^\top \mathbf{X}_B = \mathbf{0}$ (Theorem 8.2.2). Such an $\mathbf{a}$ satisfies $\mathbf{a} = (\mathbf{I} - \mathbf{M}_B)\mathbf{a}$, so $\mathbf{c} \in \mathcal{C}(\tilde{\mathbf{Z}}^\top) = \mathcal{C}(\mathbf{C})$, which is the space of contrasts because $\mathbf{C}$ is a positive multiple of the centring projection. Conversely, for a contrast $\mathbf{c} = \mathbf{C}\mathbf{h}$, the vector $\mathbf{a} = \tilde{\mathbf{Z}}\mathbf{h}$ works. Its least squares estimate is $\mathbf{a}^\top \mathbf{y} = \mathbf{h}^\top \mathbf{Q}$. With the generalized inverse $\mathbf{C}^- = \frac{k}{\lambda t}\mathbf{I}$, which satisfies $\mathbf{C}\mathbf{C}^-\mathbf{C} = \mathbf{C}$ because $\mathbf{I} - \mathbf{J}/t$ is idempotent, we have $\mathbf{C}\mathbf{C}^-\mathbf{c} = \mathbf{c}$ for a contrast, so we can take $\mathbf{h} = \mathbf{C}^-\mathbf{c}$, and the estimate is $\frac{k}{\lambda t}\mathbf{c}^\top \mathbf{Q}$. Its variance is $\sigma^2 \|\tilde{\mathbf{Z}}\mathbf{h}\|^2 = \sigma^2 \mathbf{h}^\top \mathbf{C}\mathbf{h} = \sigma^2 \mathbf{c}^\top \mathbf{C}^-\mathbf{c} = \frac{k}{\lambda t}\sigma^2 \|\mathbf{c}\|^2$.
- (b) The extra sum of squares for treatments after blocks is the squared length of the projection onto $\mathcal{C}(\tilde{\mathbf{Z}})$, $\mathbf{y}^\top \tilde{\mathbf{Z}}\mathbf{C}^-\tilde{\mathbf{Z}}^\top \mathbf{y} = \mathbf{Q}^\top \mathbf{C}^-\mathbf{Q} = \frac{k}{\lambda t} \sum_i Q_i^2$ (Lemma 9.2.1). The block sum of squares is $\|(\mathbf{M}_B - \mathbf{P}_0)\mathbf{y}\|^2$, and the block, adjusted treatment and residual projections are mutually orthogonal and sum to $\mathbf{I} - \mathbf{P}_0$ (Theorem 6.3.7). The model has rank $b + t - 1$.
- (c) is Theorem 11.1.1. The noncentrality is the same quadratic form evaluated at the mean, where $\tilde{\mathbf{Z}}^\top \boldsymbol{\mu} = \mathbf{C}\boldsymbol{\tau}$, giving $\boldsymbol{\tau}^\top \mathbf{C}\mathbf{C}^-\mathbf{C}\boldsymbol{\tau}/\sigma^2 = \frac{\lambda t}{k} \sum_i (\tau_i - \bar{\tau})^2/\sigma^2$.
- (d) The ratio is $(1/r)/(k/(\lambda t))$, and $\lambda = r(k-1)/(t-1)$ by Lemma 18.5.2(a). Since $k < t$, $(k-1)/k < (t-1)/t$.

■

The adjusted total Q_i compares treatment i with the blocks it appeared in, and $E Q_i = \frac{\lambda t}{k}(\tau_i - \bar{\tau})$ with no β 's left (Exercise B3): this is the **intra-block analysis**. The efficiency factor is the fraction of information that survives the elimination of blocks: about one half for $k = 2$, close to one for $k = t - 1$. Smaller blocks are often more homogeneous, and the smaller σ^2 can more than make up for E . Every pair sharing a block makes the design connected (Theorem 8.6.1), and balance gives every $\tau_i - \tau_{i'}$ the same variance $2k\sigma^2/(\lambda t)$. Unbalanced connected designs are analysed the same way with a different information matrix $\mathbf{C}$.

Example. (Seven recipes, fourteen tasters)

In a synthetic tasting experiment, seven recipes of a sports drink are rated on a 0–10 scale by 14 tasters, each of whom can judge only three. The blocks are the lines of two Fano planes, the cyclic sets $\{0, 1, 3\} + s$ and $\{0, 1, 5\} + s$ modulo 7 for $s = 0, \dots, 6$ (recipes numbered $0, \dots, 6$ in this description and $1, \dots, 7$ below). This is a BIBD with $t = 7$, $b = 14$, $k = 3$, $r = 6$ and $\lambda = 2$. There are 42 ratings and 22 error degrees of freedom.

Tasters use the scale very differently: the unadjusted block sum of squares is 69.72 out of a corrected total of 80.71. The raw recipe means, 6.15, 6.10, 5.40, 6.60, 6.30, 6.85 and 6.02, therefore mix recipe quality with the generosity of the tasters each recipe met. The adjusted totals are $Q = (-1.30, 0.90, -3.43, 3.13, 0.43, -1.50, 1.77)$, and the adjusted means $\bar{y} + \frac{k}{\lambda t} Q_i$ are 5.92, 6.40, 5.47, 6.87, 6.30, 5.88 and 6.58. Recipe 6 had the highest raw mean. Its adjusted mean is

$$6.202 + \frac{3}{14} \times (-1.50) = 5.88,$$

among the lowest: recipe 6 happened to meet generous tasters, and the adjustment removes 0.97 from its mean.

The adjusted recipe sum of squares is 6.36, and the residual sum of squares is 4.64, so

$$F = \frac{6.36/6}{4.64/22} = 5.03$$

on 6 and 22 degrees of freedom ($p = 0.0022$). A difference of two recipes has standard error $\sqrt{2 \times 3 \times 0.2108/14} = 0.301$. A complete block design with six tasters tasting all seven recipes, with the same σ^2 , would give 0.265; the variance ratio is the efficiency factor $7 \times 2/(6 \times 3) = 0.7778$. A taster judging seven drinks would probably not rate as consistently, though.

```
import numpy as np
from scipy import stats

t, k = 7, 3
blocks = [sorted((d + s) % t for d in base) for base in ([0, 1, 3], [0, 1, 5]) for s
           in range(t)]
b = len(blocks)                                # 14 tasters
N = np.zeros((t, b), dtype=int)                # incidence: recipe i tasted
                                           by taster j
for j, blk in enumerate(blocks):
    N[blk, j] = 1
r = N.sum(axis=1)[0]
lam = (N @ N.T)[0, 1]

rng = np.random.default_rng(77)
tau = np.array([0.0, 0.4, -0.3, 0.8, 0.1, -0.6, 0.5]) # recipe effects
taster = rng.normal(0, 1.2, b)                    # tasters use the scale
                                           differently
rows = [(i, j) for j, blk in enumerate(blocks) for i in blk]
recipe = np.array([i for i, j in rows])
block = np.array([j for i, j in rows])
y = np.round(6 + tau[recipe] + taster[block] + rng.normal(0, 0.5, len(rows)), 1)
n = len(y)
```

```

T_tot = np.bincount(recipe, weights=y, minlength=t)           # recipe totals
B_tot = np.bincount(block, weights=y, minlength=b)           # taster totals
Q = T_tot - N @ B_tot / k                                     # adjusted recipe
    totals
tau_hat = k * Q / (lam * t)                                   # intra-block estimates
    (sum to zero)
ss_trt_adj = k / (lam * t) * np.sum(Q ** 2)
ss_blk = np.sum(B_tot ** 2) / k - y.sum() ** 2 / n           # blocks, ignoring
    recipes
ss_tot = np.sum((y - y.mean()) ** 2)
ss_err = ss_tot - ss_blk - ss_trt_adj
df_err = n - b - t + 1
ms_err = ss_err / df_err
F = ss_trt_adj / (t - 1) / ms_err
se_diff = np.sqrt(2 * k * ms_err / (lam * t))
eff = lam * t / (r * k)                                       # efficiency factor
print("raw recipe means      ", (T_tot / r).round(2))
print("adjusted recipe means", (y.mean() + tau_hat).round(2))
print(f"adjusted recipe SS {ss_trt_adj:.3f}, error SS {ss_err:.3f} on {df_err} df,"
      f" F = {F:.2f}, p = {stats.f.sf(F, t - 1, df_err):.2g}")
print(f"se of a difference {se_diff:.3f}; efficiency factor {eff:.4f}")

```

Remark (Recovering inter-block information). The block totals, with $E B_j = k\mu + \sum_i n_{ij}\tau_i + k\beta_j$, also carry treatment information. With random block effects they give an independent *inter-block* estimate of every contrast, whose variance grows with σ_β^2 . Combining the two estimates by inverse-variance weights, as Yates proposed, is generalized least squares in a mixed model (Chapter 32). With blocks as different as these tasters, the inter-block estimate adds little.

18.5.3 Exercises

18.5.3.1 A. Check your understanding

Exercise A1.

Show that the cyclic array $k(i, j) = i + j \bmod a$ is a Latin square, and that permuting its rows, its columns, or its symbols gives a Latin square. For $a = 3$, how many distinct Latin squares are there, and does the randomization described above reach all of them?

Exercise A2.

Check the identities of Lemma 18.5.2 for the design of Example (Seven recipes, fourteen tasters). Is there a BIBD with $t = 7$, $k = 3$ and $b = 7$? With $t = 6$, $k = 3$, $b = 6$?

Exercise A3.

From the numbers in Example (Seven recipes, fourteen tasters), compute the estimate

of $\tau_4 - \tau_3$ and its standard error, and decide whether recipe 4 is better than recipe 3 at level 0.05, considered alone.

18.5.3.2 B. Practice

Exercise B1.

In a Latin square, suppose the columns had not been used as a blocking factor, so that the treatments were randomized within rows only. Following [Proposition 18.4.4](#), show that the expected error mean square of that design is $\sigma^2 + \sum_j (\kappa_j - \bar{\kappa})^2 / (a - 1)$, and that $(\text{MS}_C + (a - 1)\text{MSE})/a$ is unbiased for it in the Latin square.

Solution. Randomizing within rows, the units of row i are assigned to the treatments by a random permutation. Within a row, the column effects $\kappa_1, \dots, \kappa_a$ play the role of the unit values, with within-row variance $S_\kappa^2 = \sum_j (\kappa_j - \bar{\kappa})^2 / (a - 1)$, the same for every row. By [Proposition 18.4.2\(b\)](#), applied to the unit values $\kappa_j + \varepsilon_{ij}$ and averaged over the errors, the expected error mean square of the row-blocked design is $\sigma^2 + S_\kappa^2$. In the Latin square, $\text{E MS}_C = \sigma^2 + a S_\kappa^2$ and $\text{E MSE} = \sigma^2$ ([Theorem 9.6.1](#)), so $\text{E}\{\text{MS}_C + (a - 1)\text{MSE}\}/a = \sigma^2 + S_\kappa^2$.

Exercise B2.

In a 4×4 Latin square, the row-by-column interaction space of the 16 cells has dimension 9. Show that the treatment space (centred) lies inside it, and that the error space is its orthogonal complement within it, of dimension 6. What does this imply about the effect of a row-by-column interaction on the treatment comparisons?

Solution. The row-by-column interaction space is the orthogonal complement, within $\mathbb{R}^{16}$, of the span of the mean, row and column indicators; it has dimension $16 - 1 - 3 - 3 = 9$. By [Theorem 18.5.1\(a\)](#) the centred treatment space is orthogonal to the mean, row and column spaces, so it lies in this complement, with dimension 3. The error space is the orthogonal complement of the mean, row, column and treatment spaces, so it is the rest of the interaction space, of dimension 6. A row-by-column interaction in the mean vector is a vector of the 9-dimensional space, and its component in the treatment space is indistinguishable from a treatment effect. Unless the interaction happens to be orthogonal to the treatment space, it biases the treatment comparisons.

Exercise B3.

Show that $\text{E } Q_i = \frac{\lambda t}{k}(\tau_i - \bar{\tau})$ in a BIBD, directly from [Eq. 18.5.2](#) and [Lemma 18.5.2](#).

Solution. $\text{E } T_i = r\mu + r\tau_i + \sum_j n_{ij}\beta_j$ and $\text{E } B_j = k\mu + \sum_{i'} n_{i'j}\tau_{i'} + k\beta_j$. So

$$\text{E } Q_i = r\tau_i - \frac{1}{k} \sum_j \sum_{i'} n_{ij} n_{i'j} \tau_{i'} = r\tau_i - \frac{1}{k} (r\tau_i + \lambda \sum_{i' \neq i} \tau_{i'}),$$

the μ 's and β 's cancelling. Writing $\sum_{i' \neq i} \tau_{i'} = t\bar{\tau} - \tau_i$ gives $\text{E } Q_i = \tau_i(r - (r - \lambda)/k) - \lambda t\bar{\tau}/k = \frac{\lambda t}{k}(\tau_i - \bar{\tau})$, using $r(k - 1) + \lambda = \lambda t$.

Exercise B4.

A **Graeco-Latin square** superimposes two Latin squares of the same order so that every ordered pair of symbols occurs exactly once. Write down one of order 3, state the model with rows, columns and two treatment factors, and give the analysis of variance table with its degrees of freedom. How many error degrees of freedom remain for $a = 3, 4$ and 5?

18.5.3.3 C. Going deeper**Exercise C1.**

For a general incomplete block design with incidence matrix $\mathbf{N}$, replication r_i and block sizes k_j , show that the information matrix is $\mathbf{C} = \text{diag}(r_i) - \mathbf{N} \text{diag}(1/k_j) \mathbf{N}^\top$, that $\mathbf{C}\mathbf{1} = \mathbf{0}$, and that every treatment contrast is estimable iff $\text{rank}(\mathbf{C}) = t - 1$. Relate this to the connectedness of [Theorem 8.6.1](#).

18.6 Missing observations in designed experiments

Designed experiments lose observations: a plot floods, a sample is dropped, a strip of timber splits. The balanced formulas of the last two sections then no longer apply. The correct response is simple: the model still holds for the remaining observations, so fit it to them and test by comparing models ([Chapter 11](#)). Before computers, experimenters instead *filled in the missing value so that the balanced formulas give the exact least squares answer*. The trick shows exactly what the balanced formulas get right and wrong with a filled-in value, and it is the simplest instance of the EM algorithm.

18.6.1 Filling in, exactly

Let $\mathbf{X}$ be the $n \times p$ model matrix of the complete design, of rank r , and suppose the observations in a set of m rows are missing. Reorder so that $\mathbf{X} = \begin{pmatrix} \mathbf{X}_o \\ \mathbf{X}_m \end{pmatrix}$ and $\mathbf{y} = \begin{pmatrix} \mathbf{y}_o \\ \cdot \end{pmatrix}$, with $\mathbf{y}_o$ the $n - m$ observed values. Let $\mathbf{M}$ be the projection onto $\mathcal{C}(\mathbf{X})$ for the *complete* design, partitioned conformably into blocks $\mathbf{M}_{oo}, \mathbf{M}_{om}, \mathbf{M}_{mo}, \mathbf{M}_{mm}$, and let $\mathbf{D} = \begin{pmatrix} \mathbf{0} \\ \mathbf{I}_m \end{pmatrix}$ be the $n \times m$ matrix of indicators of the missing rows. The key assumption is that the loss does not destroy estimability:

$$\text{rank}(\mathbf{X}_o) = \text{rank}(\mathbf{X}) = r. \quad (18.6.1)$$

Since $\mathcal{N}(\mathbf{X}) \subseteq \mathcal{N}(\mathbf{X}_o)$ always, [Eq. 18.6.1](#) says that $\mathcal{N}(\mathbf{X}_o) = \mathcal{N}(\mathbf{X})$: every function estimable in the complete design remains estimable. A single missing observation in a randomized block design with $t, b \geq 2$, or in a Latin square with $a \geq 3$, never violates it. Losing every observation on some treatment does, and so does losing the only observation of a cell in an unreplicated factorial fitted with all its interactions.

Theorem 18.6.1 — Missing observations

Assume Eq. 18.6.1, and let $\hat{\beta}_o$ be any least squares estimate from the observed data alone, that is, for the model $E(\mathbf{Y}_o) = \mathbf{X}_o\beta$. Put $\mathbf{z}^* = \mathbf{X}_m\hat{\beta}_o$, the fitted values at the missing positions, and for $\mathbf{z} \in \mathbb{R}^m$ let $\mathbf{y}(\mathbf{z}) = \begin{pmatrix} \mathbf{y}_o \\ \mathbf{z} \end{pmatrix}$ be the data completed with $\mathbf{z}$.

- (a) (*Filling in.*) $\hat{\beta}_o$ is a least squares estimate for the complete data $\mathbf{y}(\mathbf{z}^*)$, and the residual sum of squares of the complete-data analysis of $\mathbf{y}(\mathbf{z}^*)$ equals SSE_o , the residual sum of squares of the observed data.
- (b) (*Characterization.*) The eigenvalues of $\mathbf{M}_{mm}$ lie in $[0, 1)$, and $\mathbf{z}^*$ is the unique solution of

$$\mathbf{z} = \mathbf{M}_{mo}\mathbf{y}_o + \mathbf{M}_{mm}\mathbf{z}, \quad (18.6.2)$$

that is, the unique $\mathbf{z}$ that equals its own complete-data fitted value.

- (c) (*Iteration.*) For any starting value $\mathbf{z}_0$, the sequence $\mathbf{z}_{s+1} = \mathbf{M}_{mo}\mathbf{y}_o + \mathbf{M}_{mm}\mathbf{z}_s$, which fills in the current values, fits the complete-data model and replaces the missing values by their fitted values, converges to $\mathbf{z}^*$. The error $\mathbf{z}_s - \mathbf{z}^*$ equals $\mathbf{M}_{mm}^s(\mathbf{z}_0 - \mathbf{z}^*)$.
- (d) (*Covariate method.*) For any $\mathbf{w} \in \mathbb{R}^m$, the model $E \mathbf{y}(\mathbf{w}) = \mathbf{X}\beta + \mathbf{D}\gamma$ has rank $r + m$. Its least squares fit has $\mathbf{X}_o\hat{\beta} = \mathbf{X}_o\hat{\beta}_o$, $\hat{\gamma} = \mathbf{w} - \mathbf{z}^*$, and residual sum of squares SSE_o , on $n - m - r$ degrees of freedom.
- (e) (*Tests.*) Let $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\text{rank}(\mathbf{X}_{0,o}) = \text{rank}(\mathbf{X}_0)$. The correct sum of squares for the reduced model is $\text{SSE}_{0,o} - \text{SSE}_o$, the difference of the residual sums of squares of the two models fitted to the observed data, on $r - r_0$ degrees of freedom, with error degrees of freedom $n - m - r$. The sum of squares computed from the complete-data formulas applied to $\mathbf{y}(\mathbf{z}^*)$ is at least as large.

Proof.

- (a) For any $\mathbf{b}$, the complete-data criterion splits as

$$\begin{aligned} \|\mathbf{y}(\mathbf{z}^*) - \mathbf{X}\mathbf{b}\|^2 &= \|\mathbf{y}_o - \mathbf{X}_o\mathbf{b}\|^2 + \|\mathbf{z}^* - \mathbf{X}_m\mathbf{b}\|^2 \\ &\geq \|\mathbf{y}_o - \mathbf{X}_o\mathbf{b}\|^2 \geq \text{SSE}_o. \end{aligned}$$

At $\mathbf{b} = \hat{\beta}_o$ both inequalities are equalities, because $\mathbf{z}^* = \mathbf{X}_m\hat{\beta}_o$ and $\hat{\beta}_o$ minimizes the observed-data criterion. So $\hat{\beta}_o$ minimizes the complete-data criterion, and the minimum is SSE_o .

- (b) By (a), the complete-data fitted vector of $\mathbf{y}(\mathbf{z}^*)$ is $\mathbf{X}\hat{\beta}_o$, whose missing part is $\mathbf{z}^*$. The fitted vector is $\mathbf{M}\mathbf{y}(\mathbf{z}^*)$, whose missing part is $\mathbf{M}_{mo}\mathbf{y}_o + \mathbf{M}_{mm}\mathbf{z}^*$. So $\mathbf{z}^*$ solves Eq. 18.6.2. For uniqueness, note that $\mathbf{M}_{mm} = \mathbf{D}^\top \mathbf{M} \mathbf{D}$ is symmetric and nonnegative definite, and for $\mathbf{u} \in \mathbb{R}^m$,

$$\mathbf{u}^\top \mathbf{M}_{mm} \mathbf{u} = \|\mathbf{M} \mathbf{D} \mathbf{u}\|^2 \leq \|\mathbf{D} \mathbf{u}\|^2 = \|\mathbf{u}\|^2,$$

with equality iff $\mathbf{D} \mathbf{u} \in \mathcal{C}(\mathbf{X})$, that is, iff $\mathbf{D} \mathbf{u} = \mathbf{X} \mathbf{b}$ for some $\mathbf{b}$. Such a $\mathbf{b}$ has $\mathbf{X}_o \mathbf{b} = \mathbf{0}$ and $\mathbf{X}_m \mathbf{b} = \mathbf{u}$. Under Eq. 18.6.1, $\mathbf{X}_o \mathbf{b} = \mathbf{0}$ implies $\mathbf{X} \mathbf{b} = \mathbf{0}$, so $\mathbf{u} = \mathbf{0}$. Hence $\mathbf{u}^\top \mathbf{M}_{mm} \mathbf{u} < \|\mathbf{u}\|^2$ for $\mathbf{u} \neq \mathbf{0}$, every eigenvalue of $\mathbf{M}_{mm}$ is less than 1, and

$\mathbf{I} - \mathbf{M}_{mm}$ is nonsingular. Equation Eq. 18.6.2 is $(\mathbf{I} - \mathbf{M}_{mm})\mathbf{z} = \mathbf{M}_{mo}\mathbf{y}_o$, which has exactly one solution.

- (c) Subtracting Eq. 18.6.2 for $\mathbf{z}^*$ from the recursion gives $\mathbf{z}_{s+1} - \mathbf{z}^* = \mathbf{M}_{mm}(\mathbf{z}_s - \mathbf{z}^*)$. The spectral radius of the symmetric matrix $\mathbf{M}_{mm}$ is its largest eigenvalue, which is less than 1 by (b), so $\mathbf{M}_{mm}^s \rightarrow \mathbf{0}$.
- (d) The argument of (b) shows that $\mathcal{C}(\mathbf{X}) \cap \mathcal{C}(\mathbf{D}) = \{\mathbf{0}\}$, so $\text{rank}[\mathbf{X}, \mathbf{D}] = r + m$. For any $\mathbf{b}$ and $\mathbf{g}$,

$$\|\mathbf{y}(\mathbf{w}) - \mathbf{X}\mathbf{b} - \mathbf{D}\mathbf{g}\|^2 = \|\mathbf{y}_o - \mathbf{X}_o\mathbf{b}\|^2 + \|\mathbf{w} - \mathbf{X}_m\mathbf{b} - \mathbf{g}\|^2.$$

For each $\mathbf{b}$ the second term is minimized, at zero, by $\mathbf{g} = \mathbf{w} - \mathbf{X}_m\mathbf{b}$. What remains is the observed-data criterion, so the minimizing $\mathbf{b}$ are the observed-data least squares estimates, $\mathbf{X}_o\hat{\boldsymbol{\beta}} = \mathbf{X}_o\hat{\boldsymbol{\beta}}_o$, and the minimum is SSE_o . Since $\mathbf{X}_m\mathbf{b}$ is the same for every least squares estimate (by Eq. 18.6.1, every row of $\mathbf{X}$ is an estimable function in the observed-data model), $\hat{\boldsymbol{\gamma}} = \mathbf{w} - \mathbf{X}_m\hat{\boldsymbol{\beta}}_o = \mathbf{w} - \mathbf{z}^*$.

- (e) The first statement is Theorem 11.1.1 for the observed-data model, of rank r with $n - m$ observations. For the second, the complete-data reduced-model fit of $\mathbf{y}(\mathbf{z}^*)$ has residual sum of squares $\min_{\mathbf{b}} (\|\mathbf{y}_o - \mathbf{X}_{0,o}\mathbf{b}\|^2 + \|\mathbf{z}^* - \mathbf{X}_{0,m}\mathbf{b}\|^2) \geq \text{SSE}_{0,o}$, while by (a) the complete-data full-model fit has residual sum of squares exactly SSE_o . Their difference is therefore at least $\text{SSE}_{0,o} - \text{SSE}_o$.

■

Part (a) is the classical claim. Part (e) gives the two classical corrections. The residual sum of squares is right, but it has $n - m - r$ degrees of freedom, not the $n - r$ that the complete-data formulas assign, since the filled-in values fit perfectly. And the treatment sum of squares is biased upward, because the filled-in value suits the full model and the reduced model cannot choose its own. Part (d) is Theorem 18.1.1 with indicator covariates: each gap gets its own parameter, the model fits it exactly and learns nothing from it, and the indicator's coefficient measures how far the number in the gap was from the least squares value.

Idea. A missing observation can be filled in with the value that the model, fitted to the remaining data, predicts for it. Then the balanced analysis of the completed data gives the exact least squares estimates and residual sum of squares. Subtract one error degree of freedom for each filled-in value, and compute tests by fitting the reduced model to the observed data.

18.6.2 The randomized block design with one missing value

For the randomized complete block design, Eq. 18.6.2 can be solved by hand. The projection of the complete design is $\mathbf{M} = \mathbf{P}_T + \mathbf{P}_B - \mathbf{P}_0$ (Example (Additive two-factor model, one observation per cell)), so the entry of $\mathbf{M}$ for two units is

$$m_{uv} = \frac{[\text{same treatment}]}{b} + \frac{[\text{same block}]}{t} - \frac{1}{bt},$$

where $[\cdot]$ is 1 if the condition holds and 0 otherwise.

Corollary 18.6.2 — Yates's missing value formula

In a randomized complete block design with t treatments and b blocks, suppose the observation on treatment i in block j is missing. Let T' and B' be the totals of the observed values of treatment i and of block j , and G' the total of all observed values. The least squares estimate of the missing value is

$$z^* = \frac{tT' + bB' - G'}{(t-1)(b-1)}. \quad (18.6.3)$$

The iteration of [Theorem 18.6.1\(c\)](#) reduces the error by the factor $1/b + 1/t - 1/(bt)$ at every step.

Proof. Here $m = 1$, and $\mathbf{M}_{mm} = 1/b + 1/t - 1/(bt)$, so $1 - \mathbf{M}_{mm} = (b-1)(t-1)/(bt)$. The row of $\mathbf{M}$ belonging to the missing unit, restricted to the observed units, sums the observed values of treatment i with weight $1/b - 1/(bt)$, those of block j with weight $1/t - 1/(bt)$, and all others with weight $-1/(bt)$. No observed unit shares both the treatment and the block. So $\mathbf{M}_{mo}\mathbf{y}_o = T'/b + B'/t - G'/(bt)$. Solving [Eq. 18.6.2](#),

$$z^* = \frac{bt}{(b-1)(t-1)} \left(\frac{T'}{b} + \frac{B'}{t} - \frac{G'}{bt} \right) = \frac{tT' + bB' - G'}{(t-1)(b-1)}.$$

The rate is $\mathbf{M}_{mm}$ by [Theorem 18.6.1\(c\)](#). ■

Example. (A strip that split)

Suppose that in [Example \(Five wood adhesives on six boards\)](#) the strip from board 4 for adhesive 2 had split while being cut, so its strength (in fact 8.62) was never measured. The observed totals are $T' = 45.33$ for adhesive 2, $B' = 36.25$ for board 4, and $G' = 263.95$ overall. Yates's formula gives

$$z^* = \frac{5 \times 45.33 + 6 \times 36.25 - 263.95}{4 \times 5} = 9.010.$$

The iteration started from the mean of the observed values, 9.102, gives 9.041, 9.020, 9.013, The distance to 9.010 shrinks by the factor $1/6 + 1/5 - 1/30 = 1/3$ at each step. Filling the gap with 0 and adding an indicator column gives $\hat{\gamma} = -9.010$, so the covariate method recovers the same value.

The completed table gives residual sum of squares 1.2788, exactly that of the 29 observed values, but on 19 degrees of freedom: the error mean square is $1.2788/19 = 0.0673$, not 0.0639. Its adhesive sum of squares, 4.0534, exceeds the correct 4.0512 by 0.0022. The correct F is 15.05 on 4 and 19 degrees of freedom; the naive analysis would report 15.85, mostly because of the degrees of freedom.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(606)
```

```

t, b = 5, 6                                # adhesives, boards

    y_fill = yv.copy()
    y_fill[miss] = z
    coef_fill, _ = fit(X, y_fill)                # complete-data analysis
    z = X[miss] @ coef_fill                      # replace the gap by its
fitted value

```

```
history.append(z[0])
print("iterates", np.round(history[:6], 3))
```

With several missing values, Eq. 18.6.2 is an $m \times m$ system, and the iteration converges at the rate of the largest eigenvalue of $\mathbf{M}_{mm}$. In the adhesive experiment with a second value also lost (adhesive 5 on board 1), that rate is 0.367, a little slower than $1/3$, because the two gaps are coupled through the grand mean (Exercise (B2)).

18.6.3 Why the method works, and when it does not

The iteration of Theorem 18.6.1(c) is the EM algorithm for the normal linear model with missing responses: the E-step replaces each missing value by its current fitted value, and the M-step refits. Part (b) proves convergence directly.

Everything assumes that the loss is unrelated to what the value would have been. A strip that split before gluing qualifies; a joint that failed in handling because its glue was weak does not, and then both filling in and dropping make the adhesive look stronger than it is. The observed data cannot reveal this. Chapter 41 treats missing data in general, including the kinds of missingness (Definition 41.1.1) and multiple imputation (Definition 41.5.1).

Warning. Never analyse filled-in values as if they were data without the corrections of Theorem 18.6.1(e). The residual degrees of freedom must be reduced by one for each filled-in value, and tests must be computed by comparing models fitted to the observed data. Standard errors computed from the completed data with the balanced formulas are also too small, because they treat $\mathbf{z}^*$ as observed.

18.6.4 Exercises

18.6.4.1 A. Check your understanding

Exercise A1.

Verify the arithmetic of Yates's formula in Example (A strip that split), and check that the filled-in value 9.010 makes the residual of that cell in the completed table exactly zero.

Exercise A2.

In a randomized block design with $t = 3$ and $b = 2$, suppose both observations on treatment 1 are lost. Show that Eq. 18.6.1 fails, and that $\mathbf{M}_{mm}$ has an eigenvalue equal to 1. What happens to the iteration?

Exercise A3.

Derive the analogue of Yates's formula for one missing value in an $a \times a$ Latin square: $z^* = \{a(R' + C' + T') - 2G'\} / \{(a-1)(a-2)\}$, where R' , C' and T' are the observed

totals of the row, column and treatment of the missing cell.

18.6.4.2 B. Practice

Exercise B1.

In the randomized block design with one missing value, show that the treatment sum of squares computed from the completed table exceeds the correct one by

$$\frac{\{B' - (t-1)z^*\}^2}{t(t-1)}.$$

Check the formula against the numbers in [Example \(A strip that split\)](#).

Solution. The correct treatment sum of squares is $\text{SSE}_{0,o} - \text{SSE}_o$, where $\text{SSE}_{0,o}$ is the residual sum of squares of the blocks-only model on the observed data. The complete-data sum of squares is $\text{SSE}_0(\mathbf{y}(z^*)) - \text{SSE}_o$ by [Theorem 18.6.1\(a\)](#). So the bias is $\text{SSE}_0(\mathbf{y}(z^*)) - \text{SSE}_{0,o}$. In the blocks-only model, the missing cell's fitted value from the observed data is the mean of the observed values of its block, $B'/(t-1)$, and by [Theorem 18.6.1\(a\)](#) applied to that model, filling the gap with $B'/(t-1)$ would give $\text{SSE}_{0,o}$ exactly. Only the within-block sum of squares of block j depends on the filled value z . It equals a constant plus $z^2 - (B' + z)^2/t$, a quadratic in z with leading coefficient $1 - 1/t$ and minimum at $z = B'/(t-1)$. Hence $\text{SSE}_0(\mathbf{y}(z)) - \text{SSE}_{0,o} = (1 - 1/t)\{z - B'/(t-1)\}^2 = \{(t-1)z - B'\}^2/(t(t-1))$. With $B' = 36.25$, $t = 5$ and $z^* = 9.010$: $(36.25 - 36.04)^2/20 = 0.0022$, as in the example.

Exercise B2.

Suppose two values are missing in a randomized block design, in different treatments and different blocks. Write $\mathbf{M}_{mm}$ explicitly and find its eigenvalues. Check the rate 0.367 quoted for the adhesive experiment.

Solution. With the two missing cells in different treatments and different blocks, they share neither, so $\mathbf{M}_{mm}$ has diagonal entries $d = 1/b + 1/t - 1/(bt)$ and off-diagonal entries $-1/(bt)$. Its eigenvalues are $d \pm 1/(bt)$, and the larger is $1/b + 1/t = 1/6 + 1/5 = 0.367$ for $t = 5$, $b = 6$.

18.6.4.3 C. Going deeper

Exercise C1.

Show that the covariance method of [Theorem 18.6.1\(d\)](#) gives correct standard errors for estimable functions of $\boldsymbol{\beta}$, without any correction, when the software's estimated covariance matrix of $(\hat{\boldsymbol{\beta}}, \hat{\boldsymbol{\gamma}})$ is used. Why does this not contradict the warning at the end of the section?

18.7 Summary and Notes

18.7.1 Summary

Idea.

1. Analysis of covariance is a projection problem. With design part $\mathbf{X}$ (any rank) and covariates $\mathbf{Z}$, the model space splits orthogonally as $\mathcal{C}(\mathbf{X}) \oplus \mathcal{C}((\mathbf{I} - \mathbf{M})\mathbf{Z})$. The covariate coefficients are estimated from within-group variation, $\hat{\boldsymbol{\gamma}} = \mathbf{E}_{zz}^{-1} \mathbf{E}_{zy}$, and the design part is fitted to the adjusted response $\mathbf{y} - \mathbf{Z}\hat{\boldsymbol{\gamma}}$. Tests compare residual sums of squares of nested models ([Theorem 18.1.1](#)).
2. In a randomized experiment a covariate measured before randomization reduces the variance of treatment comparisons by the factor $(1 - \rho^2)\{1 + 1/(N - g - 2)\}$ ([Proposition 18.1.2](#)), and it removes the conditional bias caused by chance imbalance ([Section 18.1](#)). A covariate affected by the treatment must not be adjusted for (same section).
3. Adjusted means are estimable functions $\mu_k + \mathbf{z}_0^\top \boldsymbol{\gamma}$, estimated by $\bar{y}_k - (\bar{\mathbf{z}}_k - \mathbf{z}_0)^\top \hat{\boldsymbol{\gamma}}$. They are correlated, their variances grow with the distance of $\bar{\mathbf{z}}_k$ from $\mathbf{z}_0$, and their differences do not depend on $\mathbf{z}_0$ ([Definition 18.2.1](#) and [Proposition 18.2.1](#)). Scheffé's intervals are exact for all their contrasts; Tukey-type intervals are approximate.
4. The test of parallel slopes is a weighted test of homogeneity of the within-group slopes ([Theorem 18.3.1](#)). When slopes differ, the treatment difference is a line in the covariate, to be reported with a band or a Johnson–Neyman region ([Proposition 18.3.2](#)).
5. In a randomized complete block design, block effects cancel from every treatment contrast. The analysis is the additive two-way analysis ([Theorem 18.4.1](#)). Randomization alone makes the contrast estimates unbiased and the error mean square unbiased for their variance ([Proposition 18.4.2](#)). The block experiment estimates the error variance a completely randomized design would have had ([Proposition 18.4.4](#)).
6. A Latin square blocks in two crossed directions with mutually orthogonal row, column and treatment spaces. Its error consists of confounded interaction pieces ([Theorem 18.5.1](#)).
7. A balanced incomplete block design has information matrix $(\lambda t/k)(\mathbf{I} - \mathbf{J}/t)$. Contrasts are estimated from the adjusted totals Q_i with variance $(k/\lambda t)\sigma^2 \sum c_i^2$, and the efficiency factor relative to complete blocks is $\lambda t/(rk)$ ([Theorem 18.5.3](#)).
8. A lost observation is handled exactly by least squares on the remaining data. Filling it with its fitted value, found by Yates's formula, by iteration or by the covariate method, reproduces the exact estimates and residual sum of squares. The error degrees of freedom must be reduced, and tests must be computed by comparing models ([Theorem 18.6.1](#) and [Corollary 18.6.2](#)).

18.7.2 Notes and sources

Analysis of covariance. Fisher introduced the analysis of covariance in the 1930s, in later editions of *Statistical Methods for Research Workers* (Fisher 1925 and later editions), as a

way of using a concomitant measurement to increase the precision of agricultural experiments. Cochran's review (Cochran 1957) remains an excellent account of its uses, including the dangers of adjusting for a covariate affected by treatment and of adjusting non-randomized groups. Rencher and Schaalje (2008, chapter 16) treat one-way, two-way and multi-covariate layouts and the test of homogeneous slopes. Christensen (2020, chapter 9) derives the analysis through the projection $(\mathbf{I} - \mathbf{M})\mathbf{Z}$, which is the route taken in [Theorem 18.1.1](#), and uses the same device for missing data and for incomplete block designs. The case against testing baseline balance in randomized trials was made forcefully by Senn (1994). The modern debate on regression adjustment in randomized experiments, which asks whether adjustment can hurt when the model is wrong, was opened by Freedman (2008) and answered, for the interacted estimator of [Exercise \(C1\)](#), by Lin (2013). [Chapter 25](#) returns to it ([Theorem 25.6.2](#)).

Heterogeneous slopes. The region of significance for non-parallel lines is due to Johnson and Neyman (1936), who developed it for comparisons of teaching methods with an ability covariate. Simultaneous versions use the Scheffé argument of [Chapter 13](#).

Block designs and randomization. Randomization, blocking and the Latin square as a design are Fisher's, set out in *The Design of Experiments* (Fisher 1935). The randomization moments of [Proposition 18.4.2](#) and the view of the linear model as an approximation justified by randomization are developed in Kempthorne (1952) and Hinkelmann and Kempthorne (2008). Cox (1958) remains the best short account of the ideas behind designed experiments, and Bailey (2008) gives a modern treatment of block designs built on the same orthogonal decompositions as this chapter. Relative efficiencies such as [Eq. 18.4.2](#) are standard in the design literature, for instance Cochran and Cox (1957). Christensen (2020, chapter 8) presents the randomized complete block and Latin square models as additive multi-way layouts and discusses their assumptions.

Incomplete blocks. Balanced incomplete block designs were introduced by Yates (1936), who also showed how to recover inter-block information (Yates 1940). Fisher (1940) proved the inequality $b \geq t$ of [Lemma 18.5.2](#). Christensen (2020, section 9.4) derives the intra-block analysis as an analysis of covariance with the treatment indicators as covariates, as in the proof of [Theorem 18.5.3](#).

Missing values. Yates (1933) derived the missing value formula [Eq. 18.6.3](#) and the rule of subtracting a degree of freedom for each estimated value. Bartlett (1937) proposed the covariance method with indicator covariates, and Healy and Westmacott (1956) the iterative method of [Theorem 18.6.1\(c\)](#), convenient for early computers. Dempster, Laird and Rubin (1977) placed the iteration within the EM algorithm. Christensen (2020, section 9.3) treats missing observations through the covariance model.

Chapter 19

What Goes Wrong: A Theory of Departures

Parts II to IV derived everything from a short list of assumptions: the mean is $\mathbf{X}\boldsymbol{\beta}$ for the regressors actually used, the errors are uncorrelated with a common variance, they are normal, and the regressors are fixed and measured without error. Real data meet each of these only approximately. This chapter asks, one assumption at a time, what a specific departure does to the least squares estimator, to s^2 and to the tests and intervals built from them. Omitting a regressor biases the coefficients, and yet the biased estimator can still have the smaller mean squared error. A wrong covariance matrix leaves the estimator nearly efficient but can make its standard error wrong by a factor of two or more. With non-normal errors the t and F tests are asymptotically valid when no observation has large leverage, while tests and intervals for σ^2 are not valid in any sample size. A single bad observation can move the estimate arbitrarily far. With random regressors and a curved mean, the usual standard errors describe the wrong target. Collinearity breaks no assumption at all, but it inflates variances. Chapters 20–22 turn to diagnosis and remedies, and Chapter 23 to inference that relies less on the assumptions.

What you need. Chapter 5 (the moments of $\hat{\boldsymbol{\beta}}$ under departures, Proposition 5.5.7, and omitted regressors, Proposition 5.7.2), Chapter 6 (the Frisch–Waugh–Lovell theorem, leverage, Kruskal’s theorem and the population projection), Chapter 7 (Gauss–Markov and Aitken), Chapter 10 (the deletion formulas, Proposition 10.6.2), and the tests and intervals of Chapter 11 and Chapter 12. Section 14.1 treats random regressors under the normal model, and Section 19.5 builds on it.

19.0.1 Roadmap

- Omitting and adding regressors
- An incorrect covariance matrix
- Non-normal errors
- A single bad observation
- Random regressors and a curved mean
- Collinearity, previewed
- Summary and notes

19.1 Omitting and adding regressors

The assumption $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ claims that the columns of $\mathbf{X}$ are the right ones. This section compares two ways of getting them wrong. *Underfitting* leaves out regressors that matter. *Overfitting* includes regressors that do not. This is a first look at the bias–variance trade-off of [Part VI](#).

19.1.1 The setting

Throughout the section the truth is

$$E(\mathbf{Y}) = \mathbf{X}_1\boldsymbol{\beta}_1 + \mathbf{X}_2\boldsymbol{\beta}_2, \quad \text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}_n,$$

where $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2]$ has full column rank $p = p_1 + p_2 < n$. The *long* regression fits both blocks and gives $\hat{\boldsymbol{\beta}} = (\hat{\boldsymbol{\beta}}_1^\top, \hat{\boldsymbol{\beta}}_2^\top)^\top$ and $s^2 = \|(\mathbf{I} - \mathbf{M})\mathbf{Y}\|^2 / (n - p)$. The *short* regression fits $\mathbf{X}_1$ alone and gives

$$\hat{\boldsymbol{\beta}}_1^S = (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top \mathbf{Y}, \quad s_1^2 = \frac{\|(\mathbf{I} - \mathbf{M}_1)\mathbf{Y}\|^2}{n - p_1},$$

where the superscript S marks the short fit and $\mathbf{M}_1$ projects onto $\mathcal{C}(\mathbf{X}_1)$. Two quantities recur. The first is $\boldsymbol{\Pi} = (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top \mathbf{X}_2$, the coefficients from regressing each column of $\mathbf{X}_2$ on $\mathbf{X}_1$, as in [Proposition 5.7.2](#). The second is

$$\gamma = \frac{\|(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\boldsymbol{\beta}_2\|^2}{\sigma^2} = \frac{\boldsymbol{\beta}_2^\top \mathbf{X}_2^\top (\mathbf{I} - \mathbf{M}_1) \mathbf{X}_2 \boldsymbol{\beta}_2}{\sigma^2}. \quad (19.1.1)$$

Since $(\mathbf{M} - \mathbf{M}_1)\mathbf{X}\boldsymbol{\beta} = (\mathbf{I} - \mathbf{M}_1)\mathbf{X}\boldsymbol{\beta} = (\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\boldsymbol{\beta}_2$, this is the noncentrality parameter [Eq. 11.1.2](#) of the F test of $\boldsymbol{\beta}_2 = \mathbf{0}$ in the long model. It measures how far the true mean lies from the short model's column space, in units of σ^2 . It is zero iff $\boldsymbol{\beta}_2 = \mathbf{0}$, because $\mathbf{X}_2\boldsymbol{\beta}_2 \in \mathcal{C}(\mathbf{X}_1)$ forces $\boldsymbol{\beta}_2 = \mathbf{0}$ when $\mathbf{X}$ has full rank.

Both regressions are linked by an exact identity and by one covariance.

Lemma 19.1.1 — Short and long regressions

In this setting:

- (a) $\hat{\boldsymbol{\beta}}_2 = (\mathbf{X}_2^\top (\mathbf{I} - \mathbf{M}_1) \mathbf{X}_2)^{-1} \mathbf{X}_2^\top (\mathbf{I} - \mathbf{M}_1) \mathbf{Y}$ and $\hat{\boldsymbol{\beta}}_1 = \hat{\boldsymbol{\beta}}_1^S - \boldsymbol{\Pi} \hat{\boldsymbol{\beta}}_2$;
- (b) $\text{Cov}(\hat{\boldsymbol{\beta}}_1^S, \hat{\boldsymbol{\beta}}_2) = \mathbf{0}$ and $\text{Cov}(\hat{\boldsymbol{\beta}}_2) = \sigma^2 \mathbf{C}$, where $\mathbf{C} = (\mathbf{X}_2^\top (\mathbf{I} - \mathbf{M}_1) \mathbf{X}_2)^{-1}$.

Proof.

- (a) The first formula is [Theorem 6.6.2\(a\)](#) with the roles of the two blocks exchanged, and the second is [Proposition 5.7.2\(a\)](#). (b) Both estimators are linear in $\mathbf{Y}$. By [Theorem 2.2.1](#),

$$\text{Cov}(\hat{\boldsymbol{\beta}}_1^S, \hat{\boldsymbol{\beta}}_2) = \sigma^2 (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top (\mathbf{I} - \mathbf{M}_1) \mathbf{X}_2 \mathbf{C} = \mathbf{0},$$

because $\mathbf{X}_1^\top (\mathbf{I} - \mathbf{M}_1) = \mathbf{0}$. Similarly $\text{Cov}(\hat{\boldsymbol{\beta}}_2) = \sigma^2 \mathbf{C} \mathbf{X}_2^\top (\mathbf{I} - \mathbf{M}_1)^2 \mathbf{X}_2 \mathbf{C} = \sigma^2 \mathbf{C}$.

19.1.2 Underfitting

Theorem 19.1.2 — Omitted regressors

Fit the short model when the long model is true.

- (a) $E(\hat{\beta}_1^S) = \beta_1 + \Pi\beta_2$ and $\text{Cov}(\hat{\beta}_1^S) = \sigma^2(\mathbf{X}_1^\top \mathbf{X}_1)^{-1}$. The bias $\Pi\beta_2$ vanishes iff $\mathbf{X}_1^\top \mathbf{X}_2\beta_2 = \mathbf{0}$, and it vanishes for every β_2 iff $\mathbf{X}_1^\top \mathbf{X}_2 = \mathbf{0}$.
- (b) The fitted values have mean $\mathbf{X}\beta - (\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2$. The residuals have mean $(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2$ and covariance $\sigma^2(\mathbf{I} - \mathbf{M}_1)$, as if the short model were right.
- (c) $E(s_1^2) = \sigma^2(1 + \gamma/(n - p_1))$, so s_1^2 overestimates σ^2 unless $\beta_2 = \mathbf{0}$.
- (d) At a new point with regressors $(\mathbf{x}_{10}, \mathbf{x}_{20})$, the short prediction $\mathbf{x}_{10}^\top \hat{\beta}_1^S$ has bias $(\Pi^\top \mathbf{x}_{10} - \mathbf{x}_{20})^\top \beta_2$ for the mean $\mathbf{x}_{10}^\top \beta_1 + \mathbf{x}_{20}^\top \beta_2$.

Proof.

- (a) The mean is Proposition 5.7.2(b). The covariance is Theorem 5.5.1(b) for the model matrix $\mathbf{X}_1$, which needs only $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}$. Since $(\mathbf{X}_1^\top \mathbf{X}_1)^{-1}$ is nonsingular, $\Pi\beta_2 = \mathbf{0}$ iff $\mathbf{X}_1^\top \mathbf{X}_2\beta_2 = \mathbf{0}$, and this holds for all β_2 iff $\mathbf{X}_1^\top \mathbf{X}_2 = \mathbf{0}$.
- (b) $E(\mathbf{M}_1\mathbf{Y}) = \mathbf{X}_1\beta_1 + \mathbf{M}_1\mathbf{X}_2\beta_2 = \mathbf{X}\beta - (\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2$, and $E((\mathbf{I} - \mathbf{M}_1)\mathbf{Y}) = (\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2$ because $(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_1 = \mathbf{0}$. The covariance is $(\mathbf{I} - \mathbf{M}_1)\sigma^2\mathbf{I}(\mathbf{I} - \mathbf{M}_1) = \sigma^2(\mathbf{I} - \mathbf{M}_1)$.
- (c) By Eq. 2.3.1 with $\mathbf{M}_1$ of rank p_1 and mean $\mathbf{X}\beta$, $E\|(\mathbf{I} - \mathbf{M}_1)\mathbf{Y}\|^2 = \sigma^2(n - p_1) + \|(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2\|^2 = \sigma^2(n - p_1 + \gamma)$.
- (d) Take expectations in $\mathbf{x}_{10}^\top \hat{\beta}_1^S$ using (a), and subtract the true mean.

Nothing in the second moments signals the omission: the covariances of $\hat{\beta}_1^S$ and of the residuals are exactly what the short model claims. The damage is in the first moments. The estimator is centred at the wrong place, and the residuals carry the systematic component $(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\beta_2$ that added-variable plots (Theorem 6.6.2) and lack-of-fit tests (Theorem 14.6.2) look for. Because s_1^2 is inflated, the reported variances are on average too large, yet as n grows they shrink while the bias does not, so the coverage of intervals for β_1 tends to zero. Nothing requires a coefficient to be omitted: for any true mean $\mathbf{X}_1\beta_1 + \delta$, such as a curved mean fitted by a line, (a)–(c) hold with $\mathbf{X}_2\beta_2$ replaced by δ (Proposition 5.5.7(a)).

19.1.3 Overfitting

Theorem 19.1.3 — Irrelevant regressors

Suppose $\beta_2 = \mathbf{0}$, so the short model is correct, but the long model is fitted.

- (a) $E(\hat{\beta}_1) = \beta_1$, $E(\hat{\beta}_2) = \mathbf{0}$ and $E(s^2) = \sigma^2$.
- (b) $\text{Cov}(\hat{\beta}_1) = \text{Cov}(\hat{\beta}_1^S) + \sigma^2 \Pi C \Pi^\top$. Hence $\text{Var}(\mathbf{a}^\top \hat{\beta}_1) \geq \text{Var}(\mathbf{a}^\top \hat{\beta}_1^S)$ for every $\mathbf{a} \in \mathbb{R}^{p_1}$, with equality iff $\Pi^\top \mathbf{a} = \mathbf{0}$, and $\text{Cov}(\hat{\beta}_1) = \text{Cov}(\hat{\beta}_1^S)$ iff $\mathbf{X}_1^\top \mathbf{X}_2 = \mathbf{0}$.
- (c) At a new point $\mathbf{x}_0 = (\mathbf{x}_{10}^\top, \mathbf{x}_{20}^\top)^\top$,

$$\begin{aligned} \text{Var}(\mathbf{x}_0^\top \hat{\beta}) &= \text{Var}(\mathbf{x}_{10}^\top \hat{\beta}_1^S) \\ &\quad + \sigma^2 (\mathbf{x}_{20} - \Pi^\top \mathbf{x}_{10})^\top \mathbf{C} (\mathbf{x}_{20} - \Pi^\top \mathbf{x}_{10}), \end{aligned}$$

and summed over the design points $E\|\mathbf{X}\hat{\beta} - \mathbf{X}\beta\|^2 = \sigma^2 p$, against $\sigma^2 p_1$ for the short fit.

Proof.

- (a) The long model is correct (with $\beta_2 = \mathbf{0}$), so [Theorem 5.5.1\(a\)](#) and [Theorem 5.6.1](#) apply.
- (b) By [Lemma 19.1.1\(a\)](#), $\hat{\beta}_1 = \hat{\beta}_1^S - \Pi \hat{\beta}_2$ with the two terms uncorrelated, so $\text{Cov}(\hat{\beta}_1) = \text{Cov}(\hat{\beta}_1^S) + \Pi \text{Cov}(\hat{\beta}_2) \Pi^\top$, and [Lemma 19.1.1\(b\)](#) gives $\text{Cov}(\hat{\beta}_2)$. Because $\mathbf{C}$ is positive definite, $\mathbf{a}^\top \Pi C \Pi^\top \mathbf{a} = 0$ iff $\Pi^\top \mathbf{a} = \mathbf{0}$, and $\Pi C \Pi^\top = \mathbf{0}$ iff $\Pi = \mathbf{0}$, iff $\mathbf{X}_1^\top \mathbf{X}_2 = \mathbf{0}$.
- (c) Write $\mathbf{x}_0^\top \hat{\beta} = \mathbf{x}_{10}^\top \hat{\beta}_1^S + (\mathbf{x}_{20} - \Pi^\top \mathbf{x}_{10})^\top \hat{\beta}_2$ using [Lemma 19.1.1\(a\)](#), and use the zero covariance of (b) of that lemma. For the sum, $\mathbf{X}\hat{\beta} = \mathbf{M}\mathbf{Y}$ is unbiased for $\mathbf{X}\beta$ with covariance $\sigma^2 \mathbf{M}$, so $E\|\mathbf{M}\mathbf{Y} - \mathbf{X}\beta\|^2 = \sigma^2 \text{tr } \mathbf{M} = \sigma^2 p$. The short fit $\mathbf{M}_1 \mathbf{Y}$ is also unbiased, and its trace is p_1 . ■

An irrelevant regressor costs no bias, only variance, and the price grows with its correlation with the relevant columns: for one extra column the variance of a coefficient is multiplied by $1/(1 - r^2)$, with r the partial correlation of the two regressors ([Eq. 6.6.2](#)).

19.1.4 Bias against variance

When β_2 is small but not zero, the short regression is biased but less variable. Which is better? Compare the two estimators of β by their mean squared error matrices, writing $\hat{\beta}^S = ((\hat{\beta}_1^S)^\top, \mathbf{0}^\top)^\top$ for the short estimator, which sets β_2 to zero.

Lemma 19.1.4 — A rank-one comparison

Let $\mathbf{C}$ be a positive definite $q \times q$ matrix, $\mathbf{b} \in \mathbb{R}^q$ and $c > 0$. Then $c\mathbf{C} - \mathbf{b}\mathbf{b}^\top$ is nonnegative definite iff $\mathbf{b}^\top \mathbf{C}^{-1} \mathbf{b} \leq c$.

Proof. By [Lemma 12.2.3](#) with $\mathbf{W} = \mathbf{C}$ and $\mathbf{u} = \mathbf{b}$, the inequality $\mathbf{b}^\top \mathbf{C}^{-1} \mathbf{b} \leq c$ holds iff $(\mathbf{a}^\top \mathbf{b})^2 \leq c \mathbf{a}^\top \mathbf{C} \mathbf{a}$ for every $\mathbf{a}$, that is, iff $\mathbf{a}^\top (c\mathbf{C} - \mathbf{b}\mathbf{b}^\top) \mathbf{a} \geq 0$ for every $\mathbf{a}$. ■

Theorem 19.1.5 — When the short regression wins

In the setting of this section, let $\mathbf{G} = \begin{pmatrix} -\mathbf{\Pi} \\ \mathbf{I}_{p_2} \end{pmatrix}$, a $p \times p_2$ matrix.

- (a) The mean squared error matrix of $\hat{\boldsymbol{\beta}}^S$ is

$$E[(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})^\top] = \text{Cov}(\hat{\boldsymbol{\beta}}) - \mathbf{G}(\sigma^2 \mathbf{C} - \boldsymbol{\beta}_2 \boldsymbol{\beta}_2^\top) \mathbf{G}^\top.$$

- (b) $E(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}^S - \boldsymbol{\lambda}^\top \boldsymbol{\beta})^2 \leq \text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}})$ for every $\boldsymbol{\lambda} \in \mathbb{R}^p$ iff $\gamma \leq 1$. If $\gamma > 1$, the reverse strict inequality holds for some $\boldsymbol{\lambda}$.
- (c) Over the design points, $E\|\mathbf{X}\hat{\boldsymbol{\beta}}^S - \mathbf{X}\boldsymbol{\beta}\|^2 = \sigma^2(p_1 + \gamma)$, against $\sigma^2 p$ for the long fit. The short fit is better there iff $\gamma < p_2$.

Proof.

- (a) By Lemma 19.1.1(a), $\hat{\boldsymbol{\beta}} = \hat{\boldsymbol{\beta}}^S + \mathbf{G}\hat{\boldsymbol{\beta}}_2$, and $\hat{\boldsymbol{\beta}}^S$ is uncorrelated with $\hat{\boldsymbol{\beta}}_2$ by part (b) of the lemma. Since $E(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta}$ and $E(\hat{\boldsymbol{\beta}}_2) = \boldsymbol{\beta}_2$, $E(\hat{\boldsymbol{\beta}}^S) - \boldsymbol{\beta} = -\mathbf{G}\boldsymbol{\beta}_2$. Expand $\text{Cov}(\hat{\boldsymbol{\beta}}) = E[(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta} + \mathbf{G}\hat{\boldsymbol{\beta}}_2)(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta} + \mathbf{G}\hat{\boldsymbol{\beta}}_2)^\top]$. The cross term is $E[(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})\hat{\boldsymbol{\beta}}_2^\top] = \text{Cov}(\hat{\boldsymbol{\beta}}^S, \hat{\boldsymbol{\beta}}_2) + (E\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})\boldsymbol{\beta}_2^\top = -\mathbf{G}\boldsymbol{\beta}_2\boldsymbol{\beta}_2^\top$, and $E(\hat{\boldsymbol{\beta}}_2\hat{\boldsymbol{\beta}}_2^\top) = \sigma^2 \mathbf{C} + \boldsymbol{\beta}_2\boldsymbol{\beta}_2^\top$. So

$$\text{Cov}(\hat{\boldsymbol{\beta}}) = E[(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})(\hat{\boldsymbol{\beta}}^S - \boldsymbol{\beta})^\top] + \mathbf{G}(\sigma^2 \mathbf{C} + \boldsymbol{\beta}_2\boldsymbol{\beta}_2^\top - 2\boldsymbol{\beta}_2\boldsymbol{\beta}_2^\top) \mathbf{G}^\top.$$

- (b) Put $\mathbf{A} = \sigma^2 \mathbf{C} - \boldsymbol{\beta}_2\boldsymbol{\beta}_2^\top$. The claimed inequality for all $\boldsymbol{\lambda}$ says that $\mathbf{GAG}^\top$ is nonnegative definite. The matrix $\mathbf{L} = [\mathbf{0}, \mathbf{I}_{p_2}]$ satisfies $\mathbf{LG} = \mathbf{I}$, so $\mathbf{A} = \mathbf{L}(\mathbf{GAG}^\top)\mathbf{L}^\top$. Hence $\mathbf{GAG}^\top$ is nonnegative definite iff $\mathbf{A}$ is, and by Lemma 19.1.4 iff $\boldsymbol{\beta}_2^\top \mathbf{C}^{-1} \boldsymbol{\beta}_2 \leq \sigma^2$, which is $\gamma \leq 1$. If $\gamma > 1$, the same lemma gives $\mathbf{a}$ with $\mathbf{a}^\top \mathbf{A} \mathbf{a} < 0$, and $\boldsymbol{\lambda} = \mathbf{L}^\top \mathbf{a}$ satisfies $\mathbf{G}^\top \boldsymbol{\lambda} = \mathbf{a}$, so $\boldsymbol{\lambda}^\top \mathbf{GAG}^\top \boldsymbol{\lambda} < 0$.
- (c) $\mathbf{X}\hat{\boldsymbol{\beta}}^S = \mathbf{M}_1 \mathbf{Y}$, whose mean is $\mathbf{M}_1 \mathbf{X}\boldsymbol{\beta}$ and covariance $\sigma^2 \mathbf{M}_1$. So $E\|\mathbf{M}_1 \mathbf{Y} - \mathbf{X}\boldsymbol{\beta}\|^2 = \sigma^2 p_1 + \|(\mathbf{I} - \mathbf{M}_1)\mathbf{X}\boldsymbol{\beta}\|^2 = \sigma^2(p_1 + \gamma)$. The long fit is Theorem 19.1.3(c), whose proof did not use $\boldsymbol{\beta}_2 = \mathbf{0}$ for this part. ■

The threshold in (b) depends only on the noncentrality, not on the design or on n . It covers all linear functions at once; for a particular function the short estimator can win for larger γ , as (c) shows. Since γ is unknown, neither criterion applies directly. But the F statistic for $\boldsymbol{\beta}_2 = \mathbf{0}$ depends on the parameters only through γ (Theorem 11.1.1), so a small F is evidence that γ is small. Turning this into a procedure, and paying for having chosen the model from the data, is the subject of Chapter 29.

Example. (A biased estimator that wins)

Take $n = 30$ observations of two centred regressors with unit sample variances and sample correlation $r = 0.9$, an intercept, $\sigma = 1$ and $\beta_2 = 0.301$, chosen so that $\gamma = 0.5$. Here $\mathbf{\Pi}$ has slope entry r , so the short slope on x_1 has bias $r\beta_2 = 0.271$. Its standard deviation is 0.186, against 0.426 for the long slope, and the ratio of mean squared error to long variance is 0.595. A simulation with 200000 data sets gives 0.594.

For two standardized regressors the ratio has a closed form ([Exercise \(B2\)](#)):

$$\frac{E(\hat{\beta}_1^S - \beta_1)^2}{\text{Var}(\hat{\beta}_1)} = 1 - r^2 + r^2\gamma = 1 + r^2(\gamma - 1), \quad (19.1.2)$$

which is $1 - 0.81 + 0.81 \times 0.5 = 0.595$. The short slope wins iff $\gamma < 1$, as [Theorem 19.1.5\(b\)](#) requires, and the stakes, gain or loss, are proportional to r^2 . This is panel (a) of [Figure 19.1.1](#). The short model's s_1^2 has mean $1 + \gamma/(n-2) = 1.0179$, a bias too small to notice.

```
import numpy as np
rng = np.random.default_rng(1901)
n, r, sigma = 30, 0.9, 1.0

# two centred, unit-variance regressors with sample correlation exactly r:
# orthonormalize (1, z1, z2) and keep the last two columns, which are centred
Z = np.linalg.qr(np.column_stack([np.ones(n), rng.normal(size=(n, 2))]))[0][:, 1:]
Z *= np.sqrt(n - 1)
x1 = Z[:, 0]
x2 = r * Z[:, 0] + np.sqrt(1 - r**2) * Z[:, 1]
X1 = np.column_stack([np.ones(n), x1])          # the short model
X = np.column_stack([X1, x2])                  # the long model

M1 = X1 @ np.linalg.solve(X1.T @ X1, X1.T)
S22_1 = x2 @ (np.eye(n) - M1) @ x2              # ||(I - M1) x2||^2
beta2 = np.sqrt(0.5 * sigma**2 / S22_1)          # chosen so that gamma = 0.5
gamma = beta2**2 * S22_1 / sigma**2

var_long = sigma**2 * np.linalg.inv(X.T @ X)[1, 1] # Var of the long slope on x1
Pi = np.linalg.solve(X1.T @ X1, X1.T @ x2)[1]    # slope of x2 on x1
var_short = sigma**2 * np.linalg.inv(X1.T @ X1)[1, 1]
mse_short = var_short + (Pi * beta2) ** 2          # variance + squared bias
print(f"gamma = {gamma:.3f}, MSE(short)/Var(long) = {mse_short / var_long:.4f}")
print(f"formula 1 - r^2 + r^2 gamma = {1 - r**2 + r**2 * gamma:.4f}")

reps = 200_000
beta = np.array([1.0, 1.0, beta2])
Y = X @ beta + sigma * rng.normal(size=(reps, n))
b_long = np.linalg.solve(X.T @ X, X.T @ Y.T)[1]
b_short = np.linalg.solve(X1.T @ X1, X1.T @ Y.T)[1]
print("simulated MSE ratio:", np.mean((b_short - 1) ** 2) / np.mean((b_long - 1) ** 2))
```

Example. (Choosing a polynomial degree)

Part (c) of [Theorem 19.1.5](#) applies to any nested sequence of models. Take $n = 40$ equally spaced points on $[-1, 1]$, the mean $\mu(x) = e^x \sin 3x$, which is not a polynomial, and $\sigma = 0.25$. A polynomial of degree d has $p = d + 1$ columns, and its risk at the design points is $\sigma^2(d + 1) + \|(\mathbf{I} - \mathbf{M}_d)\boldsymbol{\mu}\|^2$. Panel (b) of [Figure 19.1.1](#) shows the two terms. In units of σ^2 the risk is 161.41 for a straight line, falls to 5.52 at degree 4, and climbs back to 11.00 at degree 10, where the fit is almost unbiased and pays only for its variance. [Exercise \(B3\)](#) shows that adding one term lowers the risk iff that term's own noncentrality exceeds 1.

Figure 19.1.1: (a) Mean squared error of the short slope relative to the variance of the long slope, Eq. 19.1.2, for three correlations. All lines cross at $\gamma = 1$; the point is the simulation of Example (A biased estimator that wins). (b) Squared bias, variance and their sum for polynomial fits of increasing degree (Example (Choosing a polynomial degree)), in units of σ^2 and on a logarithmic scale.

Idea. Omitting a regressor that matters costs bias; keeping one that does not costs variance, and for $\gamma < 1$ the bias is the cheaper. This does not make the biased coefficient *interpretable*: it still estimates $\beta_1 + \Pi\beta_2$, and whether that answers the question is a matter for Chapter 25.

19.1.5 Exercises

19.1.5.1 A. Check your understanding

Exercise A1.

A straight line is fitted at $x = 0, 1, 2, 3$ when the true mean is $\beta_0 + \beta_1 x + \beta_2 x^2$. Find the biases of the fitted intercept and slope.

Exercise A2.

True or false: if the omitted regressors are orthogonal to the included ones ($\mathbf{X}_1^\top \mathbf{X}_2 = \mathbf{0}$), the short regression is harmless, including its estimate of σ^2 .

19.1.5.2 B. Practice

Exercise B1.

In Exercise (A1), show that $\|(\mathbf{I} - \mathbf{M}_1)\mathbf{X}_2\|^2 = 4$. For which values of β_2/σ does the straight line have a smaller mean squared error matrix than the quadratic fit, in the sense of Theorem 19.1.5(b)? For which values is it better at the four design points?

Exercise B2.

Derive Eq. 19.1.2. Take an intercept and two centred regressors with $\|\mathbf{x}_1\|^2 = \|\mathbf{x}_2\|^2 = S$ and sample correlation r . Show that $\text{Var}(\hat{\beta}_1) = \sigma^2/(S(1-r^2))$, that the short slope has variance σ^2/S and bias $r\beta_2$, and that $\gamma = \beta_2^2 S(1-r^2)/\sigma^2$.

Solution. The long variance is Eq. 6.6.2 with $R_1^2 = r^2$. The short slope is $\mathbf{x}_1^\top \mathbf{Y}/S$, with variance σ^2/S and mean $\beta_1 + \beta_2 \mathbf{x}_1^\top \mathbf{x}_2/S = \beta_1 + r\beta_2$. The residual of $\mathbf{x}_2$ after regression on $(\mathbf{1}, \mathbf{x}_1)$ has squared length $S(1-r^2)$, which gives γ . Then $(\sigma^2/S + r^2\beta_2^2)S(1-r^2)/\sigma^2 = 1 - r^2 + r^2\gamma$.

Exercise B3.

Let $\mathcal{C}(\mathbf{X}_1) \subset \mathcal{C}(\mathbf{X}_2) \subset \dots$ be nested model spaces with dimensions $p_1 < p_2 < \dots$, and let $\boldsymbol{\mu} = \mathbf{E}(\mathbf{Y})$ be arbitrary. Show that the risk $\mathbf{E}\|\mathbf{M}_k \mathbf{Y} - \boldsymbol{\mu}\|^2$ of model k exceeds that of model $k+1$ iff $\gamma_k = \|(\mathbf{M}_{k+1} - \mathbf{M}_k)\boldsymbol{\mu}\|^2/\sigma^2 > p_{k+1} - p_k$.

Solution. As in Theorem 19.1.5(c), the risk of model k is $\sigma^2 p_k + \|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2$. By Theorem 6.5.1, $\mathbf{I} - \mathbf{M}_k = (\mathbf{I} - \mathbf{M}_{k+1}) + (\mathbf{M}_{k+1} - \mathbf{M}_k)$ with orthogonal ranges, so $\|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2 = \|(\mathbf{I} - \mathbf{M}_{k+1})\boldsymbol{\mu}\|^2 + \sigma^2 \gamma_k$. The difference of the two risks is $\sigma^2(\gamma_k - (p_{k+1} - p_k))$.

19.1.5.3 C. Going deeper**Exercise C1.**

Assume normal errors. Compare s_1^2 (short) and s^2 (long) as estimators of σ^2 by mean squared error, when $\boldsymbol{\beta}_2 \neq \mathbf{0}$. Show that s_1^2 is better iff $2(n - p_1) + 4\gamma + \gamma^2 < 2(n - p_1)^2/(n - p)$, and interpret the condition when n is large.

19.2 An incorrect covariance matrix

Suppose the mean is right but the errors are correlated or have unequal variances. Write

$$\mathbf{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{V}, \quad (19.2.1)$$

with $\mathbf{V}$ positive definite and $\mathbf{X}$ of full rank $p < n$. The analyst fits ordinary least squares and reports $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ as if $\mathbf{V} = \mathbf{I}$. Two things go wrong: $\hat{\boldsymbol{\beta}}$ is no longer the best linear unbiased estimator (Corollary 7.2.3), and $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ no longer estimates its covariance. The second failure is usually much more serious.

19.2.1 What happens to the estimator and its standard error

The bounds below need a fact about traces of projections, a special case of an inequality of Ky Fan.

Lemma 19.2.1 — Trace of a compressed matrix

Let $\mathbf{A}$ be symmetric with eigenvalues $\lambda_1 \geq \cdots \geq \lambda_n$, and let $\mathbf{P}$ be a symmetric idempotent matrix of rank k . Then

$$\sum_{i=n-k+1}^n \lambda_i \leq \operatorname{tr}(\mathbf{P}\mathbf{A}) \leq \sum_{i=1}^k \lambda_i.$$

Proof. By Theorem 1.7.2, $\mathbf{A} = \sum_i \lambda_i \mathbf{q}_i \mathbf{q}_i^\top$ with orthonormal $\mathbf{q}_i$. So $\operatorname{tr}(\mathbf{P}\mathbf{A}) = \sum_i \lambda_i w_i$ with $w_i = \mathbf{q}_i^\top \mathbf{P} \mathbf{q}_i = \|\mathbf{P} \mathbf{q}_i\|^2$. Each w_i lies in $[0, 1]$ because the eigenvalues of $\mathbf{P}$ are 0 or 1 (Proposition 6.3.4), so $0 \leq \mathbf{q}_i^\top \mathbf{P} \mathbf{q}_i \leq \mathbf{q}_i^\top \mathbf{q}_i = 1$, and $\sum_i w_i = \operatorname{tr}(\mathbf{P} \sum_i \mathbf{q}_i \mathbf{q}_i^\top) = \operatorname{tr} \mathbf{P} = k$. Then

$$\begin{aligned} \sum_i \lambda_i w_i - \sum_{i \leq k} \lambda_i &= \sum_{i \leq k} \lambda_i (w_i - 1) + \sum_{i > k} \lambda_i w_i \\ &\leq \lambda_k \sum_{i \leq k} (w_i - 1) + \lambda_k \sum_{i > k} w_i = \lambda_k \left(\sum_i w_i - k \right) = 0, \end{aligned}$$

since $w_i - 1 \leq 0$ and $\lambda_i \geq \lambda_k$ for $i \leq k$, while $w_i \geq 0$ and $\lambda_i \leq \lambda_k$ for $i > k$. The lower bound follows by applying this to $-\mathbf{A}$. ■

Theorem 19.2.2 — Least squares under a wrong covariance

Under Eq. 19.2.1, let $\mathbf{a} \in \mathbb{R}^p$ be nonzero and let $v = s^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}$ be the usual estimate of $\operatorname{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}})$.

- (a) $E(\hat{\boldsymbol{\beta}}) = \boldsymbol{\beta}$ and $\operatorname{Cov}(\hat{\boldsymbol{\beta}}) = \sigma^2 (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V} \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1}$.
- (b) $E(s^2) = \sigma^2 \operatorname{tr}((\mathbf{I} - \mathbf{M})\mathbf{V}) / (n - p)$.
- (c) With $\mathbf{u} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a} / \|\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}\|$, a unit vector in $\mathcal{C}(\mathbf{X})$,

$$\frac{E(v)}{\operatorname{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}})} = \frac{\operatorname{tr}((\mathbf{I} - \mathbf{M})\mathbf{V}) / (n - p)}{\mathbf{u}^\top \mathbf{V} \mathbf{u}}. \quad (19.2.2)$$

- (d) Let $\lambda_1 \geq \cdots \geq \lambda_n > 0$ be the eigenvalues of $\mathbf{V}$, let $\bar{\lambda}_-$ be the mean of the $n - p$ smallest and $\bar{\lambda}_+$ the mean of the $n - p$ largest. Then

$$\frac{\bar{\lambda}_-}{\lambda_1} \leq \frac{E(v)}{\operatorname{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}})} \leq \frac{\bar{\lambda}_+}{\lambda_n}.$$

Proof.

- (a) is [Proposition 5.5.7\(b\)](#) with $\Sigma = \sigma^2 \mathbf{V}$. (b) is [Theorem 2.3.1](#) with the mean term vanishing, since $(\mathbf{I} - \mathbf{M})\mathbf{X}\boldsymbol{\beta} = \mathbf{0}$. (c) Put $\mathbf{c} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\mathbf{a}$. By (a), $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) = \sigma^2 \mathbf{c}^\top \mathbf{V} \mathbf{c}$, and $\mathbf{c}^\top \mathbf{c} = \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}$. By (b), $E(v) = \sigma^2 \mathbf{c}^\top \mathbf{c} \text{tr}((\mathbf{I} - \mathbf{M})\mathbf{V})/(n - p)$. Divide, and write $\mathbf{u} = \mathbf{c}/\|\mathbf{c}\|$.
- (b) $\mathbf{I} - \mathbf{M}$ is symmetric idempotent of rank $n - p$, so by [Lemma 19.2.1](#) the numerator of [Eq. 19.2.2](#) lies in $[\bar{\lambda}_-, \bar{\lambda}_+]$. By [Theorem 1.7.7](#) the denominator lies in $[\lambda_n, \lambda_1]$. ■

Part (c) shows what the usual standard error gets wrong. The numerator of [Eq. 19.2.2](#) averages $\mathbf{V}$ over the residual space, which is what s^2 measures. The denominator evaluates $\mathbf{V}$ in the one direction $\mathbf{u}$ that $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ uses. When the errors vary more along $\mathbf{u}$ than on average, the usual standard error is too small. The bounds in (d), due to Swindel (1968), hold for every design and linear function and can be attained ([Exercise \(C1\)](#)). They are typically wide.

19.2.2 When ordinary least squares loses little

Generalized least squares has variance $\sigma^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{a}$ for $\mathbf{a}^\top \boldsymbol{\beta}$ ([Corollary 7.2.3](#)). How much larger can the variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ be? The answer again depends only on the extreme eigenvalues of $\mathbf{V}$.

Theorem 19.2.3 — Efficiency of least squares

Under [Eq. 19.2.1](#), with λ_1 and λ_n the largest and smallest eigenvalues of $\mathbf{V}$,

$$\frac{\mathbf{a}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \mathbf{a}}{\mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V} \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}} \geq \frac{4\lambda_1 \lambda_n}{(\lambda_1 + \lambda_n)^2}$$

for every $\mathbf{a} \neq \mathbf{0}$. The bound is attained for $p = 1$ and $\mathbf{X} = \mathbf{x} = (\mathbf{q}_1 + \mathbf{q}_n)/\sqrt{2}$, where $\mathbf{q}_1, \mathbf{q}_n$ are unit eigenvectors for λ_1, λ_n .

Proof. Write $\mathbf{X} = \mathbf{Q}\mathbf{R}$ with $\mathbf{Q}$ having orthonormal columns and $\mathbf{R}$ nonsingular ([Theorem 1.5.2](#)), and put $\mathbf{b} = \mathbf{R}^{-\top} \mathbf{a}$, $\mathbf{A} = \mathbf{Q}^\top \mathbf{V} \mathbf{Q}$ and $\mathbf{B} = \mathbf{Q}^\top \mathbf{V}^{-1} \mathbf{Q}$, both positive definite. Then $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{V} \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1} = \mathbf{R}^{-1} \mathbf{A} \mathbf{R}^{-\top}$ and $(\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} = \mathbf{R}^{-1} \mathbf{B}^{-1} \mathbf{R}^{-\top}$, so the ratio is $\mathbf{b}^\top \mathbf{B}^{-1} \mathbf{b} / \mathbf{b}^\top \mathbf{A} \mathbf{b}$. It suffices to show $\mathbf{A} \leq \kappa \mathbf{B}^{-1}$ in the nonnegative definite order, with $\kappa = (\lambda_1 + \lambda_n)^2 / (4\lambda_1 \lambda_n)$.

Every eigenvalue λ of $\mathbf{V}$ satisfies $(\lambda - \lambda_1)(\lambda - \lambda_n) \leq 0$, that is, $\lambda + \lambda_1 \lambda_n / \lambda \leq \lambda_1 + \lambda_n$. By the spectral decomposition this says $\mathbf{V} + \lambda_1 \lambda_n \mathbf{V}^{-1} \leq (\lambda_1 + \lambda_n) \mathbf{I}$. Multiplying by $\mathbf{Q}^\top$ on the left and $\mathbf{Q}$ on the right preserves the order, so

$$\mathbf{A} \leq (\lambda_1 + \lambda_n) \mathbf{I} - \lambda_1 \lambda_n \mathbf{B}.$$

Now let $\mu > 0$ be any eigenvalue of $\mathbf{B}$. By the inequality between arithmetic and geometric means, $\kappa/\mu + \lambda_1 \lambda_n \mu \geq 2\sqrt{\kappa \lambda_1 \lambda_n} = \lambda_1 + \lambda_n$. Applied along the eigenvectors of $\mathbf{B}$, this gives $(\lambda_1 + \lambda_n) \mathbf{I} - \lambda_1 \lambda_n \mathbf{B} \leq \kappa \mathbf{B}^{-1}$, and hence $\mathbf{A} \leq \kappa \mathbf{B}^{-1}$.

For the attainment, with $\mathbf{x} = (\mathbf{q}_1 + \mathbf{q}_n)/\sqrt{2}$ we have $\mathbf{x}^\top \mathbf{x} = 1$, $\mathbf{x}^\top \mathbf{V} \mathbf{x} = (\lambda_1 + \lambda_n)/2$ and

$\mathbf{x}^\top \mathbf{V}^{-1} \mathbf{x} = (1/\lambda_1 + 1/\lambda_n)/2$. The ratio is $1/((\mathbf{x}^\top \mathbf{V} \mathbf{x})(\mathbf{x}^\top \mathbf{V}^{-1} \mathbf{x})) = 4\lambda_1\lambda_n/(\lambda_1 + \lambda_n)^2$. ■

The scalar inequality behind the proof, $(\mathbf{x}^\top \mathbf{V} \mathbf{x})(\mathbf{x}^\top \mathbf{V}^{-1} \mathbf{x}) \leq \kappa(\mathbf{x}^\top \mathbf{x})^2$, is Kantorovich's inequality, and the proof above is a matrix form of it. Bloomfield and Watson (1975) and Knott (1975) found the corresponding sharp bound when efficiency is measured by the determinant of the whole covariance matrix.

The bound is a worst case over all designs. For particular designs ordinary least squares can be fully efficient. Kruskal's theorem (Theorem 6.9.3) says that $\hat{\boldsymbol{\beta}}$ equals the generalized least squares estimate for every $\mathbf{Y}$ iff $\mathcal{C}(\mathbf{V}\mathbf{X}) \subseteq \mathcal{C}(\mathbf{X})$, and then the efficiency is one. Even then the standard errors may be wrong.

Example. (Equicorrelated errors)

Let $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top$, with $-1/(n-1) < \rho < 1$ so that $\mathbf{V}$ is positive definite, and let the model contain an intercept, $\mathbf{X} = [\mathbf{1}, \mathbf{X}_1]$. It arises when all observations share one random shock. Since $\mathbf{V}\mathbf{X} = (1 - \rho)\mathbf{X} + \rho\mathbf{1}(\mathbf{1}^\top \mathbf{X})$ has columns in $\mathcal{C}(\mathbf{X})$, Kruskal's condition holds and $\hat{\boldsymbol{\beta}}$ is the best linear unbiased estimator. Its covariance is not $\sigma^2(\mathbf{X}^\top \mathbf{X})^{-1}$, however. Because $\mathbf{X}\mathbf{e}_1 = \mathbf{1}$ for the first standard basis vector $\mathbf{e}_1$, we have $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{1} = \mathbf{e}_1$, and Theorem 19.2.2(a) gives

$$\text{Cov}(\hat{\boldsymbol{\beta}}) = \sigma^2(1 - \rho)(\mathbf{X}^\top \mathbf{X})^{-1} + \sigma^2\rho\mathbf{e}_1\mathbf{e}_1^\top.$$

By Exercise (B2), $E(s^2) = \sigma^2(1 - \rho)$. So $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ is exactly unbiased for the covariance of the slopes, whose information comes from comparisons in which the common shock cancels. For the intercept it misses the term $\sigma^2\rho$. When $\rho > 0$ this term does not shrink as n grows, so the intercept is not even consistent, and its reported standard error goes to zero anyway (Exercise (B2)). The same holds for any fitted mean $\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}$, since $\mathbf{x}_0^\top \mathbf{e}_1 = 1$ whenever $\mathbf{x}_0$ has a leading 1.

19.2.3 Autocorrelated errors

Example. (A trend with autocorrelated errors)

Take $n = 20$ equally spaced times and errors with $v_{st} = \rho^{|s-t|}$, the covariance of a stationary first-order autoregression, with $\rho = 0.6$. Fit a straight line in two designs, a linear trend $x_t = t$ and an alternating regressor $x_t = (-1)^t$. For the trend, the expected usual variance of the slope is 0.256 times its true variance, so the root of the expected usual variance is 0.506 of the true standard error. Yet ordinary least squares is nearly efficient: generalized least squares has 0.905 of its variance. For the alternating regressor the error goes the other way. The ratio is 3.271, so the standard error is too large by a factor 1.809, and the efficiency is 0.950. Swindel's bounds for this $\mathbf{V}$ are 0.193 and 4.31, so both designs lie well towards the extremes. The Kantorovich bound, 0.2351 from $\lambda_1 = 3.757$ and $\lambda_n = 0.2514$, is far below either efficiency.

In 100000 simulated series with normal errors, the nominal 95% t interval for the slope

covered the true value in 0.693 of them for the trend and 0.9976 for the alternating regressor. Figure 19.2.1 shows the whole range of ρ .

```
import numpy as np
n = 20
t = np.arange(1, n + 1)
designs = {"trend": t.astype(float), "alternating": (-1.0) ** t}

def ar1(rho):
    return rho ** np.abs(t[:, None] - t[None, :])

def slope_summary(x, V):
    """True variance, mean of the usual estimate, GLS variance of the slope (sigma = 1)."""
    X = np.column_stack([np.ones(n), x])
    G = np.linalg.inv(X.T @ X)
    A = G @ X.T                                # beta_hat = A y
    true_var = (A @ V @ A.T)[1, 1]              # the sandwich
    M = X @ A
    Es2 = np.trace((np.eye(n) - M) @ V) / (n - 2) # E(s^2)
    usual = Es2 * G[1, 1]                        # E of s^2 [(X'X)^{-1}]_{11}
    gls = np.linalg.inv(X.T @ np.linalg.solve(V, X))[1, 1]
    return true_var, usual, gls

rho = 0.6
for name, x in designs.items():
    true_var, usual, gls = slope_summary(x, ar1(rho))
    print(f"{name:12s} usual/true = {usual / true_var:.3f}    GLS/OLS variance = {gls / true_var:.3f}")

from scipy import stats
rng = np.random.default_rng(1902)
reps = 100_000
L = np.linalg.cholesky(ar1(rho))
E = rng.normal(size=(reps, n)) @ L.T          # rows are AR(1) error vectors
tq = stats.t.ppf(0.975, n - 2)
for name, x in designs.items():
    X = np.column_stack([np.ones(n), x])
    G = np.linalg.inv(X.T @ X)
    B = E @ (G @ X.T).T                        # beta_hat - beta, one row per
    data set
    s2 = np.sum((E - B @ X.T) ** 2, axis=1) / (n - 2)
    cover = np.mean(np.abs(B[:, 1]) <= tq * np.sqrt(s2 * G[1, 1]))
    print(f"{name:12s} coverage of the nominal 95% interval: {cover:.4f}")
```

Eq. 19.2.2 explains the pattern. A smooth regressor puts $\mathbf{u}$ along slowly varying directions, where positively correlated errors have their largest variance; an alternating one puts it where positive correlation cancels. Most time-series regressors are smooth, which is why positive autocorrelation usually makes ordinary standard errors too small.

Idea. A wrong covariance matrix is mainly a problem for *standard errors*, not *estimates*: $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ can be wrong by a large factor in either direction, and nothing in the fitted model reveals this. Chapter 21 shows how to estimate the correct covariance Eq. 5.5.3 without knowing $\mathbf{V}$, and how to detect serial correlation. Chapter 31 treats generalized least squares when $\mathbf{V}$ is known up to a few parameters (Definition 31.4.1).

Figure 19.2.1: Straight-line regression with $n = 20$ and first-order autoregressive errors. (a) The square root of the ratio of the expected usual variance of the slope to its true variance, for a trend and an alternating regressor, with Swindel's bounds (shaded). (b) The efficiency of ordinary least squares relative to generalized least squares, with the Kantorovich bound of Theorem 19.2.3.

19.2.4 Exercises

19.2.4.1 A. Check your understanding

Exercise A1.

Let $\mathbf{V} = \text{diag}(v_1, \dots, v_n)$. Show that $E(s^2) = \sigma^2 \sum_i (1 - h_{ii})v_i / (n - p)$, a weighted average of the variances $\sigma^2 v_i$.

Exercise A2.

Show that the bounds of Theorem 19.2.2(d) do not change when $\mathbf{V}$ is replaced by $c\mathbf{V}$ for $c > 0$, and that both equal 1 iff $\mathbf{V}$ is a multiple of $\mathbf{I}$.

19.2.4.2 B. Practice

Exercise B1.

For the regression through the origin $E(Y_i) = \beta x_i$ with $\text{Var}(Y_i) = \sigma^2 v_i$, show that $\text{Var}(\hat{\beta}) = \sigma^2 \sum_i h_i v_i / \sum_i x_i^2$ and $E(v) = \sigma^2 \sum_i (1 - h_i)v_i / ((n - 1) \sum_i x_i^2)$, where $h_i = x_i^2 / \sum_j x_j^2$ are the leverages. Conclude that the usual standard error is too small on average iff the leverage-weighted average of the v_i exceeds the $(1 - h_i)$ -weighted average.

Solution. $\hat{\beta} = \sum_i x_i Y_i / S$ with $S = \sum_j x_j^2$, so $\text{Var}(\hat{\beta}) = \sigma^2 \sum_i x_i^2 v_i / S^2 = \sigma^2 \sum_i h_i v_i / S$. Exercise (A1) with $p = 1$ gives $E(s^2)$, and $v = s^2 / S$. The weights h_i sum to 1, and so do $(1 - h_i) / (n - 1)$. The usual variance is too small on average iff $\sum_i h_i v_i > \sum_i (1 - h_i)v_i / (n - 1)$. In particular, when the error variance grows with $|x_i|$, the points that dominate $\hat{\beta}$ are the noisiest, and the usual standard error understates the truth.

Exercise B2.

In [Example \(Equicorrelated errors\)](#) with $\rho > 0$, show that $\text{Var}(\hat{\beta}_0) \geq \sigma^2 \rho$ for every n , while $E(v) \rightarrow 0$ for the intercept when $[(\mathbf{X}^\top \mathbf{X})^{-1}]_{11} \rightarrow 0$. Explain the result by writing $\varepsilon_i = \sqrt{\rho} \sigma Z + \sqrt{1-\rho} \sigma U_i$ with independent standardized $Z, U_1, \dots, U_n$.

Solution. From the covariance in the example, $\text{Var}(\hat{\beta}_0) = \sigma^2(1-\rho)[(\mathbf{X}^\top \mathbf{X})^{-1}]_{11} + \sigma^2 \rho \geq \sigma^2 \rho$, while $E(v) = \sigma^2(1-\rho)[(\mathbf{X}^\top \mathbf{X})^{-1}]_{11}$. The representation has covariance $\sigma^2 \rho \mathbf{1}\mathbf{1}^\top + \sigma^2(1-\rho)\mathbf{I} = \sigma^2 \mathbf{V}$. The shared term $\sqrt{\rho} \sigma Z \mathbf{1}$ lies in $\mathcal{C}(\mathbf{X})$ and is absorbed entirely by the intercept, since $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{1} = \mathbf{e}_1$. It never averages out, and it leaves no trace in the residuals, so s^2 cannot see it.

19.2.4.3 C. Going deeper**Exercise C1.**

Show that both bounds of [Theorem 19.2.2\(d\)](#) are attained. *Hint:* take $\mathcal{C}(\mathbf{X})$ spanned by eigenvectors of $\mathbf{V}$, and choose $\mathbf{a}$ so that $\mathbf{u}$ is one of them.

Solution. Let $\mathbf{q}_1, \dots, \mathbf{q}_n$ be orthonormal eigenvectors for $\lambda_1 \geq \dots \geq \lambda_n$. If $\mathbf{X} = [\mathbf{q}_1, \dots, \mathbf{q}_p]$, then $\mathbf{I} - \mathbf{M} = \sum_{i>p} \mathbf{q}_i \mathbf{q}_i^\top$ and $\text{tr}((\mathbf{I} - \mathbf{M})\mathbf{V}) = \sum_{i>p} \lambda_i = (n-p)\bar{\lambda}_-$. With $\mathbf{a} = \mathbf{e}_1$, $\mathbf{u} = \mathbf{q}_1$ and $\mathbf{u}^\top \mathbf{V} \mathbf{u} = \lambda_1$, so the ratio [Eq. 19.2.2](#) equals $\bar{\lambda}_-/\lambda_1$. Symmetrically, $\mathbf{X} = [\mathbf{q}_{n-p+1}, \dots, \mathbf{q}_n]$ and $\mathbf{u} = \mathbf{q}_n$ give $\bar{\lambda}_+/\lambda_n$.

19.3 Non-normal errors

Normality entered Part III at one point only: it turned the moments of $\hat{\boldsymbol{\beta}}$ and s^2 into exact distributions ([Theorem 7.5.1](#)). Everything that needs only two moments holds for any error distribution with finite variance. Inference about the mean structure survives in large samples, provided no single observation dominates the fit. Inference about σ^2 does not survive at any sample size, and neither does prediction of a single new response.

Throughout, the errors $\varepsilon_1, \dots, \varepsilon_n$ are independent and identically distributed with mean 0 and variance $\sigma^2 \in (0, \infty)$, from a distribution that does not change with n . Where fourth moments are needed, the *excess kurtosis* is $\kappa = \mu_4/\sigma^4 - 3$, where $\mu_4 = E(\varepsilon_i^4)$. It is zero for normal errors, 6 for centred exponential errors, -1.2 for uniform errors, and at least -2 for every distribution, since $\mu_4 \geq \sigma^4$ by Jensen's inequality.

19.3.1 Asymptotic normality of least squares

Large-sample statements concern a sequence of models $\mathbf{Y}_n = \mathbf{X}_n \boldsymbol{\beta} + \boldsymbol{\varepsilon}_n$, $n = 1, 2, \dots$, with p fixed and $\mathbf{X}_n$ of rank p . We write $h_n^* = \max_i h_{ii}$ for the largest leverage of $\mathbf{X}_n$. Besides the three limit theorems recalled in [Section 14.4](#) (the central limit theorem, Slutsky's lemma and the delta method), we need two more standard results of probability theory.

Remark (Two more limit theorems).

- (i) *Lindeberg–Feller*. For each n let $Z_{n1}, \dots, Z_{nn}$ be independent with mean zero and $\sum_i \text{Var}(Z_{ni}) = 1$. If $\sum_i E[Z_{ni}^2 \mathbf{1}\{|Z_{ni}| > \eta\}] \rightarrow 0$ for every $\eta > 0$, then $\sum_i Z_{ni} \rightarrow N(0, 1)$ in distribution (Billingsley 1995, section 27).
- (ii) *Cramér–Wold and continuous mapping*. Random vectors $\mathbf{T}_n$ in $\mathbb{R}^q$ converge in distribution to $\mathbf{T}$ iff $\mathbf{c}^\top \mathbf{T}_n \rightarrow \mathbf{c}^\top \mathbf{T}$ for every $\mathbf{c} \in \mathbb{R}^q$, and then $g(\mathbf{T}_n) \rightarrow g(\mathbf{T})$ for every continuous g (van der Vaart 1998, chapter 2).

Lemma 19.3.1 — Weighted sums of errors

Let $\mathbf{w}_n = (w_{n1}, \dots, w_{nn})^\top$ be constant vectors with $\|\mathbf{w}_n\| = 1$ and $m_n = \max_i |w_{ni}| \rightarrow 0$. Then $\sigma^{-1} \sum_i w_{ni} \varepsilon_i \rightarrow N(0, 1)$ in distribution.

Proof. Put $Z_{ni} = w_{ni} \varepsilon_i / \sigma$, so that $\sum_i \text{Var}(Z_{ni}) = \sum_i w_{ni}^2 = 1$. With $U = \varepsilon_1 / \sigma$, for every $\eta > 0$,

$$\begin{aligned} \sum_i E[Z_{ni}^2 \mathbf{1}\{|Z_{ni}| > \eta\}] &= \sum_i w_{ni}^2 E[U^2 \mathbf{1}\{|w_{ni} U| > \eta\}] \\ &\leq E[U^2 \mathbf{1}\{|U| > \eta/m_n\}], \end{aligned}$$

because $|w_{ni}| \leq m_n$ and the weights w_{ni}^2 sum to one. Since $E U^2 = 1$ and $\eta/m_n \rightarrow \infty$, the right side tends to zero by dominated convergence. The Lindeberg–Feller theorem applies. ■

Theorem 19.3.2 — Least squares with non-normal errors

In the sequence of models above, suppose $h_n^* \rightarrow 0$. Let $s^2 = \|(\mathbf{I} - \mathbf{M})\mathbf{Y}_n\|^2 / (n - p)$.

- (a) For every sequence of nonzero vectors $\mathbf{a}_n \in \mathbb{R}^p$,

$$\frac{\mathbf{a}_n^\top \hat{\boldsymbol{\beta}} - \mathbf{a}_n^\top \boldsymbol{\beta}}{\sigma \sqrt{\mathbf{a}_n^\top (\mathbf{X}_n^\top \mathbf{X}_n)^{-1} \mathbf{a}_n}} \rightarrow N(0, 1) \quad \text{in distribution.}$$

- (b) $s^2 \rightarrow \sigma^2$ in probability. This part does not need $h_n^* \rightarrow 0$.
- (c) The t statistic, with s in place of σ in (a), tends to $N(0, 1)$, and the nominal $1 - \alpha$ interval $\mathbf{a}_n^\top \hat{\boldsymbol{\beta}} \pm t_{n-p, \alpha/2} s \sqrt{\mathbf{a}_n^\top (\mathbf{X}_n^\top \mathbf{X}_n)^{-1} \mathbf{a}_n}$ has coverage tending to $1 - \alpha$.
- (d) Let $\boldsymbol{\Lambda}$ be a fixed $p \times q$ matrix of rank q , and suppose $\boldsymbol{\Lambda}^\top \boldsymbol{\beta} = \mathbf{d}$. The statistic

$$F_n = \frac{(\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}} - \mathbf{d})^\top [\boldsymbol{\Lambda}^\top (\mathbf{X}_n^\top \mathbf{X}_n)^{-1} \boldsymbol{\Lambda}]^{-1} (\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}} - \mathbf{d})}{q s^2}$$

satisfies $q F_n \rightarrow \chi^2(q)$ in distribution, and $\Pr\{F_n > F_\alpha(q, n - p)\} \rightarrow \alpha$.

Proof.

- (a) Put $\mathbf{G}_n = (\mathbf{X}_n^\top \mathbf{X}_n)^{-1}$ and $\tau_n^2 = \mathbf{a}_n^\top \mathbf{G}_n \mathbf{a}_n$. Since $\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} = \mathbf{G}_n \mathbf{X}_n^\top \boldsymbol{\varepsilon}_n$, the nu-

erator is $\sum_i c_{ni}\varepsilon_i$ with $c_{ni} = \mathbf{a}_n^\top \mathbf{G}_n \mathbf{x}_{(i)}$, and $\sum_i c_{ni}^2 = \mathbf{a}_n^\top \mathbf{G}_n \mathbf{X}_n^\top \mathbf{X}_n \mathbf{G}_n \mathbf{a}_n = \tau_n^2$. The Cauchy–Schwarz inequality in the inner product $\langle \mathbf{u}, \mathbf{v} \rangle = \mathbf{u}^\top \mathbf{G}_n \mathbf{v}$ (Proposition 1.1.1 applied to $\mathbf{G}_n^{1/2} \mathbf{a}_n$ and $\mathbf{G}_n^{1/2} \mathbf{x}_{(i)}$) gives

$$c_{ni}^2 \leq (\mathbf{a}_n^\top \mathbf{G}_n \mathbf{a}_n)(\mathbf{x}_{(i)}^\top \mathbf{G}_n \mathbf{x}_{(i)}) = \tau_n^2 h_{ii}.$$

So $w_{ni} = c_{ni}/\tau_n$ has unit length and $\max_i |w_{ni}| \leq \sqrt{h_n^*} \rightarrow 0$. Apply Lemma 19.3.1.

- (b) $(n-p)s^2 = \boldsymbol{\varepsilon}_n^\top \boldsymbol{\varepsilon}_n - \boldsymbol{\varepsilon}_n^\top \mathbf{M} \boldsymbol{\varepsilon}_n$, since $(\mathbf{I} - \mathbf{M})\mathbf{X}_n \boldsymbol{\beta} = \mathbf{0}$. By the weak law of large numbers, $\boldsymbol{\varepsilon}_n^\top \boldsymbol{\varepsilon}_n/n \rightarrow \sigma^2$ in probability. The second term is nonnegative with $E(\boldsymbol{\varepsilon}_n^\top \mathbf{M} \boldsymbol{\varepsilon}_n) = \sigma^2 \text{tr} \mathbf{M} = \sigma^2 p$ (Theorem 2.3.1), so by Markov's inequality $\Pr(\boldsymbol{\varepsilon}_n^\top \mathbf{M} \boldsymbol{\varepsilon}_n/n > \delta) \leq \sigma^2 p/(n\delta) \rightarrow 0$. Since $n/(n-p) \rightarrow 1$, $s^2 \rightarrow \sigma^2$. Under a finite fourth moment this is Corollary 5.6.4; the argument here needs only a finite variance.
- (c) The t statistic is the ratio in (a) multiplied by $\sigma/s \rightarrow 1$, so Slutsky's lemma gives the limit. The quantile $t_{n-p, \alpha/2}$ tends to $z_{\alpha/2}$, because the $t(\nu)$ distribution tends to $N(0, 1)$ and the normal distribution function is continuous and strictly increasing. Hence $|T_n| - t_{n-p, \alpha/2} \rightarrow |Z| - z_{\alpha/2}$, and the coverage tends to $\Pr(|Z| \leq z_{\alpha/2}) = 1 - \alpha$.
- (d) Let $\mathbf{W}_n = \boldsymbol{\Lambda}^\top \mathbf{G}_n \boldsymbol{\Lambda}$, which is positive definite, and $\mathbf{Z}_n = \mathbf{W}_n^{-1/2} \boldsymbol{\Lambda}^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})/\sigma$. Under the hypothesis the numerator of F_n is $\sigma^2 \|\mathbf{Z}_n\|^2$. For a unit vector $\mathbf{c} \in \mathbb{R}^q$, $\mathbf{c}^\top \mathbf{Z}_n = \mathbf{a}_n^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})/\sigma$ with $\mathbf{a}_n = \boldsymbol{\Lambda} \mathbf{W}_n^{-1/2} \mathbf{c}$, and $\mathbf{a}_n^\top \mathbf{G}_n \mathbf{a}_n = \mathbf{c}^\top \mathbf{W}_n^{-1/2} \mathbf{W}_n \mathbf{W}_n^{-1/2} \mathbf{c} = 1$. By (a), $\mathbf{c}^\top \mathbf{Z}_n \rightarrow N(0, 1)$, which is the law of $\mathbf{c}^\top \mathbf{Z}$ for $\mathbf{Z} \sim N_q(\mathbf{0}, \mathbf{I})$. By Cramér–Wold, $\mathbf{Z}_n \rightarrow \mathbf{Z}$, and by continuous mapping $\|\mathbf{Z}_n\|^2 \rightarrow \chi^2(q)$. Then $qF_n = \|\mathbf{Z}_n\|^2 \sigma^2/s^2 \rightarrow \chi^2(q)$ by (b) and Slutsky's lemma. Finally, $qF(q, \nu)$ is $\chi^2(q)$ divided by an independent $\chi^2(\nu)/\nu$, which tends to one, so $qF_\alpha(q, n-p)$ tends to the upper α point of $\chi^2(q)$, and the rejection probability tends to α as in (c).

■

Part (a) allows $\mathbf{a}_n$ to depend on the design. The condition $h_n^* \rightarrow 0$ says that no observation keeps a non-negligible share of the fit. For a straight line at $x = 1, \dots, n$ the largest leverage is below $4/n$ (Exercise (A1)). The condition is not a technicality, as the next example shows.

Example. (An observation with its own parameter)

Fit an intercept together with an indicator of the first observation, $\mathbf{X}_n = [\mathbf{1}, \mathbf{e}_1]$, so that $h_{11} = 1$ for every n . The least squares estimates are $\hat{\mu} = \bar{Y}_{(1)}$, the mean of observations $2, \dots, n$, and $\hat{\delta} = Y_1 - \bar{Y}_{(1)}$. Hence

$$\hat{\delta} - \delta = \varepsilon_1 - \bar{\varepsilon}_{(1)}, \quad \text{Var}(\hat{\delta}) = \sigma^2 \left(1 + \frac{1}{n-1} \right),$$

and since $\bar{\varepsilon}_{(1)} \rightarrow 0$ in probability, $\hat{\delta} - \delta \rightarrow \varepsilon_1$ in distribution. The limit is the error distribution itself. No amount of other data can average away the error of one observation.

19.3.2 How far from normal in a finite sample

[Theorem 19.3.2](#) is a limit statement. A finite-sample measure of the approach comes from the third and fourth cumulants of the numerator, which leverage controls directly.

Proposition 19.3.3 — Skewness and kurtosis of a linear estimate

Let the errors have finite fourth moment, skewness $\gamma_1 = \mu_3/\sigma^3$ with $\mu_3 = E(\varepsilon_i^3)$, and excess kurtosis κ . For $\mathbf{a} \neq \mathbf{0}$ let $Z = (\mathbf{a}^\top \hat{\boldsymbol{\beta}} - \mathbf{a}^\top \boldsymbol{\beta})/\sqrt{\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}})}$, and let $w_i = c_i/\|\mathbf{c}\|$ with $\mathbf{c} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1}\mathbf{a}$. Then

$$E(Z^3) = \gamma_1 \sum_i w_i^3, \quad E(Z^4) - 3 = \kappa \sum_i w_i^4,$$

and $|\sum_i w_i^3| \leq \sqrt{h^*}$, $\sum_i w_i^4 \leq h^*$, where $h^* = \max_i h_{ii}$.

Proof. $Z = \sigma^{-1} \sum_i w_i \varepsilon_i$ with $\sum_i w_i^2 = 1$. Expanding the cube, every term with some index appearing exactly once has mean zero, by independence and $E \varepsilon_i = 0$. Only the terms $w_i^3 \varepsilon_i^3$ remain, so $E(Z^3) = \sigma^{-3} \mu_3 \sum_i w_i^3$. In the fourth power the surviving terms are $w_i^4 \varepsilon_i^4$ and, for $i \neq j$, the 3 pairings of $w_i^2 \varepsilon_i^2 w_j^2 \varepsilon_j^2$. So

$$\begin{aligned} E(Z^4) &= \frac{\mu_4}{\sigma^4} \sum_i w_i^4 + 3 \sum_{i \neq j} w_i^2 w_j^2 \\ &= (\kappa + 3) \sum_i w_i^4 + 3 \left(1 - \sum_i w_i^4\right), \end{aligned}$$

using $\sum_{i \neq j} w_i^2 w_j^2 = (\sum_i w_i^2)^2 - \sum_i w_i^4$. As in the proof of [Theorem 19.3.2\(a\)](#), $w_i^2 \leq h_{ii} \leq h^*$. Hence $|\sum_i w_i^3| \leq \max_i |w_i| \sum_i w_i^2 \leq \sqrt{h^*}$ and $\sum_i w_i^4 \leq \max_i w_i^2 \leq h^*$. ■

So skewness is averaged away more slowly than heavy tails, although with symmetric weights it can cancel exactly ([Exercise \(B1\)](#)). The denominator s of the t statistic adds terms of the same order, so the proposition describes the leading effect only.

Example. (Coverage of the t interval)

Fit a straight line with normal, centred exponential and scaled $t(3)$ errors, each with variance one, in two designs. In the *spread* design $x = 1, \dots, n$, and h_n^* is 0.345, 0.096 and 0.025 at $n = 10, 40$ and 160. In the *far-point* design the last value is moved to $x = 4n$, and h_n^* is 0.954, 0.800 and 0.485. With 100000 data sets per case, the coverages of the nominal 95% interval for the slope are:

Design	Errors	$n = 10$	$n = 40$	$n = 160$
spread	normal	0.950	0.951	0.950
spread	exponential	0.955	0.953	0.950
spread	$t(3)$	0.955	0.952	0.951
far point	normal	0.951	0.950	0.951

far point	exponential	0.933	0.948	0.950
far point	$t(3)$	0.931	0.944	0.953

The two-sided coverages hide unbalanced tails. With exponential errors and the far point, the interval misses above the slope in 0.067 of the data sets at $n = 10$ and below it in only 0.001. At $n = 160$ the two proportions are 0.038 and 0.012, still far from 0.025 each, as the slowly falling leverage predicts. A one-sided test in this design has nearly three times its nominal size at $n = 10$. Panel (a) of [Figure 19.3.1](#) shows the skewed t statistic at $n = 40$. The $t(3)$ errors have no fourth moment, but [Theorem 19.3.2](#) still applies.

```

19.3.3 Inference about the error variance

The interval for σ^2 (Proposition 12.1.4) rests on SSE, a sum of *squared* errors, whose variance depends on the kurtosis (Proposition 7.5.4). A central limit theorem applies, but with the wrong variance.

Proposition 19.3.4 — The interval for sigma squared

In the sequence of models above, let the errors have finite fourth moment with $\kappa > -2$. Then $\sqrt{n}(s^2/\sigma^2 - 1) \rightarrow N(0, 2 + \kappa)$, and the coverage of the nominal $1 - \alpha$ interval of Proposition 12.1.4 tends to

$$2\Phi\left(z_{\alpha/2}\sqrt{2/(2+\kappa)}\right) - 1, \quad (19.3.1)$$

where Φ is the standard normal distribution function. The limit equals $1 - \alpha$ iff $\kappa = 0$.

Proof. As in the proof of Theorem 19.3.2(b),

$$\begin{aligned} \sqrt{n}(s^2 - \sigma^2) &= \frac{n}{n-p}\sqrt{n}\left(\frac{\boldsymbol{\varepsilon}_n^\top \boldsymbol{\varepsilon}_n}{n} - \sigma^2\right) \\ &\quad + \frac{\sqrt{n}p\sigma^2}{n-p} - \frac{\sqrt{n}}{n-p}\boldsymbol{\varepsilon}_n^\top \mathbf{M}\boldsymbol{\varepsilon}_n. \end{aligned}$$

The ε_i^2 are independent with mean σ^2 and variance $\mu_4 - \sigma^4 = \sigma^4(2 + \kappa)$, so by the central limit theorem the first term tends to $N(0, \sigma^4(2 + \kappa))$. The second term tends to zero, and so does the third in probability, because $E(\boldsymbol{\varepsilon}_n^\top \mathbf{M}\boldsymbol{\varepsilon}_n) = \sigma^2 p$ and Markov's inequality applies to $\boldsymbol{\varepsilon}_n^\top \mathbf{M}\boldsymbol{\varepsilon}_n/\sqrt{n}$. Slutsky's lemma gives the first claim.

Write $\nu = n - p$ and let c_ν^- and c_ν^+ be the lower and upper $\alpha/2$ points of $\chi^2(\nu)$. The interval covers σ^2 iff $c_\nu^- \leq \nu s^2/\sigma^2 \leq c_\nu^+$, that is, iff

$$\frac{c_\nu^- - \nu}{\sqrt{\nu}} \leq \sqrt{\nu}\left(\frac{s^2}{\sigma^2} - 1\right) \leq \frac{c_\nu^+ - \nu}{\sqrt{\nu}}.$$

A $\chi^2(\nu)$ variable is a sum of ν independent squared standard normals, each with variance 2, so by the central limit theorem $(c_\nu^\pm - \nu)/\sqrt{2\nu} \rightarrow \pm z_{\alpha/2}$, and the bounds tend to $\pm z_{\alpha/2}\sqrt{2}$. The middle term tends to $N(0, 2 + \kappa)$ because $\nu/n \rightarrow 1$. The coverage therefore tends to $\Pr(|Z|\sqrt{2+\kappa} \leq z_{\alpha/2}\sqrt{2})$, which is Eq. 19.3.1. ■

For centred exponential errors, $\kappa = 6$, the nominal 95% interval has limiting coverage $2\Phi(1.96/2) - 1 = 0.673$. For uniform errors, $\kappa = -1.2$, it tends to 0.998. Panel (b) of Figure 19.3.1 shows simulated coverages with the spread design. For exponential errors they are 0.786 at $n = 10$, 0.717 at $n = 40$ and 0.672 at $n = 2560$: more data make it *worse*. This answers Exercise (B3) and explains the failure reported in Section 12.1.

```
def sigma2_coverage(law, n, reps, rng):
    X = design("spread", n)
    E = errors(law, (reps, n), rng)
```

Figure 19.3.1: (a) The t statistic for the slope in the far-point design with $n = 40$ and centred exponential errors (100000 data sets), with the $t(38)$ density. (b) Coverage of the nominal 95% interval for σ^2 in the spread design, against n , with the limits Eq. 19.3.1 dashed.

```
B = np.linalg.solve(X.T @ X, X.T @ E.T).T
sse = np.sum((E - B @ X.T) ** 2, axis=1) # sigma^2 = 1
lo, hi = stats.chi2.ppf([0.025, 0.975], n - 2)
return np.mean((sse >= lo) & (sse <= hi))

def limit(kappa, z=stats.norm.ppf(0.975)):
    """Limiting coverage of the nominal 95% chi-squared interval."""
    return 2 * stats.norm.cdf(z * np.sqrt(2 / (2 + kappa))) - 1

print("limits:", {k: round(limit(k), 3) for k in [0, 6, -1.2]})
```

Prediction intervals fail for the same reason: they must cover a single new error, which no averaging acts on (Proposition 12.3.3).

19.3.4 Why the F test is protected and the variance-ratio test is not

The F statistic is a ratio of two quadratic forms, each with a kurtosis-dependent variance. The effects can cancel, as Box and Watson (1962) and Atiqullah (1962) found. Since $\log F$ is approximately the difference of the two mean squares divided by σ^2 , it suffices to study that difference.

Proposition 19.3.5 — Kurtosis and a ratio of mean squares

Let $\mathbf{P}_1$ and $\mathbf{P}_2$ be symmetric idempotent with $\mathbf{P}_1\mathbf{P}_2 = \mathbf{0}$, ranks f_1 and f_2 , and $\mathbf{P}_1\mathbf{X}\boldsymbol{\beta} = \mathbf{P}_2\mathbf{X}\boldsymbol{\beta} = \mathbf{0}$. Let the errors have finite fourth moment and excess kurtosis κ , put $S_j^2 = \mathbf{Y}^\top \mathbf{P}_j \mathbf{Y} / f_j$, and let $\mathbf{p}_j$ be the vector of diagonal entries of $\mathbf{P}_j$. Then $L = (S_1^2 - S_2^2) / \sigma^2$ has mean zero and

$$\text{Var}(L) = \frac{2}{f_1} + \frac{2}{f_2} + \kappa \|\mathbf{d}\|^2, \quad \mathbf{d} = \frac{\mathbf{p}_1}{f_1} - \frac{\mathbf{p}_2}{f_2}.$$

In particular, if both $\mathbf{P}_1$ and $\mathbf{P}_2$ have constant diagonals, then $\mathbf{d} = \mathbf{0}$ and $\text{Var}(L)$ is the same as under normality.

Proof. Since $\mathbf{P}_j \mathbf{Y} = \mathbf{P}_j \boldsymbol{\varepsilon}$, $L = \boldsymbol{\varepsilon}^\top \mathbf{A} \boldsymbol{\varepsilon} / \sigma^2$ with $\mathbf{A} = \mathbf{P}_1 / f_1 - \mathbf{P}_2 / f_2$, whose diagonal is $\mathbf{d}$. By [Theorem 2.3.1](#), $E(L) = \text{tr} \mathbf{A} = 1 - 1 = 0$. By [Theorem 2.3.3](#) with zero means, $\text{Var}(\boldsymbol{\varepsilon}^\top \mathbf{A} \boldsymbol{\varepsilon}) = (\mu_4 - 3\sigma^4) \mathbf{d}^\top \mathbf{d} + 2\sigma^4 \text{tr}(\mathbf{A}^2)$, and $\text{tr}(\mathbf{A}^2) = \text{tr} \mathbf{P}_1 / f_1^2 + \text{tr} \mathbf{P}_2 / f_2^2 - 2 \text{tr}(\mathbf{P}_1 \mathbf{P}_2) / (f_1 f_2) = 1/f_1 + 1/f_2$. Divide by σ^4 . If the diagonals are constant, $\mathbf{p}_j = (f_j/n) \mathbf{1}$ because $\text{tr} \mathbf{P}_j = f_j$, and $\mathbf{d} = \mathbf{0}$. ■

For the F test of a linear hypothesis, $\mathbf{P}_1 = \mathbf{M} - \mathbf{M}_0$ and $\mathbf{P}_2 = \mathbf{I} - \mathbf{M}$. Designs in which both have constant diagonals are called *quadratically balanced*. Every balanced one-way or complete factorial layout is an example. In such designs the kurtosis of the errors does not affect the F statistic to first order. The variance-ratio test for comparing the error variances of two independent samples is the opposite case. With n_1 and n_2 observations, each sample centred at its own mean, $\mathbf{d}$ has entries $1/n_1$ on the first sample and $-1/n_2$ on the second ([Exercise \(B2\)](#)), so

$$\text{Var}(L) = \frac{2}{f_1} + \frac{2}{f_2} + \kappa \left(\frac{1}{n_1} + \frac{1}{n_2} \right),$$

and the kurtosis term is as large as the normal-theory term. The test is not robust at any sample size. For exponential errors and $n_1 = n_2 = 20$, the nominal 5% test rejected equal variances in 0.268 of 100000 simulated pairs of samples. Its large-sample limit is 0.327 ([Exercise \(B2\)](#)). The F test for equal means in a balanced one-way layout with three groups of eight had size 0.042, and with unbalanced groups of 2, 4 and 18 it had size 0.058. In the unbalanced layout $\text{Var}(L)$ is 1.870 instead of 1.095, which overstates the effect on the size: in the tail, skewness and the curvature of the logarithm also matter.

Idea. Inference about $\boldsymbol{\beta}$ is robust to the *shape* of the errors when no observation has large leverage. Inference about σ^2 , variance ratios or single future responses is not, at any sample size.

19.3.5 Exercises

19.3.5.1 A. Check your understanding

Exercise A1.

For a straight line at $x = 1, \dots, n$, show that the largest leverage is $1/n + 3(n-1)/(n(n+1)) < 4/n$.

Exercise A2.

In the far-point design of [Example \(Coverage of the t interval\)](#), show that the leverage of the far point is approximately $147/(n+147)$ for large n . Why does the table still show nearly nominal two-sided coverage at $n = 160$, when the leverage is almost one half?

19.3.5.2 B. Practice

Exercise B1.

In a one-way layout with m observations per group and skewed errors, compute $\sum_i w_i^3$ of Proposition 19.3.3 for (i) a single group mean and (ii) the difference of two group means. What does this say about one-sample and two-sample t tests with skewed data?

Solution.

- (i) The mean of group 1 has $c_i = 1/m$ on its m observations, so $w_i = m^{-1/2}$ there and $\sum_i w_i^3 = m \cdot m^{-3/2} = m^{-1/2}$. (ii) The difference has $c_i = \pm 1/m$ on the two groups, so $w_i = \pm(2m)^{-1/2}$, and the cubes cancel: $\sum_i w_i^3 = 0$. The numerator of a one-sample t statistic has skewness $\gamma_1/\sqrt{m}$. That of a two-sample comparison with equal group sizes has none, and its non-normality starts with the kurtosis term, of order $1/m$. Equal-sized two-sample comparisons are therefore much better protected against skewness.

Exercise B2.

Two independent samples of size m are each centred at their own mean. Let S_1^2 and S_2^2 be the sample variances. (i) Show that the vector $\mathbf{d}$ of Proposition 19.3.5 has entries $1/m$ and $-1/m$. (ii) Using the first part of Proposition 19.3.4 for each sample, show that when the two variances are equal the two-sided variance-ratio test of nominal size α has size tending to $2(1 - \Phi(z_{\alpha/2}\sqrt{2/(2+\kappa)}))$ as $m \rightarrow \infty$.

Solution.

- (i) $\mathbf{P}_1$ is the centring matrix on the first sample and zero elsewhere, so its diagonal is $1 - 1/m = f_1/m$ there, and $\mathbf{p}_1/f_1$ has entries $1/m$ on the first sample. Likewise $\mathbf{p}_2/f_2$ has entries $1/m$ on the second, which enter $\mathbf{d}$ with a minus sign. (ii) By Proposition 19.3.4 (with $p = 1$), $\sqrt{m}(S_j^2/\sigma^2 - 1) \rightarrow N(0, 2 + \kappa)$ for $j = 1, 2$, independently. By the delta method, $\sqrt{m} \log(S_1^2/S_2^2) \rightarrow N(0, 2(2 + \kappa))$. Under normality the same statistic tends to $N(0, 4)$, and the critical values of the $F(m-1, m-1)$ distribution satisfy $\sqrt{m} \log F_{\alpha/2} \rightarrow 2z_{\alpha/2}$. The rejection probability therefore tends to $\Pr(|Z|\sqrt{2/(2+\kappa)} > 2z_{\alpha/2}) = 2(1 - \Phi(z_{\alpha/2}\sqrt{2/(2+\kappa)}))$. For $\kappa = 6$ and $\alpha = 0.05$ this is 0.327.

19.3.5.3 C. Going deeper

Exercise C1.

Let the errors be independent with mean zero, variances $\sigma_i^2 \in [m_0, M_0]$ with $m_0 > 0$, and $\sup_i E|\varepsilon_i|^3 < \infty$. Suppose $h_n^* \rightarrow 0$. Show that for every nonzero $\mathbf{a}_n$, $(\mathbf{a}_n^\top \hat{\boldsymbol{\beta}} - \mathbf{a}_n^\top \boldsymbol{\beta})/\sqrt{\text{Var}(\mathbf{a}_n^\top \hat{\boldsymbol{\beta}})} \rightarrow N(0, 1)$, where the variance is the sandwich Eq. 5.5.3. Explain why this does not make the usual t statistic asymptotically standard normal.

Solution. With c_{ni} as in the proof of Theorem 19.3.2, $\text{Var}(\mathbf{a}_n^\top \hat{\boldsymbol{\beta}}) = \sum_i c_{ni}^2 \sigma_i^2 \geq m_0 \tau_n^2$. Put $Z_{ni} = c_{ni} \varepsilon_i / \sqrt{\text{Var}(\mathbf{a}_n^\top \hat{\boldsymbol{\beta}})}$. Lyapunov's bound $E[Z^2 \mathbf{1}\{|Z| > \eta\}] \leq E|Z|^3/\eta$ gives the

Lindeberg sum at most

$$\begin{aligned} & \frac{\sup_i E|\varepsilon_i|^3 \sum_i |c_{ni}|^3}{\eta (m_0 \tau_n^2)^{3/2}} \\ & \leq \frac{\sup_i E|\varepsilon_i|^3}{\eta m_0^{3/2}} \max_i \frac{|c_{ni}|}{\tau_n} \\ & \leq \frac{\sup_i E|\varepsilon_i|^3}{\eta m_0^{3/2}} \sqrt{h_n^*} \rightarrow 0, \end{aligned}$$

using $\sum_i |c_{ni}|^3 \leq \max_i |c_{ni}| \tau_n^2$. The usual t statistic divides by $s \tau_n$, and $s^2 \tau_n^2$ estimates $\bar{\sigma}^2 \tau_n^2$ with $\bar{\sigma}^2$ an average variance, not $\sum_i c_{ni}^2 \sigma_i^2$. The ratio of the two is the quantity of [Exercise \(B1\)](#), and it need not tend to one. [Chapter 21](#) replaces $s^2 \tau_n^2$ by a consistent estimate of the sandwich.

19.4 A single bad observation

Some failures affect a single case, such as a misplaced decimal point. How much one bad case matters depends on its leverage and on how far its response is from the rest of the data. This section makes that exact; [Chapter 20](#) turns it into diagnostics.

19.4.1 The effect of contaminating one response

Theorem 19.4.1 — One contaminated response

Let $\mathbf{X}$ have full column rank. For a data vector $\mathbf{y}$, a case k and a shift Δ , let $\mathbf{y}_\Delta = \mathbf{y} + \Delta \mathbf{e}_k$, where $\mathbf{e}_k$ is the k th standard basis vector.

- (a) The estimate moves by $\hat{\boldsymbol{\beta}}(\mathbf{y}_\Delta) - \hat{\boldsymbol{\beta}}(\mathbf{y}) = \Delta(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}$. The fitted vector moves by $\Delta \mathbf{M} \mathbf{e}_k$, a vector of length $|\Delta| \sqrt{h_{kk}}$. The fitted value of case k moves by Δh_{kk} , and its residual by only $\Delta(1 - h_{kk})$.
- (b) If $E(\mathbf{Y}) = \mathbf{X} \boldsymbol{\beta}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, then $\hat{\boldsymbol{\beta}}(\mathbf{Y}_\Delta)$ has mean $\boldsymbol{\beta} + \Delta(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}$, and the residual sum of squares has mean $\sigma^2(n - p) + \Delta^2(1 - h_{kk})$.
- (c) Suppose $h_{kk} < 1$, and let $\hat{\boldsymbol{\beta}}_{(k)}$ be the estimate without case k . Then for every $\mathbf{y}$,

$$\|\mathbf{X}(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(k)})\|^2 = \frac{h_{kk}}{1 - h_{kk}} \cdot \frac{\hat{\varepsilon}_k^2}{1 - h_{kk}}. \quad (19.4.1)$$

- (d) Under the conditions of (c), adding $\mathbf{e}_k$ to the model matrix as an extra column gives the coefficients $\hat{\boldsymbol{\beta}}_{(k)}$ for $\mathbf{X}$ and $\hat{\delta} = y_k - \mathbf{x}_{(k)}^\top \hat{\boldsymbol{\beta}}_{(k)} = \hat{\varepsilon}_k / (1 - h_{kk})$ for the new column.

Proof.

- (a) $\hat{\boldsymbol{\beta}}(\mathbf{y}_\Delta) - \hat{\boldsymbol{\beta}}(\mathbf{y}) = \Delta(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{e}_k = \Delta(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}$. Multiplying by $\mathbf{X}$ gives $\Delta \mathbf{M} \mathbf{e}_k$, with squared length $\Delta^2 \mathbf{e}_k^\top \mathbf{M} \mathbf{e}_k = \Delta^2 h_{kk}$, since $\mathbf{M}$ is symmetric and idempotent. Its k th entry is Δh_{kk} , and the residual vector moves by $\Delta(\mathbf{I} - \mathbf{M}) \mathbf{e}_k$, whose k th entry is $\Delta(1 - h_{kk})$.
- (b) The mean follows from (a) and [Theorem 5.5.1\(a\)](#). The residual vector $(\mathbf{I} - \mathbf{M}) \mathbf{Y}_\Delta$

has mean $\Delta(\mathbf{I} - \mathbf{M})\mathbf{e}_k$, so Eq. 2.3.1 gives $\sigma^2(n - p) + \Delta^2\|(\mathbf{I} - \mathbf{M})\mathbf{e}_k\|^2 = \sigma^2(n - p) + \Delta^2(1 - h_{kk})$.

- (c) By Proposition 10.6.2(a), $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(k)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)} \hat{\varepsilon}_k / (1 - h_{kk})$, and $\|\mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}\|^2 = \mathbf{x}_{(k)}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)} = h_{kk}$.
- (d) With the extra column, the criterion is $\sum_{i \neq k} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2 + (y_k - \mathbf{x}_{(k)}^\top \mathbf{b} - \delta)^2$. For any $\mathbf{b}$ the choice $\delta = y_k - \mathbf{x}_{(k)}^\top \mathbf{b}$ makes the last term zero, so the minimizing $\mathbf{b}$ minimizes the first sum alone, which is $\hat{\boldsymbol{\beta}}_{(k)}$. The augmented matrix has full rank because $h_{kk} < 1$ means $\mathbf{e}_k \notin \mathcal{C}(\mathbf{X})$ (Proposition 6.8.1). Then $\hat{\delta} = y_k - \mathbf{x}_{(k)}^\top \hat{\boldsymbol{\beta}}_{(k)}$, which is $\hat{\varepsilon}_k / (1 - h_{kk})$ by Proposition 10.6.2(b). ■

Part (a), which needs no model, says that a high-leverage case *hides* its own contamination: of a shift Δ , the fraction h_{kk} goes into its fitted value and only $1 - h_{kk}$ shows in its residual. Raw residuals therefore miss the cases that matter most, and Chapter 20 rescales them.

Part (c) makes “influence is leverage times residual” exact: a leverage factor $h_{kk} / (1 - h_{kk})$ times the squared *deleted* residual $\hat{\varepsilon}_k^2 / (1 - h_{kk})$. Either factor alone is harmless. Divided by $p s^2$, Eq. 19.4.1 is Cook’s distance (Definition 20.4.1). Part (d) is the *mean-shift outlier model*: giving case k its own parameter is the same as deleting it. Part (b) adds a second cost: s^2 is inflated by about $\Delta^2(1 - h_{kk}) / (n - p)$, which weakens every test, even for coefficients the bad case hardly moves.

Example. (The last day of the stack loss data)

In the stack loss data of Example (Stack loss), $n = 21$ days of a plant oxidizing ammonia, regress the stack loss on air flow, water temperature and acid concentration with an intercept. The average leverage is $p/n = 0.190$. By Eq. 19.4.1, the case whose deletion moves the fitted vector most is day 21, with leverage 0.285 and residual -7.238 . Deleting it moves the fitted vector by a distance of 5.396. The next largest move, for day 1, is 2.543, and the median over all days is 1.228. The largest leverage, 0.412 for day 17, comes with a residual of only -1.520 , and that day has little influence.

Without day 21, the air-flow coefficient rises from 0.716 to 0.889, the water temperature coefficient falls from 1.295 to 0.817, and s drops from 3.243 to 2.569. The mean-shift estimate for day 21 is $\hat{\delta} = -10.116$. The listing computes every deletion effect from the single fit (Theorem 19.4.1(c)).

Adding $\Delta = 10$ to the response of the lowest-leverage day, day 5 with $h_{55} = 0.052$, moves the fitted vector by 2.285 and its own residual by 9.478. The same shift on day 17 moves the fitted vector by 6.420 and its residual by only 5.879.

```
import numpy as np
import statsmodels.api as sm
data = sm.datasets.stackloss.load_pandas().data
y = data["STACKLOSS"].to_numpy()
X = np.column_stack([np.ones(len(y)), data[["AIRFLOW", "WATERTEMP", "ACIDCONC"]].to_numpy()])
n, p = X.shape

G = np.linalg.inv(X.T @ X)
```

Figure 19.4.1: A straight line through 15 points. (a) The same upward shift of 6 applied to a point in the middle of the design barely moves the line; applied to the high-leverage point on the right, it tilts the line, and that point's residual stays small. (b) A *bad leverage point*: one case keeps its response while its x value is moved to the right, and the fitted slope (dotted: its original value) is dragged towards zero.

```

beta_hat = G @ X.T @ y

          f" |Delta| sqrt(h) = {Delta * np.sqrt(h[j]):.3f}")

```

19.4.2 Breakdown

By [Theorem 19.4.1\(a\)](#) the effect of one case grows without bound with Δ . Contaminated regressors can be as bad: in panel (b) of [Figure 19.4.1](#) a single case moved far out in x takes control of the slope. The following definition, from Donoho and Huber (1983), makes this precise.

Definition 19.4.1 — Breakdown point

Let T be an estimator that maps a data set Z of n cases $(\mathbf{x}_{(i)}, y_i)$ to a vector in $\mathbb{R}^p$. For $m \leq n$, let $b(m; T, Z)$ be the supremum of $\|T(Z') - T(Z)\|$ over all data sets Z' obtained from Z by replacing any m of its cases with arbitrary values, for which $T(Z')$ is defined. The **finite-sample breakdown point** of T at Z is

$$\varepsilon^*(T, Z) = \min \left\{ \frac{m}{n} : b(m; T, Z) = \infty \right\}.$$

Proposition 19.4.2 — Least squares breaks down at one case

For least squares and every data set with a full-rank model matrix, $\varepsilon^* = 1/n$.

Proof. Since $\mathbf{X}$ has full rank, some row $\mathbf{x}_{(k)}$ is nonzero, and then $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)} \neq \mathbf{0}$. Replace case k by $(\mathbf{x}_{(k)}, y_k + \Delta)$. The model matrix is unchanged, so the estimate is defined, and by [Theorem 19.4.1\(a\)](#) it moves by $|\Delta| \|(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}\|$, which is unbounded in Δ . So $b(1) = \infty$. No smaller fraction than $1/n$ is possible. ■

So least squares offers no protection against gross errors. The sample median, by contrast, has breakdown point close to one half ([Exercise A1](#)). High-breakdown regression estimators exist too, at a cost in efficiency discussed with robust fitting in [Section 20.6](#). Hampel (1974) introduced the related *influence function*, the effect of an infinitesimal contamination at a point $(\mathbf{x}_0, y_0)$. For least squares it is unbounded in both $\mathbf{x}_0$ and y_0 ([Exercise C1](#)).

Idea. High leverage makes a case both more influential and better hidden, and one case can move the estimate arbitrarily far.

19.4.3 Exercises**19.4.3.1 A. Check your understanding****Exercise A1.**

Show that the sample median of n numbers has breakdown point $\lfloor (n+1)/2 \rfloor / n$, in the sense of [Definition 19.4.1](#) with $p = 1$ and no regressors.

Exercise A2.

In [Theorem 19.4.1\(a\)](#), show that the residual of every other case i moves by $-\Delta m_{ik}$, where m_{ik} is an entry of $\mathbf{M}$. Which cases' residuals are most affected by a contaminated high-leverage case?

19.4.3.2 B. Practice

Exercise B1.

In a straight-line regression, move the x value of case k to t while keeping y_k fixed. Show that the fitted slope tends to 0 as $t \rightarrow \infty$. If instead $y_k = ct + d$ moves with t , show that the slope tends to c .

Solution. Let $\bar{x}_t$ and $\bar{y}$ be the means with case k at t . The slope is $\sum_i (x_i - \bar{x}_t)(y_i - \bar{y}) / \sum_i (x_i - \bar{x}_t)^2$. As $t \rightarrow \infty$, $t - \bar{x}_t = (1 - 1/n)t + O(1)$ while the other deviations $x_i - \bar{x}_t$ are $-t/n + O(1)$. The denominator is $(1 - 1/n)t^2 + O(t)$. With y_k fixed, the numerator is $O(t)$, since each term is a deviation of order t times a bounded $y_i - \bar{y}$, so the slope is $O(1/t)$. With $y_k = ct + d$, put $r_i = y_i - cx_i$, so that $r_k = d$ and all the r_i stay bounded. Since $y_i = cx_i + r_i$ and least squares is linear in the response, the slope is c plus the slope of r on x , which is $O(1/t)$ as before. The far case dictates the slope.

Exercise B2.

Suppose case k is contaminated by Δ , and consider the t statistic for a coefficient β_j whose estimate is unaffected, $[(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(k)}]_j = 0$. Using [Theorem 19.4.1\(b\)](#), explain how the contamination still changes the test, and show that its effect on $E(s^2)$ is largest for low-leverage cases.

19.4.3.3 C. Going deeper**Exercise C1.**

Let $(\mathbf{x}, Y)$ have a joint distribution F with $\Sigma = E(\mathbf{x}\mathbf{x}^\top)$ positive definite, and let $\beta^*(F) = \Sigma^{-1} E(\mathbf{x}Y)$ be the population least squares coefficient. For the mixture $F_\epsilon = (1 - \epsilon)F + \epsilon \delta_{(\mathbf{x}_0, y_0)}$, which puts mass ϵ at a single point, show that

$$\left. \frac{d}{d\epsilon} \beta^*(F_\epsilon) \right|_{\epsilon=0} = \Sigma^{-1} \mathbf{x}_0 (y_0 - \mathbf{x}_0^\top \beta^*(F)),$$

and compare with [Theorem 19.4.1\(c\)](#) for a sample of size n .

Solution. Under F_ϵ , $\Sigma_\epsilon = (1 - \epsilon)\Sigma + \epsilon \mathbf{x}_0 \mathbf{x}_0^\top$ and $\mathbf{m}_\epsilon = (1 - \epsilon)E(\mathbf{x}Y) + \epsilon \mathbf{x}_0 y_0$, and $\Sigma_\epsilon \beta^*(F_\epsilon) = \mathbf{m}_\epsilon$. Differentiate at $\epsilon = 0$, writing $\mathbf{d}$ for the derivative: $(\mathbf{x}_0 \mathbf{x}_0^\top - \Sigma) \beta^* + \Sigma \mathbf{d} = \mathbf{x}_0 y_0 - E(\mathbf{x}Y)$. Since $\Sigma \beta^* = E(\mathbf{x}Y)$, this gives $\Sigma \mathbf{d} = \mathbf{x}_0 (y_0 - \mathbf{x}_0^\top \beta^*)$. The influence is the product of a leverage-like factor $\Sigma^{-1} \mathbf{x}_0$ and a residual, unbounded in both. In a sample, replacing F by the empirical distribution and ϵ by $1/n$ gives $n^{-1}(\mathbf{X}^\top \mathbf{X}/n)^{-1} \mathbf{x}_{(k)} \hat{\epsilon}_k$, which is [Proposition 10.6.2\(a\)](#) without the factor $1/(1 - h_{kk})$.

19.5 Random regressors and a curved mean

When the regressors are random, as in almost every observational study, the linear model is read conditionally on $\mathbf{X}$. [Section 14.1](#) settled the case in which the conditional model is right. If $\mathbf{Y} | \mathbf{X} \sim N_n(\mathbf{X}\beta, \sigma^2 \mathbf{I})$, every t and F procedure keeps its exact level unconditionally, whatever the distribution of the regressors ([Theorem 14.1.2](#)), and $\hat{\beta}$ is unbiased with covariance

$\sigma^2 \mathbb{E}[(\mathbf{X}^\top \mathbf{X})^{-1}]$ (Corollary 5.5.5). Nothing further needs to be proved about that case.

Random regressors create new problems only when the conditional model fails, and it can fail in two essentially different ways. The regressors can be correlated with the errors, as when they are measured with error or when a common cause of regressor and response is omitted. Then least squares does not even estimate a coefficient of interest, a problem taken up in Chapter 24 and Chapter 25. Or the conditional mean $\mathbb{E}(Y | \mathbf{x})$ is not linear in $\mathbf{x}$. This section treats the second case. Its message is that a curved mean, fitted by a linear model with random regressors, behaves like heteroscedastic error, and the usual standard errors are wrong even when the true errors are homoscedastic.

19.5.1 What least squares estimates, conditionally

Proposition 19.5.1 — The design-dependent target

Let $(\mathbf{X}, \mathbf{Y})$ be random with $\text{rank}(\mathbf{X}) = p < n$ almost surely, $\mathbb{E}(\mathbf{Y} | \mathbf{X}) = \boldsymbol{\mu}(\mathbf{X})$ for some function $\boldsymbol{\mu}$ with values in $\mathbb{R}^n$, not necessarily in $\mathcal{C}(\mathbf{X})$, and $\text{Cov}(\mathbf{Y} | \mathbf{X}) = \sigma^2 \mathbf{I}_n$. Put $\boldsymbol{\beta}_{\mathbf{X}} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \boldsymbol{\mu}(\mathbf{X})$.

- (a) $\mathbb{E}(\hat{\boldsymbol{\beta}} | \mathbf{X}) = \boldsymbol{\beta}_{\mathbf{X}}$ and $\text{Cov}(\hat{\boldsymbol{\beta}} | \mathbf{X}) = \sigma^2 (\mathbf{X}^\top \mathbf{X})^{-1}$.
- (b) If the second moments below are finite, $\text{Cov}(\hat{\boldsymbol{\beta}}) = \sigma^2 \mathbb{E}[(\mathbf{X}^\top \mathbf{X})^{-1}] + \text{Cov}(\boldsymbol{\beta}_{\mathbf{X}})$.
- (c) $\mathbb{E}(s^2 | \mathbf{X}) = \sigma^2 + \|(\mathbf{I} - \mathbf{M})\boldsymbol{\mu}(\mathbf{X})\|^2 / (n - p)$.

Proof.

- (a) Given $\mathbf{X}$, apply Proposition 5.5.7 with $\boldsymbol{\delta} = \boldsymbol{\mu}(\mathbf{X}) - \mathbf{X}\boldsymbol{\beta}_{\mathbf{X}}$, which satisfies $\mathbf{X}^\top \boldsymbol{\delta} = \mathbf{0}$, and Theorem 5.5.1(b). (b) is the law of total covariance (Proposition 2.5.4) applied to (a). (c) is Eq. 2.3.1 given $\mathbf{X}$.

■

Given the design, $\hat{\boldsymbol{\beta}}$ scatters around $\boldsymbol{\beta}_{\mathbf{X}}$ exactly as the usual formula says. But $\boldsymbol{\beta}_{\mathbf{X}}$, the least squares coefficient of the true mean over the design drawn, changes from design to design. When $\boldsymbol{\mu}(\mathbf{X}) = \mathbf{X}\boldsymbol{\beta}$ it is constant (Corollary 5.5.5). Otherwise (b) adds a *between-design* component that no conditional calculation can see, while (c) inflates s^2 by the misfit, which compensates only partly.

19.5.2 The large-sample picture

The natural fixed target is the population projection of Section 6.11, $\boldsymbol{\beta}^* = \boldsymbol{\Sigma}^{-1} \mathbb{E}(\mathbf{x}Y)$, which least squares estimates consistently whatever the form of the mean (Proposition 6.11.3). Its sampling distribution is the following.

Theorem 19.5.2 — Least squares for the population projection

Let $(\mathbf{x}_i, Y_i)$, $i = 1, \dots, n$, be independent copies of $(\mathbf{x}, Y)$, where $\mathbf{x} \in \mathbb{R}^p$ (whose first component may be the constant 1) and Y have finite fourth moments and $\boldsymbol{\Sigma} = \mathbb{E}(\mathbf{x}\mathbf{x}^\top)$

is positive definite. Let $\beta^* = \Sigma^{-1} E(\mathbf{x}Y)$, $U = Y - \mathbf{x}^\top \beta^*$ and $\Omega = E(U^2 \mathbf{x}\mathbf{x}^\top)$. Then $E(\mathbf{x}U) = \mathbf{0}$, and as $n \rightarrow \infty$:

- (a) $\sqrt{n}(\hat{\beta} - \beta^*) \rightarrow N_p(\mathbf{0}, \Sigma^{-1}\Omega\Sigma^{-1})$ in distribution;
- (b) $s^2 \rightarrow E(U^2)$ and $n s^2(\mathbf{X}^\top \mathbf{X})^{-1} \rightarrow E(U^2) \Sigma^{-1}$ in probability;
- (c) if $E(U^2 | \mathbf{x}) = E(U^2)$ almost surely, the two limiting covariances agree. Otherwise the usual interval for $\mathbf{a}^\top \beta^*$ of nominal level $1 - \alpha$ has coverage tending to $2\Phi(z_{\alpha/2}\sqrt{\rho_{\mathbf{a}}}) - 1$, with $\rho_{\mathbf{a}} = E(U^2) \mathbf{a}^\top \Sigma^{-1} \mathbf{a} / \mathbf{a}^\top \Sigma^{-1} \Omega \Sigma^{-1} \mathbf{a}$.

Proof. $E(\mathbf{x}U) = E(\mathbf{x}Y) - \Sigma\beta^* = \mathbf{0}$. Write $\mathbf{U} = \mathbf{Y} - \mathbf{X}\beta^*$, so that

$$\sqrt{n}(\hat{\beta} - \beta^*) = \left(\frac{\mathbf{X}^\top \mathbf{X}}{n} \right)^{-1} \frac{\mathbf{X}^\top \mathbf{U}}{\sqrt{n}}.$$

By the weak law of large numbers $\mathbf{X}^\top \mathbf{X}/n = n^{-1} \sum_i \mathbf{x}_i \mathbf{x}_i^\top \rightarrow \Sigma$ in probability, so it is invertible with probability tending to one and its inverse tends to Σ^{-1} , inversion being continuous at Σ . The vectors $\mathbf{x}_i U_i$ are independent with mean $\mathbf{0}$ and covariance Ω , which is finite because $|E(U^2 x_j x_k)| \leq (E U^4 E x_j^2 x_k^2)^{1/2}$ and U has a finite fourth moment. By the central limit theorem $\mathbf{X}^\top \mathbf{U}/\sqrt{n} = \sqrt{n} \cdot n^{-1} \sum_i \mathbf{x}_i U_i \rightarrow N_p(\mathbf{0}, \Omega)$. If a random matrix $\mathbf{A}_n$ tends in probability to a constant $\mathbf{A}$ and a random vector $\mathbf{T}_n$ tends in distribution to $\mathbf{T}$, then $\mathbf{A}_n \mathbf{T}_n \rightarrow \mathbf{A}\mathbf{T}$: the difference $(\mathbf{A}_n - \mathbf{A})\mathbf{T}_n$ tends to zero in probability because $\mathbf{T}_n$ is bounded in probability, $\mathbf{A}\mathbf{T}_n \rightarrow \mathbf{A}\mathbf{T}$ by continuous mapping, and Slutsky's lemma combines the two. This proves (a).

- (b) $(n-p)s^2 = \mathbf{U}^\top (\mathbf{I} - \mathbf{M}) \mathbf{U} = \mathbf{U}^\top \mathbf{U} - Q_n$, where $Q_n = (\mathbf{X}^\top \mathbf{U}/\sqrt{n})^\top (\mathbf{X}^\top \mathbf{X}/n)^{-1} (\mathbf{X}^\top \mathbf{U}/\sqrt{n})$ converges in distribution by the argument for (a) and continuous mapping. Hence $Q_n/n \rightarrow 0$ in probability, while $\mathbf{U}^\top \mathbf{U}/n \rightarrow E(U^2)$ by the law of large numbers. Then $n s^2(\mathbf{X}^\top \mathbf{X})^{-1} = s^2(\mathbf{X}^\top \mathbf{X}/n)^{-1} \rightarrow E(U^2) \Sigma^{-1}$.
- (c) If $E(U^2 | \mathbf{x}) = c$, then $\Omega = E[E(U^2 | \mathbf{x}) \mathbf{x}\mathbf{x}^\top] = c \Sigma$, with $c = E(U^2)$, and $\Sigma^{-1} \Omega \Sigma^{-1} = c \Sigma^{-1}$. In general, the t statistic for $\mathbf{a}^\top \beta^*$ is $\sqrt{n} \mathbf{a}^\top (\hat{\beta} - \beta^*)$ divided by $(n s^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a})^{1/2}$. By (a), (b) and Slutsky's lemma it tends to $N(0, 1/\rho_{\mathbf{a}})$, and the coverage follows as in [Theorem 19.3.2\(c\)](#).

■

The condition in (c) holds when the mean is linear and the errors are homoscedastic. It typically fails when either assumption fails ([Exercise B2](#)) gives an exception), and a curved mean alone is enough. If $E(Y | \mathbf{x}) = m(\mathbf{x})$ and $\text{Var}(Y | \mathbf{x}) = \sigma^2$, then $U = (m(\mathbf{x}) - \mathbf{x}^\top \beta^*) + \varepsilon$ and

$$E(U^2 | \mathbf{x}) = (m(\mathbf{x}) - \mathbf{x}^\top \beta^*)^2 + \sigma^2,$$

which varies with $\mathbf{x}$ wherever the linear approximation is poor, exactly like a heteroscedastic error. The correct covariance $\Sigma^{-1} \Omega \Sigma^{-1}$ is a population version of the sandwich [Eq. 5.5.3](#), and [Chapter 21](#) shows how to estimate it.

Example. (A line through a parabola)

Let X be uniform on $(0, 2)$, $E(Y | X) = X^2$ and $\text{Var}(Y | X) = 0.04$, with normal errors. A straight line is fitted. The population line has slope $\beta^* = \text{Cov}(X, X^2)/\text{Var}(X) = 2$ and intercept $-2/3$, and the approximation error is $U_0^2 - 1/3$ with $U_0 = X - 1$

uniform on $(-1, 1)$. The slope's component of $\Sigma^{-1}\Omega\Sigma^{-1}$ is $E[(X - 1)^2 U^2] / \text{Var}(X)^2$ (Exercise A1), which equals $9(44/945 + 0.04/3) = 0.5390$. The usual formula estimates $E(U^2) / \text{Var}(X) = 3(4/45 + 0.04) = 0.3867$ instead. The true standard error is 1.181 times what the usual one estimates, and by Theorem 19.5.2(c) the nominal 95% interval for β^* has limiting coverage 0.903.

Simulation agrees. With 40000 samples the interval covered $\beta^* = 2$ in 0.896 of samples of size 50 and 0.900 of size 400; with 10000 samples of size 1600, in 0.908. Over the same samples, n times the variance of the slope was 0.584, 0.546 and 0.530, approaching the sandwich value 0.5390, not the usual 0.3867. As a statement about the design-dependent target $\beta_{\mathbf{X}}$, the same intervals are *conservative*. They covered it in 0.999 of the samples of size 50, because s^2 estimates $E(U^2) = 0.1289$ rather than $\sigma^2 = 0.04$. In a larger simulation of 200000 samples of size 50, the variance of the slope, 0.01163, splits as in Proposition 19.5.1(b) into 0.00249 from the errors and 0.00913 from the variation of $\beta_{\mathbf{X}}$ between designs.

    print(f"n = {n}: covers beta* {c_star:.3f}, covers beta_X {c_X:.3f}, n Var(slope)
          {nvar:.3f}")
```

Which target is right depends on the question: β^* summarizes the population, $\beta_{\mathbf{X}}$ this design. With a curved mean, neither describes $E(Y | \mathbf{x})$ itself.

19.5.3 Controlled regressors

One situation with random regressors is more benign than it looks. In a controlled experiment the analyst sets a nominal value x_i , but the value actually delivered is $x_i + \delta_i$, with an error δ_i independent of x_i . If the response follows $\beta_0 + \beta_1(x_i + \delta_i) + \varepsilon_i$, then regressing on the nominal values gives

$$Y_i = \beta_0 + \beta_1 x_i + (\beta_1 \delta_i + \varepsilon_i),$$

a correct linear model with a larger error variance ([Exercise \(B1\)](#)). Least squares on the nominal settings is unbiased, as Berkson (1950) pointed out. Contrast the *classical* measurement error model, in which the true value is fixed and the *recorded* value carries the error. There the error is correlated with the recorded regressor, and least squares is biased towards zero ([Theorem 24.1.1](#)).

Rounding can fall on either side. If the grid value is what was set, as with a dial, the model is Berkson's. If a continuous true value is *recorded* rounded to a grid of width w , the rounding error is roughly uniform with variance $w^2/12$ and roughly independent of the true value, so the error is classical. In simple regression, classical error of variance τ^2 multiplies the slope by $\text{Var}(x)/(\text{Var}(x) + \tau^2)$ ([Chapter 24](#)). So measurement error, rounding included, can be ignored when its variance is a small fraction of $\text{Var}(x)$.

Idea. With random regressors, what matters is whether the conditional model holds. If it does, nothing changes; if the mean is curved, $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ is not the covariance.

19.5.4 Exercises

19.5.4.1 A. Check your understanding

Exercise A1.

With $\mathbf{x} = (1, X)^\top$, show that the slope entries of $\Sigma^{-1}\Omega\Sigma^{-1}$ and $E(U^2)\Sigma^{-1}$ are $E[(X - \mu_X)^2 U^2] / \text{Var}(X)^2$ and $E(U^2) / \text{Var}(X)$.

Solution. $\Sigma = \begin{pmatrix} 1 & \mu_X \\ \mu_X & E X^2 \end{pmatrix}$ has determinant $\text{Var}(X)$, and the second row of Σ^{-1} is $(-\mu_X, 1) / \text{Var}(X)$. So $\mathbf{e}_2^\top \Sigma^{-1} \mathbf{x} = (X - \mu_X) / \text{Var}(X)$, and $\mathbf{e}_2^\top \Sigma^{-1} \Omega \Sigma^{-1} \mathbf{e}_2 = E[U^2 (X - \mu_X)^2] / \text{Var}(X)^2$. Similarly $[\Sigma^{-1}]_{22} = 1 / \text{Var}(X)$.

Exercise A2.

In [Proposition 19.5.1](#), show that $\text{Cov}(\boldsymbol{\beta}_\mathbf{X}) = \mathbf{0}$ when $\boldsymbol{\mu}(\mathbf{X}) = \mathbf{X}\boldsymbol{\beta}$, and give an example of a nonlinear $\boldsymbol{\mu}$ for which $\text{Cov}(\boldsymbol{\beta}_\mathbf{X}) = \mathbf{0}$ anyway.

19.5.4.2 B. Practice

Exercise B1.

In the controlled-regressor model, let δ_i and ε_i be independent, with variances τ^2 and σ^2 , independent of the settings. Show that least squares on the nominal x_i is unbiased

for (β_0, β_1) , that the usual standard errors are valid with error variance $\sigma^2 + \beta_1^2 \tau^2$, and that s^2 estimates this variance.

Solution. The composite errors $\eta_i = \beta_1 \delta_i + \varepsilon_i$ are independent of the fixed settings, with mean 0 and variance $\sigma^2 + \beta_1^2 \tau^2$, and uncorrelated across i . The model $Y_i = \beta_0 + \beta_1 x_i + \eta_i$ therefore satisfies the second-moment assumptions of [Chapter 5](#), so [Theorem 5.5.1](#) and [Theorem 5.6.1](#) apply with σ^2 replaced by $\sigma^2 + \beta_1^2 \tau^2$. If δ_i and ε_i are normal, so is η_i , and the exact theory of Part III applies too.

Exercise B2.

In [Theorem 19.5.2](#), show that $\Sigma^{-1} \Omega \Sigma^{-1} = E(U^2) \Sigma^{-1}$ iff $E[(E(U^2 | \mathbf{x}) - E(U^2)) \mathbf{x} \mathbf{x}^\top] = \mathbf{0}$. Give an example of a nonconstant $E(U^2 | \mathbf{x})$ for which the usual standard errors are nevertheless consistent.

19.5.4.3 C. Going deeper

Exercise C1.

In [Theorem 19.5.2](#), let $E(Y | \mathbf{x}) = m(\mathbf{x})$, $\text{Var}(Y | \mathbf{x}) = \sigma^2$, and put $d(\mathbf{x}) = m(\mathbf{x}) - \mathbf{x}^\top \beta^*$. Show that $\sqrt{n}(\beta_{\mathbf{X}} - \beta^*) \rightarrow N_p(\mathbf{0}, \Sigma^{-1} E(d^2 \mathbf{x} \mathbf{x}^\top) \Sigma^{-1})$, and that $\Sigma^{-1} \Omega \Sigma^{-1} = \sigma^2 \Sigma^{-1} + \Sigma^{-1} E(d^2 \mathbf{x} \mathbf{x}^\top) \Sigma^{-1}$. Interpret the two terms in the light of [Proposition 19.5.1\(b\)](#).

Solution. $\beta_{\mathbf{X}} - \beta^* = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{d}$ with $\mathbf{d} = (d(\mathbf{x}_1), \dots, d(\mathbf{x}_n))^\top$, and $E(\mathbf{x} d(\mathbf{x})) = E(\mathbf{x} U) = \mathbf{0}$ because $E(U | \mathbf{x}) = d(\mathbf{x})$. The argument of [Theorem 19.5.2\(a\)](#) with U replaced by $d(\mathbf{x})$ gives the first limit. Since $U = d(\mathbf{x}) + \varepsilon$ with $E(\varepsilon | \mathbf{x}) = 0$, $E(U^2 | \mathbf{x}) = d(\mathbf{x})^2 + \sigma^2$, and $\Omega = \sigma^2 \Sigma + E(d^2 \mathbf{x} \mathbf{x}^\top)$. The first term, $\sigma^2 \Sigma^{-1}$, is the asymptotic version of $n \sigma^2 E[(\mathbf{X}^\top \mathbf{X})^{-1}]$, the within-design part; the second is the asymptotic version of $n \text{Cov}(\beta_{\mathbf{X}})$, the between-design part. (They are limits of those moments only under uniform integrability, and for some designs the finite-sample moments do not even exist.)

19.6 Collinearity, previewed

Collinearity, near-linear dependence among the columns of $\mathbf{X}$, violates none of the assumptions of Part III. As long as $\mathbf{X}$ has full rank, every result of Parts II and III holds. What collinearity does is make some of them unhelpful: intervals that are correct but very wide. [Chapter 26](#) develops diagnostics, and [Chapter 27](#) remedies that trade bias for variance.

19.6.1 Variance inflation

For a single coefficient, the Frisch–Waugh–Lovell theorem gave [Eq. 6.6.2](#):

$$\text{Var}(\hat{\beta}_j) = \frac{\sigma^2}{S_{jj}} \cdot \frac{1}{1 - R_j^2},$$

where S_{jj} is the centred sum of squares of $\mathbf{x}_j$ and R_j^2 is the coefficient of determination from regressing $\mathbf{x}_j$ on the other regressors. The first factor is the variance $\mathbf{x}_j$ would give if it were

orthogonal to the other regressors. The second, the **variance inflation factor** $\text{VIF}_j = 1/(1 - R_j^2)$, is the price of the part of $\mathbf{x}_j$ that the others can already explain. A variance inflation factor of 100 means the standard error is ten times what an orthogonal design with the same spread would give.

The factors have a compact matrix form. Let $\mathbf{R}$ be the correlation matrix of the k regressors other than the intercept. Then $\text{VIF}_j = [\mathbf{R}^{-1}]_{jj}$ ([Exercise \(A1\)](#)), and the eigenvalues of $\mathbf{R}$ show where the problem lies.

Proposition 19.6.1 — Where collinearity costs variance

Let $\mathbf{X}$ have full rank and let $\mathbf{X}^\top \mathbf{X} = \sum_{\ell=1}^p \lambda_\ell \mathbf{v}_\ell \mathbf{v}_\ell^\top$ with orthonormal eigenvectors $\mathbf{v}_\ell$ and eigenvalues $\lambda_\ell > 0$.

- (a) For every $\mathbf{a} \in \mathbb{R}^p$, $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) = \sigma^2 \sum_{\ell} (\mathbf{a}^\top \mathbf{v}_\ell)^2 / \lambda_\ell$.
- (b) The fitted values at the design points have average variance $\sigma^2 p/n$, whatever the eigenvalues.
- (c) With $\mathbf{R}$ as above, $\sum_j \text{VIF}_j = \text{tr } \mathbf{R}^{-1} = \sum_{\ell} 1/\lambda_\ell(\mathbf{R})$, and every $\text{VIF}_j \leq 1/\lambda_{\min}(\mathbf{R})$.

Proof.

- (a) By [Theorem 1.7.2](#), $(\mathbf{X}^\top \mathbf{X})^{-1} = \sum_{\ell} \lambda_\ell^{-1} \mathbf{v}_\ell \mathbf{v}_\ell^\top$, and $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) = \sigma^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{a}$ ([Corollary 5.5.2](#)). (b) $\text{Cov}(\hat{\mathbf{Y}}) = \sigma^2 \mathbf{M}$, and $\text{tr } \mathbf{M} = p$ ([Proposition 6.3.4](#)). (c) The first equality is $\text{VIF}_j = [\mathbf{R}^{-1}]_{jj}$ summed over j . The trace is the sum of the eigenvalues of $\mathbf{R}^{-1}$, which are $1/\lambda_\ell(\mathbf{R})$. Each diagonal entry of $\mathbf{R}^{-1}$ is at most its largest eigenvalue, by [Theorem 1.7.7](#) applied to a standard basis vector.

■

Part (a) locates the damage. A small eigenvalue inflates the variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ only through the component of $\mathbf{a}$ along its eigenvector. Individual coefficients usually have such components, and so do predictions at points that break the pattern of the regressors; predictions that follow the pattern do not, and by (b) fitted values at the design points are as precise on average as in any design. Collinearity is a problem about *attributing* an effect to one of several regressors that moved together, not about fitting.

Example. (Longley's regression)

Longley's (1967) data, which [Example \(Longley's data, exactly\)](#) used to test the accuracy of least squares algorithms, regress total employment on six economic series over $n = 16$ years. The variance inflation factors range from 3.59 for ARMED (the size of the armed forces) to 1788.5 for GNP. The eigenvalues of the correlation matrix run from 4.603 down to 0.00038, and the factors sum to 3119.4, which is the sum of the reciprocal eigenvalues, as [Proposition 19.6.1\(c\)](#) requires. Four of the series (the price deflator, GNP, population and the year itself) rose almost in step over the sixteen years, each with correlation above 0.99 with the year. The data can say much about their joint movement and almost nothing about any one of them with the others held fixed.

```
import numpy as np
import statsmodels.api as sm
```

```

data = sm.datasets.longley.load_pandas().data
Z = data.drop(columns="TOTEMP").to_numpy()           # six regressors
n, k = Z.shape

def r_squared(v, W):
    W1 = np.column_stack([np.ones(len(v)), W])
    fitted = W1 @ np.linalg.lstsq(W1, v, rcond=None)[0]
    return 1 - np.sum((v - fitted) ** 2) / np.sum((v - v.mean()) ** 2)

vif = np.array([1 / (1 - r_squared(Z[:, j], np.delete(Z, j, axis=1))) for j in range
(k)])
R = np.corrcoef(Z, rowvar=False)
print(dict(zip(data.columns[1:], np.round(vif, 1))))
print("diagonal of R^{-1}:", np.round(np.diag(np.linalg.inv(R)), 1))
print("eigenvalues of R: ", np.round(np.linalg.eigvalsh(R), 5))

```

Example. (Predicting along and across the pattern)

Draw $m = 40$ pairs of regressors with sample correlation 0.9868, so that each has a variance inflation factor of 38.1, and fit $E(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2$. In units of σ , the two slopes have standard deviations 0.904 and 0.907. At the new point $(x_1, x_2) = (1, 1)$, which follows the pattern of the data, the fitted mean has standard deviation 0.228, close to the root mean square over the design points, $\sqrt{3/40} = 0.274$. At $(1, -1)$, which is just as far from the origin but against the pattern, it is 1.809. [Figure 19.6.1](#) shows the contours of this standard deviation. They are long ellipses aligned with the data cloud.

```

rng = np.random.default_rng(1906)
m, rho = 40, 0.98
x1 = rng.normal(size=m)
x2 = rho * x1 + np.sqrt(1 - rho**2) * rng.normal(size=m)
X = np.column_stack([np.ones(m), x1, x2])
G = np.linalg.inv(X.T @ X)           # Cov(beta_hat) / sigma^2
along = np.array([1.0, 1.0, 1.0])    # a new point that follows the
    pattern
across = np.array([1.0, 1.0, -1.0])   # same distance, against the
    pattern
print("sd of beta_1, beta_2 (units of sigma):", np.round(np.sqrt(np.diag(G)[1:]), 3)
)
print("sd of the fitted mean, along :", round(np.sqrt(along @ G @ along), 3))
print("sd of the fitted mean, across:", round(np.sqrt(across @ G @ across), 3))
print("average over the design points:", round(np.trace(X @ G @ X.T) / m, 3), "= p/n
")

```

19.6.2 How collinearity interacts with the other departures

Collinearity causes no bias, but it amplifies the departures of the earlier sections. By [Eq. 19.1.2](#) the stakes of omitting x_2 are $r^2|\gamma - 1|$, so the choice between short and long models matters most exactly when the data are least able to make it. Perturbations of the regressors, from rounding or measurement error, are governed by the condition number of $\mathbf{X}$ ([Theorem 10.5.1](#)), which is large for the same reason. And a single case can have high leverage without being extreme in

Figure 19.6.1: Standard deviation of the fitted mean, in units of σ , over the regressor plane for [Example \(Predicting along and across the pattern\)](#), with the 40 design points. The contours are elongated along the data: prediction at the circle, which follows the pattern, is precise; prediction at the square, which breaks it, is not.

any one regressor, because leverage measures distance in the metric of the regressors' covariance ([Proposition 6.8.2](#)).

Idea. Collinearity is a shortage of information, not a failure of the model, and it magnifies every other departure.

19.6.3 Exercises

19.6.3.1 A. Check your understanding

Exercise A1.

Let $\mathbf{Z}$ be the $n \times k$ matrix of centred regressors, each scaled to unit length, so that $\mathbf{Z}^\top \mathbf{Z} = \mathbf{R}$. Use [Eq. 6.6.1](#) to show that $[\mathbf{R}^{-1}]_{jj} = 1/(1 - R_j^2)$.

Solution. By [Eq. 6.6.1](#) with $\mathbf{X}_1 = \mathbf{z}_j$ and $\mathbf{X}_2$ the other columns, $[\mathbf{R}^{-1}]_{jj} = 1/\|(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{z}_j\|^2$, where $\mathbf{M}_{(j)}$ projects onto the other centred columns. Since $\mathbf{z}_j$ is centred with unit length, the squared residual length is $1 - R_j^2$, as in [Exercise \(B1\)](#) (the intercept only removes means, and the columns are already centred).

Exercise A2.

Show that $\text{VIF}_j \geq 1$, with equality iff the centred $\mathbf{x}_j$ is orthogonal to every other centred regressor.

19.6.3.2 B. Practice

Exercise B1.

For two centred regressors with $\|\mathbf{x}_1\|^2 = \|\mathbf{x}_2\|^2 = S$ and correlation r , show that $\text{Var}(\hat{\beta}_1 + \hat{\beta}_2) = 2\sigma^2/(S(1+r))$ and $\text{Var}(\hat{\beta}_1 - \hat{\beta}_2) = 2\sigma^2/(S(1-r))$. Relate the result to [Proposition 19.6.1\(a\)](#) and to [Figure 19.6.1](#).

Solution. The slope block of $\mathbf{X}^\top \mathbf{X}$ is $S \begin{pmatrix} 1 & r \\ r & 1 \end{pmatrix}$, with eigenvalues $S(1+r)$ and $S(1-r)$ and eigenvectors $(1, 1)^\top/\sqrt{2}$ and $(1, -1)^\top/\sqrt{2}$. The intercept is orthogonal to the centred slopes and plays no role. With $\mathbf{a} = (1, \pm 1)^\top$, $\mathbf{a}^\top \mathbf{v}$ is $\sqrt{2}$ on one eigenvector and 0 on the other, so part (a) gives $2\sigma^2/(S(1 \pm r))$. When r is near one, the sum, the combined effect of two regressors that move together, is well determined, and the difference is not. In the figure, the new point $(1, 1)$ asks for the sum and $(1, -1)$ for the difference.

Exercise B2.

Show that $\sum_j \text{VIF}_j \geq k$, and that $\max_j \text{VIF}_j \geq (\sum_j \text{VIF}_j)/k$. Deduce that a correlation matrix with a small eigenvalue must have at least one large variance inflation factor, and conversely.

19.6.3.3 C. Going deeper

Exercise C1.

Show that if $\mathbf{x}_0$ is a convex combination of the rows of $\mathbf{X}$, then $\text{Var}(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}) \leq \sigma^2 \max_i h_{ii}$. Is the converse true: does a small prediction variance mean $\mathbf{x}_0$ lies inside the data? Compare with [Example \(Hidden extrapolation\)](#).

19.7 Summary and Notes

19.7.1 Summary

Idea.

1. Omitting regressors biases $\hat{\boldsymbol{\beta}}_1^S$ by $\boldsymbol{\Pi}\boldsymbol{\beta}_2$ and inflates s^2 , while the covariances look exactly as the short model claims ([Theorem 19.1.2](#)). Irrelevant regressors cost only variance ([Theorem 19.1.3](#)).
2. The short regression has the smaller mean squared error matrix iff $\gamma \leq 1$; at the design points the threshold is p_2 ([Theorem 19.1.5](#)).
3. Under $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{V}$ the usual variance estimate is off by a factor bounded by eigenvalue ratios of $\mathbf{V}$ ([Theorem 19.2.2](#)), while the efficiency loss is bounded by Kantorovich's constant ([Theorem 19.2.3](#)).
4. With non-normal errors and $\max_i h_{ii} \rightarrow 0$, linear estimates are asymptotically normal and t and F tests asymptotically valid ([Theorem 19.3.2](#)); leverage bounds

the finite-sample skewness and kurtosis ([Proposition 19.3.3](#)).

5. Intervals for σ^2 , variance-ratio tests and prediction intervals stay wrong in large samples ([Proposition 19.3.4](#), [Proposition 12.3.3](#)); quadratic balance protects F tests ([Proposition 19.3.5](#)).
6. One contaminated case moves $\hat{\beta}$ by a leverage factor times its residual, hides itself in the fit ([Theorem 19.4.1](#)), and can move the estimate arbitrarily far ([Proposition 19.4.2](#)).
7. With random regressors and a curved mean, least squares estimates the population projection with a sandwich covariance that the usual formula misses ([Proposition 19.5.1](#), [Theorem 19.5.2](#)).
8. Collinearity breaks no assumption but inflates the variance of coefficients and of predictions against the pattern of the data ([Proposition 19.6.1](#)).

19.7.2 Notes and sources

Coverage. The chapter covers the topics of Seber and Lee (2003, chapter 9) with its own arguments, and adds [Theorem 19.1.5](#), [Proposition 19.3.3](#), the limiting coverages and the breakdown point. Measurement error is in [Chapter 24](#) (rounding in [Section 19.5](#)), perturbation theory in [Chapter 10](#).

Underfitting and overfitting. The omitted-variable formula is classical; it is [Proposition 5.7.2](#) in [Chapter 5](#). The criterion $\gamma \leq 1$ for the restricted estimator to have the smaller mean squared error matrix is due to Toro-Vizcarrondo and Wallace (1968) (in their notation, with the factor $1/2$ in the noncentrality, the condition reads $\lambda \leq 1/2$), who also proposed testing it with the noncentral F distribution. Pretest estimators, which choose between the two models from the data, are taken up with model selection in [Section 29.2](#) and [Section 29.5](#).

Wrong covariance. The bounds on the bias of the usual variance estimate are Swindel's (1968). The efficiency bound of [Theorem 19.2.3](#) rests on Kantorovich's inequality. The sharp bound for the determinant of the whole covariance matrix is due to Bloomfield and Watson (1975) and Knott (1975). Grenander (1954) showed that least squares is asymptotically efficient for polynomial trends under stationary errors, the phenomenon of [Example \(A trend with autocorrelated errors\)](#). Kruskal's (1968) condition for exact equality is [Theorem 6.9.3](#).

Non-normality. The Lindeberg–Feller theorem is in Billingsley (1995), and Cramér–Wold, Slutsky and continuous mapping in van der Vaart (1998). The leverage condition $h_n^* \rightarrow 0$ is the one used by Huber (1973) in his asymptotic theory of robust regression. That tests on variances are sensitive to non-normality while tests on means are not was emphasized by Box (1953). Box and Watson (1962) and Atiqullah (1962) studied the regression F test through its first two moments, and Atiqullah introduced quadratic balance. [Proposition 19.3.5](#) is a compact version of their calculation.

Outliers and breakdown. The breakdown point in its finite-sample form is from Donoho and Huber (1983), and the influence function from Hampel (1974). Regression estimators with breakdown point near one half exist, least median of squares (Rousseeuw 1984) being the first. The stack loss data are from Brownlee (1965), and their last observation is a much-analysed outlier. [Chapter 20](#) develops diagnostics for such cases.

Random regressors. The view of least squares as estimating a best linear approximation, with a sandwich covariance that the usual formula gets wrong, is due to White (1980). Berkson

(1950) distinguished controlled regressors from regressors measured with error. Longley's (1967) data are the standard example of severe collinearity.

Chapter 20

Residuals, Leverage and Influence

Every result of Parts II–IV was proved for a model that holds for all n cases. A record is mistyped, one unit is unlike the others, or the model is right for most of the range and wrong at its edge. Least squares treats every case as equally credible, so a single bad case can move the fit a long way, and it can do so without leaving a large residual behind. This chapter builds the tools for finding such cases. Residuals, rescaled so that they can be compared, show cases that the model fits badly. Leverage shows cases whose position among the regressors gives them a strong pull on the fit. Deleting one case at a time, cheap by the updating formulas of [Chapter 10](#), turns these two ingredients into exact tests and into measures of influence. Two warnings run through the chapter. Diagnostics that look at one case at a time can be defeated by a few bad cases acting together. And a flagged case is a question to be investigated, not a verdict. The last section uses a robust fit as a second opinion: a fit that the bad cases cannot capture shows them by their residuals.

What you need. [Chapter 4](#) (independent projections), [Chapter 5](#) (moments of fitted values and residuals, [Proposition 5.5.3](#)), [Chapter 6](#) (the hat matrix and its properties, [Proposition 6.8.1](#) and [Proposition 6.8.2](#); the Frisch–Waugh–Lovell theorem, [Theorem 6.6.2](#)), [Chapter 10](#) (the deletion formulas, [Proposition 10.6.2](#)), [Chapter 11](#) (t and F tests), and [Chapter 13](#) (the Bonferroni inequality). [Chapter 19](#) describes in general terms what a contaminated case does to least squares ([Theorem 19.4.1](#)); this chapter is about finding such cases in a particular data set.

20.0.1 Roadmap

- [Leverage and the hat matrix](#)
- [Deletion diagnostics](#)
- [Cook's distance, DFFITS and DFBETAS](#)
- [Masking and swamping](#)
- [Robust fitting as a diagnostic](#)
- [Summary and notes](#)

20.1 Kinds of residuals

The model makes its assumptions about the errors, which are never observed. The residuals are their visible stand-ins, imperfect in a precise way: they are the projection of the errors onto a subspace of dimension $n - p$, so they are correlated, have unequal variances, and are shrunk most at the cases that matter most. This section defines rescaled residuals, finds their laws, and asks what residual plots reveal.

20.1.1 The setting

Throughout the chapter,

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}, \quad \mathbf{E}(\boldsymbol{\varepsilon}) = \mathbf{0}, \quad \text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I},$$

with $\mathbf{X}$ of size $n \times p$ and full column rank $p < n$. Results that need normal errors say so and then assume [Eq. 7.3.1](#). The hat matrix is $\mathbf{M} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top$, and h_{ij} denotes its (i, j) entry, so that h_{ii} is the leverage of case i ([Definition 6.8.1](#)). The i th row of $\mathbf{X}$, written as a column, is $\mathbf{x}_{(i)}$, and $\mathbf{e}_i$ is the i th coordinate vector of $\mathbb{R}^n$. The residual vector is $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{Y}$, with entries $\hat{\varepsilon}_i$, and $s^2 = \|\hat{\boldsymbol{\varepsilon}}\|^2 / (n - p)$.

Everything in the chapter depends on $\mathbf{X}$ only through $\mathcal{C}(\mathbf{X})$. If $\mathbf{X}$ has rank $r < p$, replace p by r in every degree of freedom and every formula that involves $\mathbf{M}$ alone. Formulas that involve $(\mathbf{X}^\top \mathbf{X})^{-1}$ hold for any full-rank reparameterization ([Theorem 6.7.1](#)).

Two facts from earlier chapters drive everything that follows. First, by [Proposition 6.4.3\(e\)](#),

$$\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}, \tag{20.1.1}$$

so the residuals are a fixed linear image of the errors. Second, by [Proposition 5.5.3\(b\)](#), $\text{Cov}(\hat{\boldsymbol{\varepsilon}}) = \sigma^2(\mathbf{I} - \mathbf{M})$. So $\text{Var}(\hat{\varepsilon}_i) = \sigma^2(1 - h_{ii})$ and, for $i \neq j$,

$$\text{Corr}(\hat{\varepsilon}_i, \hat{\varepsilon}_j) = \frac{-h_{ij}}{\sqrt{(1 - h_{ii})(1 - h_{jj})}}. \tag{20.1.2}$$

A case with leverage near one has a residual with variance near zero: the fit passes close to it whatever its response. Raw residuals are therefore not comparable across cases.

20.1.2 Four residuals

Definition 20.1.1 — Standardized and studentized residuals

Let $h_{ii} < 1$. For case i :

- (a) the **raw residual** is $\hat{\varepsilon}_i = y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}$;
- (b) the **standardized residual** is $z_i = \hat{\varepsilon}_i / (\sigma \sqrt{1 - h_{ii}})$, which needs the true σ ;

(c) the **internally studentized residual** is

$$r_i = \frac{\hat{\varepsilon}_i}{s\sqrt{1-h_{ii}}};$$

(d) the **externally studentized residual** is

$$t_i = \frac{\hat{\varepsilon}_i}{s_{(i)}\sqrt{1-h_{ii}}},$$

where $s_{(i)}^2 = \text{SSE}_{(i)}/(n-p-1)$ is the residual mean square of the least squares fit to the $n-1$ cases other than i .

Under normal errors z_i is exactly $N(0, 1)$, but it cannot be computed. The studentized residuals replace σ by an estimate: s , which includes case i , or $s_{(i)}$, which does not, so that a gross error in y_i cannot inflate the yardstick it is measured against. [Section 20.3](#) shows that $s_{(i)}$ costs nothing extra and that t_i has an exact t law.

Remark (Names). Terminology varies. Some authors call r_i , or even $\hat{\varepsilon}_i/s$, the standardized residual, and t_i is also called the studentized deleted residual or RSTUDENT. R's `rstandard` and `rstudent` return r_i and t_i , as do `resid.studentized.internal` and `resid.studentized.external` in `statsmodels`.

20.1.3 The law of the internally studentized residual

The residual r_i is not t -distributed, because $\hat{\varepsilon}_i$ is part of s . Its law is a rescaled beta.

Proposition 20.1.1 — Law of the internally studentized residual

Assume [Eq. 7.3.1](#), $n-p \geq 2$ and $h_{ii} < 1$. Then:

- (a) $r_i^2/(n-p) \sim \text{Beta}(\frac{1}{2}, \frac{n-p-1}{2})$;
- (b) $|r_i| \leq \sqrt{n-p}$, $E(r_i) = 0$ and $\text{Var}(r_i) = 1$;
- (c) the law of r_i is the same for every case and does not depend on $\mathbf{X}$, $\boldsymbol{\beta}$ or σ^2 .

Proof. Put $\mathbf{u} = (\mathbf{I} - \mathbf{M})\mathbf{e}_i/\sqrt{1-h_{ii}}$. Since $\|(\mathbf{I} - \mathbf{M})\mathbf{e}_i\|^2 = \mathbf{e}_i^\top (\mathbf{I} - \mathbf{M})\mathbf{e}_i = 1 - h_{ii}$, $\mathbf{u}$ is a unit vector in $\mathcal{C}(\mathbf{X})^\perp$, and by [Eq. 20.1.1](#) $\hat{\varepsilon}_i = \mathbf{e}_i^\top (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon} = \sqrt{1-h_{ii}} \mathbf{u}^\top \boldsymbol{\varepsilon}$. Let $\mathbf{P}_1 = \mathbf{u}\mathbf{u}^\top$ and $\mathbf{P}_2 = \mathbf{I} - \mathbf{M} - \mathbf{u}\mathbf{u}^\top$. Because $(\mathbf{I} - \mathbf{M})\mathbf{u} = \mathbf{u}$, both are symmetric and idempotent, $\mathbf{P}_1\mathbf{P}_2 = \mathbf{0}$, and their ranks are 1 and $n-p-1$. They split the residual sum of squares: $\text{SSE} = \boldsymbol{\varepsilon}^\top (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon} = \|\mathbf{P}_1\boldsymbol{\varepsilon}\|^2 + \|\mathbf{P}_2\boldsymbol{\varepsilon}\|^2$. By [Theorem 4.4.4](#), applied to $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2\mathbf{I})$, the variables $U = (\mathbf{u}^\top \boldsymbol{\varepsilon})^2/\sigma^2 \sim \chi^2(1)$ and $V = \|\mathbf{P}_2\boldsymbol{\varepsilon}\|^2/\sigma^2 \sim \chi^2(n-p-1)$ are independent. Now

$$\frac{r_i^2}{n-p} = \frac{\hat{\varepsilon}_i^2}{(1-h_{ii})\text{SSE}} = \frac{U}{U+V},$$

which is $\text{Beta}(\frac{1}{2}, \frac{n-p-1}{2})$ by [Exercise \(B4\)](#). This is (a). A beta variable lies in $[0, 1]$, which gives the bound in (b). Replacing $\boldsymbol{\varepsilon}$ by $-\boldsymbol{\varepsilon}$ changes the sign of r_i and not its law, so $E(r_i) = 0$, and $E(r_i^2) = (n-p) \cdot \frac{1}{2}/\frac{n-p}{2} = 1$. Part (c) holds because the law in (a),

together with the symmetry, determines the law of r_i .

■

The bound in (b) bites when $n - p$ is small: with $n - p = 5$, no $|r_i|$ can exceed $\sqrt{5} \approx 2.236$, however wild the case, because a gross error inflates s along with $\hat{\varepsilon}_i$. The r_i are not independent either; their correlations are those of [Eq. 20.1.2 \(Exercise \(C1\)\)](#).

20.1.4 What a residual plot can show

A residual plot shows residuals against the fitted values, a regressor, an omitted variable or the order of collection, to reveal structure the model has missed. Least squares removes some structure automatically, and it is worth knowing exactly which.

Proposition 20.1.2 — What least squares leaves in the residuals

Suppose $\mathbf{1} \in \mathcal{C}(\mathbf{X})$.

- (a) The residual vector is orthogonal to $\mathbf{1}$, to every column of $\mathbf{X}$ and to $\hat{\mathbf{Y}}$. Hence the least squares line through a plot of the residuals against the fitted values, or against any regressor in the model, is the horizontal axis.
- (b) The least squares line through a plot of the residuals against the responses y_i has slope $1 - R^2$.
- (c) If in fact $\mathbf{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\delta}$ for some $\boldsymbol{\delta} \in \mathbb{R}^n$, and $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}$, then $\mathbf{E}(\hat{\boldsymbol{\varepsilon}}) = (\mathbf{I} - \mathbf{M})\boldsymbol{\delta}$ and $\text{Cov}(\hat{\boldsymbol{\varepsilon}}) = \sigma^2(\mathbf{I} - \mathbf{M})$.

Proof.

- (a) is [Proposition 6.4.3\(a\)](#) and (b). A line fitted with an intercept to points $(a_i, \hat{\varepsilon}_i)$ has slope $\sum_i (a_i - \bar{a})\hat{\varepsilon}_i / \sum_i (a_i - \bar{a})^2$, and the numerator is $\mathbf{a}^\top \hat{\boldsymbol{\varepsilon}} - \bar{a} \mathbf{1}^\top \hat{\boldsymbol{\varepsilon}} = 0$ when $\mathbf{a}$ is $\hat{\mathbf{Y}}$ or a column of $\mathbf{X}$.
- (b) With $\mathbf{a} = \mathbf{y}$ the numerator is $\mathbf{y}^\top \hat{\boldsymbol{\varepsilon}} = (\hat{\mathbf{Y}} + \hat{\boldsymbol{\varepsilon}})^\top \hat{\boldsymbol{\varepsilon}} = \|\hat{\boldsymbol{\varepsilon}}\|^2 = \text{SSE}$, and the denominator is $\sum_i (y_i - \bar{y})^2 = \text{SST}$. The slope is $\text{SSE}/\text{SST} = 1 - R^2$.
- (c) $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{Y}$, and [Theorem 2.2.1](#) gives mean $(\mathbf{I} - \mathbf{M})(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\delta}) = (\mathbf{I} - \mathbf{M})\boldsymbol{\delta}$ and covariance $\sigma^2(\mathbf{I} - \mathbf{M})^2 = \sigma^2(\mathbf{I} - \mathbf{M})$.

■

By (a), a plot against fitted values or regressors has had its linear trend removed, so any remaining trend is curved, a sign of a misspecified mean. By (b), a plot against the responses always slopes upward, even when the model is right, so it is not used.

Part (c) is the sobering one. The residuals are centred at $(\mathbf{I} - \mathbf{M})\boldsymbol{\delta}$, the part of the error in the mean orthogonal to the model space. The part of $\boldsymbol{\delta}$ inside $\mathcal{C}(\mathbf{X})$ leaves no trace, yet it is exactly this part, $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \boldsymbol{\delta}$, that biases the coefficients ([Proposition 5.5.7\(a\)](#)). An omitted regressor highly correlated with the included ones biases their coefficients ([Theorem 19.1.2](#)) while leaving the residuals almost clean. Residual plots can show that the *fitted values* are wrong, never that the *coefficients* are right.

Figure 20.1.1: Residuals against fitted values for four straight-line fits: (a) correct model, (b) curved mean, (c) variance growing with the mean, (d) one gross error.

The standard plots are these. Against **fitted values**: curvature suggests a misspecified mean, a fan shape variance that grows with the mean, isolated points outliers. Against **each regressor**: curvature points to that regressor. Against a variable **not in the model**: better replaced by the added-variable plot of [Section 6.6](#), whose slope is the coefficient the variable would receive ([Exercise \(B1\)](#)). Against **collection order**: runs of equal sign suggest serial correlation, tested in [Chapter 21](#) ([Theorem 21.5.3](#)). A **normal quantile plot**: curvature suggests skewed or heavy-tailed errors ([Proposition 21.1.1](#)). Studentized residuals are preferable to raw ones throughout, since raw residuals make high-leverage cases look better than they are.

Example. (Four residual plots)

Each panel of [Figure 20.1.1](#) comes from 80 simulated cases with x uniform on $(0, 10)$, fitted by a straight line. In (a) the model is right and the residuals form a structureless band. In (b) the mean has a quadratic term, and the residuals show the parabola the line could not absorb. In (c) the error standard deviation grows with x , and the band opens into a fan. In (d) one response has an error of 8σ ; it stands out, and the line has been pulled slightly towards it. In every panel the residuals are orthogonal to the fitted values, as [Proposition 20.1.2\(a\)](#) requires; the listing prints the inner product.

```
import numpy as np

def ls_fit(X, y):
    beta, *_ = np.linalg.lstsq(X, y, rcond=None)
    return beta, X @ beta, y - X @ beta

rng = np.random.default_rng(7)
n = 80
x = rng.uniform(0, 10, n)
eps = rng.normal(size=n)
X = np.column_stack([np.ones(n), x])
responses = {
    "(a) model correct": 1 + 0.5 * x + eps,
    "(b) curved mean": 1 + 0.5 * x + 0.08 * (x - 5) ** 2 + 0.6 * eps,
    "(c) variance grows": 1 + 0.5 * x + (0.1 + 0.25 * x) * eps,
    "(d) one gross error": 1 + 0.5 * x + eps + 8.0 * (np.arange(n) == 17),
}
for name, y in responses.items():
    beta, fitted, resid = ls_fit(X, y)
    print(f"{name:22s} slope {beta[1]:.3f}    residuals . fitted = {resid @ fitted:.1e}")
```

20.1.5 Partial residuals

A plot of residuals against a regressor $\mathbf{x}_j$ in the model has a flat least squares line ([Proposition 20.1.2\(a\)](#)). The **component-plus-residual plot**, or partial residual plot, adds the fitted linear component back. It plots

$$\hat{\varepsilon}_i + \hat{\beta}_j x_{ij} \quad \text{against} \quad x_{ij}, \quad i = 1, \dots, n.$$

Compare it with the added-variable plot of [Section 6.6](#), which plots $\tilde{\mathbf{y}} = (\mathbf{I} - \mathbf{M}_{(j)})\mathbf{y}$ against $\tilde{\mathbf{x}}_j = (\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j$, where $\mathbf{M}_{(j)}$ projects onto the span of the columns other than $\mathbf{x}_j$.

Proposition 20.1.3 — Two plots with the same line

Let $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, and let $\mathbf{x}_j$ be a column of $\mathbf{X}$ that is not a multiple of $\mathbf{1}$.

- (a) The least squares line of $\hat{\varepsilon} + \hat{\beta}_j \mathbf{x}_j$ on $[\mathbf{1}, \mathbf{x}_j]$ has intercept 0, slope $\hat{\beta}_j$, and residual vector $\hat{\varepsilon}$.
- (b) The least squares line through the origin of $\tilde{\mathbf{y}}$ on $\tilde{\mathbf{x}}_j$ has slope $\hat{\beta}_j$ and residual vector $\hat{\varepsilon}$.

Proof.

- (a) The vector $\hat{\varepsilon}$ is orthogonal to $\mathbf{1}$ and to $\mathbf{x}_j$ by [Proposition 20.1.2\(a\)](#). So $\hat{\varepsilon} + \hat{\beta}_j \mathbf{x}_j = \hat{\beta}_j \mathbf{x}_j + \hat{\varepsilon}$ is the sum of a vector in $\mathcal{C}([\mathbf{1}, \mathbf{x}_j])$ and a vector orthogonal to that space. By [Theorem 6.4.1](#) the first is the fitted vector and the second the residual.
- (b) is [Theorem 6.6.2\(a\)](#) and (b) with $\mathbf{X}_1 = \mathbf{x}_j$.

■

So the two plots share their line and their scatter about it, and differ only in the horizontal axis. The added-variable plot uses the part of $\mathbf{x}_j$ not explained by the other regressors: its spread is the information for $\hat{\beta}_j$, and cases far out along it pull on $\hat{\beta}_j$ (partial leverage, [Section 20.2](#)). The component-plus-residual plot uses $\mathbf{x}_j$ on its own scale, the scale on which a transformation would be chosen, so it shows the *form* of the dependence better. It can mislead when $\mathbf{x}_j$ is related nonlinearly to the other regressors.

Example. (Curvature seen two ways)

In 120 simulated cases, x_1 is uniform on $(0, 4)$, x_2 is correlated with it (sample correlation 0.87), and $E(Y) = 1 + x_2 + 0.7(x_1 - 2)^2$. The fitted model is linear in both, with coefficient -0.144 for x_1 , the slope of both panels of [Figure 20.1.2](#). A quadratic fitted to the component-plus-residual plot (b) has leading coefficient 0.671, close to the true 0.7. In the added-variable plot (a) the curve is smeared, because its horizontal axis mixes x_1 with x_2 , and the corresponding coefficient is 0.309.

```
rng = np.random.default_rng(11)
n2 = 120
x1 = rng.uniform(0, 4, n2)
x2 = 0.8 * x1 + rng.normal(0, 0.6, n2)          # correlated with x1
y2 = 1 + x2 + 0.7 * (x1 - 2) ** 2 + rng.normal(0, 0.4, n2)
```

Figure 20.1.2: A curved effect of x_1 , fitted linearly: (a) added-variable plot, (b) component-plus-residual plot. Same slope, same residuals ([Proposition 20.1.3](#)).

```
X2 = np.column_stack([np.ones(n2), x1, x2])          # the fitted model is linear in
x1                                                    # x1
beta2, fitted2, resid2 = ls_fit(X2, y2)

component = resid2 + beta2[1] * x1                    # component-plus-residual for x1
Z = np.column_stack([np.ones(n2), x2])              # everything except x1
x1_tilde = x1 - Z @ np.linalg.lstsq(Z, x1, rcond=None)[0]
y_tilde = y2 - Z @ np.linalg.lstsq(Z, y2, rcond=None)[0] # added-variable
coordinates

print("coefficient of x1:", beta2[1])
print("slope in component-plus-residual plot:", ls_fit(np.column_stack([np.ones(n2),
x1]), component)[0][1])
print("slope in added-variable plot:", (x1_tilde @ y_tilde) / (x1_tilde @ x1_tilde))
```

20.1.6 Exercises

20.1.6.1 A. Check your understanding

Exercise A1.

A straight line is fitted to $n = 3$ points. Show that every internally studentized residual satisfies $|r_i| = 1$ (unless all three residuals are zero), whatever the data. What does this say about using r_i to judge a fit with one residual degree of freedom?

Solution. Here $n - p = 1$, so $\mathcal{C}(\mathbf{X})^\perp$ is spanned by one unit vector $\mathbf{v}$, and $\hat{\boldsymbol{\varepsilon}} = c\mathbf{v}$ for a scalar c . Then $\hat{\varepsilon}_i = cv_i$, $s^2 = c^2$ and $1 - h_{ii} = v_i^2$ (the i th diagonal entry of $\mathbf{I} - \mathbf{M} = \mathbf{v}\mathbf{v}^\top$). So $r_i^2 = c^2 v_i^2 / (c^2 v_i^2) = 1$ whenever $v_i \neq 0$. With one degree of freedom for error the studentized residuals carry no information at all about which case fits worst.

Exercise A2.

Show that $\sum_i (1 - h_{ii}) r_i^2 = n - p$ for any data. Deduce that if every leverage is at most

$h_{\max} < 1$, then at most $(n - p)/((1 - h_{\max})c^2)$ cases can have $|r_i| > c$.

20.1.6.2 B. Practice

Exercise B1.

Let $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, let $\mathbf{z} \notin \mathcal{C}(\mathbf{X})$ be a candidate regressor, let $\hat{\gamma}$ be its coefficient when it is added to the model, and let R_z^2 be the R^2 of the regression of $\mathbf{z}$ on $\mathbf{X}$. Show that the least squares slope of the plot of $\hat{\mathbf{e}}$ against $\mathbf{z}$ is $\hat{\gamma}(1 - R_z^2)$. Why is the added-variable plot the better tool for judging whether $\mathbf{z}$ belongs in the model?

Solution. The slope is $\sum_i (z_i - \bar{z})\hat{e}_i / S_{zz} = \mathbf{z}^\top \hat{\mathbf{e}} / S_{zz}$, since $\mathbf{1}^\top \hat{\mathbf{e}} = 0$. Put $\tilde{\mathbf{z}} = (\mathbf{I} - \mathbf{M})\mathbf{z}$. Then $\mathbf{z}^\top \hat{\mathbf{e}} = \mathbf{z}^\top (\mathbf{I} - \mathbf{M})\mathbf{y} = \tilde{\mathbf{z}}^\top \mathbf{y}$, and by [Theorem 6.6.2\(a\)](#), $\hat{\gamma} = \tilde{\mathbf{z}}^\top \mathbf{y} / \|\tilde{\mathbf{z}}\|^2$. So $\mathbf{z}^\top \hat{\mathbf{e}} = \hat{\gamma} \|\tilde{\mathbf{z}}\|^2$, and $\|\tilde{\mathbf{z}}\|^2 = S_{zz}(1 - R_z^2)$ is the residual sum of squares of $\mathbf{z}$ on $\mathbf{X}$ ([Exercise \(B1\)](#)). The slope is $\hat{\gamma}(1 - R_z^2)$. When $\mathbf{z}$ is highly correlated with the columns of $\mathbf{X}$, the plot against $\mathbf{z}$ shrinks the effect towards zero, while the added-variable plot shows $\hat{\gamma}$ itself, against the horizontal spread $\|\tilde{\mathbf{z}}\|$ that actually carries information about it.

Exercise B2.

Simple linear regression is fitted to $x_i = i$, $i = 1, \dots, n$, but $E(Y_i) = \beta_0 + \beta_1 x_i + \gamma x_i^2$. Use [Proposition 20.1.2\(c\)](#) to show that the expected residuals lie on a parabola in i , and find its vertex.

20.1.6.3 C. Going deeper

Exercise C1.

Assume [Eq. 7.3.1](#) with $n - p \geq 2$ and leverages below one. Show that $E(r_i r_j) = -h_{ij} / \sqrt{(1 - h_{ii})(1 - h_{jj})}$ for $i \neq j$. *Hint:* write $r_i = \sqrt{n - p} \mathbf{u}_i^\top \mathbf{W}$ with $\mathbf{W} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon} / \|(\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}\|$, and show that $E(\mathbf{W}\mathbf{W}^\top) = (\mathbf{I} - \mathbf{M})/(n - p)$.

Solution. With $\mathbf{u}_i$ as in the proof of [Proposition 20.1.1](#), $r_i = \hat{e}_i / (s\sqrt{1 - h_{ii}}) = \sqrt{n - p} \mathbf{u}_i^\top \mathbf{W}$, because $\mathbf{u}_i^\top (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon} = \mathbf{u}_i^\top \boldsymbol{\varepsilon}$. For an orthogonal $\mathbf{Q}$ with $\mathbf{Q}(\mathbf{I} - \mathbf{M}) = (\mathbf{I} - \mathbf{M})\mathbf{Q}$ that maps $\mathcal{C}(\mathbf{X})^\perp$ to itself, $\mathbf{Q}\boldsymbol{\varepsilon}$ has the same law as $\boldsymbol{\varepsilon}$, so $\mathbf{Q}\mathbf{W}$ has the same law as $\mathbf{W}$ and $\mathbf{S} = E(\mathbf{W}\mathbf{W}^\top)$ satisfies $\mathbf{Q}\mathbf{S}\mathbf{Q}^\top = \mathbf{S}$. Since $\mathbf{W} \in \mathcal{C}(\mathbf{X})^\perp$, $\mathbf{S}$ vanishes on $\mathcal{C}(\mathbf{X})$; restricted to $\mathcal{C}(\mathbf{X})^\perp$ it commutes with every rotation of that space and is therefore a multiple of the identity there. Its trace is $E\|\mathbf{W}\|^2 = 1$, so $\mathbf{S} = (\mathbf{I} - \mathbf{M})/(n - p)$. Hence $E(r_i r_j) = (n - p) \mathbf{u}_i^\top \mathbf{S} \mathbf{u}_j = \mathbf{u}_i^\top \mathbf{u}_j = \mathbf{e}_i^\top (\mathbf{I} - \mathbf{M}) \mathbf{e}_j / \sqrt{(1 - h_{ii})(1 - h_{jj})}$, which is the stated value. Since $E(r_i) = 0$ and $\text{Var}(r_i) = 1$, this is also the correlation.

20.2 Leverage and the hat matrix

[Section 6.8](#) proved the basic properties of the leverage h_{ii} : it lies in $[0, 1]$, the leverages sum to p , $h_{ii} \geq 1/n$ with an intercept, and h_{ii} is an affine function of the Mahalanobis distance of $\mathbf{x}_{(i)}$ from the centroid of the regressors ([Proposition 6.8.1](#) and [Proposition 6.8.2](#)). This section

asks when a leverage deserves attention, how designed and observational data differ, and how to measure the pull of a case on one coefficient.

The fitted value of case i is

$$\hat{y}_i = h_{ii}y_i + \sum_{j \neq i} h_{ij}y_j,$$

so h_{ii} is the weight of a case in its own fitted value. Since $\sum_j h_{ij}^2 = h_{ii}$ (Proposition 6.8.1(a)), a case with h_{ii} near one leaves little weight for the others: its fitted value is essentially its own response, and the fit carries no information about whether y_i is right. Leverage is *potential* influence, a property of the design alone; Section 20.4 combines it with the residual.

20.2.1 How large is large?

The average leverage is p/n . The most widely used rule (Hoaglin and Welsch 1978) calls a case of high leverage if $h_{ii} > 2p/n$; a stricter variant uses $3p/n$. To see what these rules mean, compute how often they fire under a reference design with multivariate normal regressors.

Proposition 20.2.1 — Leverage under a Gaussian design

Let $\mathbf{X} = [\mathbf{1}, \mathbf{Z}]$, where the rows of the $n \times k$ matrix $\mathbf{Z}$ are independent $N_k(\boldsymbol{\mu}, \boldsymbol{\Sigma})$ vectors with $\boldsymbol{\Sigma}$ positive definite, and let $n \geq k + 2$. Then $\mathbf{X}$ has full column rank $p = k + 1$ with probability one, and for every i ,

$$\frac{h_{ii} - 1/n}{1 - 1/n} \sim \text{Beta}\left(\frac{k}{2}, \frac{n - 1 - k}{2}\right).$$

Proof. Reduction. Let $\mathbf{C} = \mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^\top$. By Lemma 6.6.1 with $\mathbf{X}_2 = \mathbf{1}$, $\mathbf{M} = n^{-1}\mathbf{1}\mathbf{1}^\top + \mathbf{P}$, where $\mathbf{P}$ is the orthogonal projection onto $\mathcal{C}(\mathbf{CZ})$, a subspace of $\mathbf{1}^\perp$. So $h_{ii} - 1/n = \mathbf{e}_i^\top \mathbf{P} \mathbf{e}_i$. Replacing $\mathbf{Z}$ by $(\mathbf{Z} - \mathbf{1}\boldsymbol{\mu}^\top)\boldsymbol{\Sigma}^{-1/2}$ does not change $\mathcal{C}(\mathbf{CZ})$, because $\mathbf{C}\mathbf{1} = \mathbf{0}$ and $\boldsymbol{\Sigma}^{-1/2}$ is nonsingular. So we may assume that the entries of $\mathbf{Z}$ are independent $N(0, 1)$. Then $\mathbf{CZ}$ has rank k with probability one (Exercise (C1)), and so does $\mathbf{X}$.

Invariance. Let $\mathbf{v} = \mathbf{C}\mathbf{e}_i / \|\mathbf{C}\mathbf{e}_i\|$, a unit vector in $\mathbf{1}^\perp$, with $\|\mathbf{C}\mathbf{e}_i\|^2 = 1 - 1/n$. Since $\mathbf{P} = \mathbf{P}\mathbf{C} = \mathbf{C}\mathbf{P}$,

$$h_{ii} - \frac{1}{n} = (\mathbf{C}\mathbf{e}_i)^\top \mathbf{P}(\mathbf{C}\mathbf{e}_i) = \left(1 - \frac{1}{n}\right) \mathbf{v}^\top \mathbf{P} \mathbf{v}.$$

Write $\mathbf{P}(\mathbf{Z})$ to show the dependence on $\mathbf{Z}$. Let $\mathbf{w}$ be any other unit vector in $\mathbf{1}^\perp$, and let $\mathbf{H} = \mathbf{I} - 2\mathbf{a}\mathbf{a}^\top / \mathbf{a}^\top \mathbf{a}$ with $\mathbf{a} = \mathbf{v} - \mathbf{w}$ (or $\mathbf{H} = \mathbf{I}$ if $\mathbf{w} = \mathbf{v}$). This is a symmetric orthogonal matrix, and $\mathbf{H}\mathbf{v} = \mathbf{w}$ because $\|\mathbf{v}\| = \|\mathbf{w}\|$. It fixes $\mathbf{1}$, because $\mathbf{1} \perp \mathbf{a}$, so $\mathbf{H}$ commutes with $\mathbf{C}$ and maps $\mathcal{C}(\mathbf{CZ})$ onto $\mathcal{C}(\mathbf{CHZ})$. Hence $\mathbf{P}(\mathbf{HZ}) = \mathbf{H}\mathbf{P}(\mathbf{Z})\mathbf{H}$, and $\mathbf{w}^\top \mathbf{P}(\mathbf{Z})\mathbf{w} = \mathbf{v}^\top \mathbf{H}\mathbf{P}(\mathbf{Z})\mathbf{H}\mathbf{v} = \mathbf{v}^\top \mathbf{P}(\mathbf{HZ})\mathbf{v}$. Each column of $\mathbf{HZ}$ is $N_n(\mathbf{0}, \mathbf{H}\mathbf{H}^\top) = N_n(\mathbf{0}, \mathbf{I})$, and the columns are independent, so $\mathbf{HZ}$ has the law of $\mathbf{Z}$. Therefore the law of $\mathbf{v}^\top \mathbf{P}(\mathbf{Z})\mathbf{v}$ is the same for every unit vector $\mathbf{v} \in \mathbf{1}^\perp$.

Averaging. Let $\mathbf{g} \sim N_n(\mathbf{0}, \mathbf{C})$ be independent of $\mathbf{Z}$, and $\mathbf{U} = \mathbf{g} / \|\mathbf{g}\|$, a random unit vector in $\mathbf{1}^\perp$. By the previous paragraph, applied conditionally on $\mathbf{U}$, the variable $\mathbf{U}^\top \mathbf{P}(\mathbf{Z})\mathbf{U}$ has the same law as $\mathbf{v}^\top \mathbf{P}(\mathbf{Z})\mathbf{v}$. Now condition on $\mathbf{Z}$ instead. Then $\mathbf{P}$ is a fixed projection of rank k onto a subspace of $\mathbf{1}^\perp$, and $\mathbf{C} - \mathbf{P}$ is a projection of rank $n - 1 - k$ orthogonal to it, so by Theorem 4.4.4 $\|\mathbf{P}\mathbf{g}\|^2 \sim \chi^2(k)$ and $\|(\mathbf{C} - \mathbf{P})\mathbf{g}\|^2 \sim \chi^2(n - 1 - k)$ are independent.

Since $\mathbf{g} = \mathbf{C}\mathbf{g}$,

$$\mathbf{U}^\top \mathbf{P}\mathbf{U} = \frac{\|\mathbf{P}\mathbf{g}\|^2}{\|\mathbf{P}\mathbf{g}\|^2 + \|(\mathbf{C} - \mathbf{P})\mathbf{g}\|^2} \sim \text{Beta}\left(\frac{k}{2}, \frac{n-1-k}{2}\right)$$

by [Exercise \(B4\)](#). This conditional law does not depend on $\mathbf{Z}$, so it is also the unconditional law. ■

The mean of the beta law is $k/(n-1)$, which gives $E(h_{ii}) = 1/n + (1 - 1/n)k/(n-1) = p/n$, as it must. As $n \rightarrow \infty$ with k fixed, $n(h_{ii} - 1/n)$ converges in law to $\chi^2(k)$ ([Exercise \(B1\)](#)), so

$$\Pr\{h_{ii} > cp/n\} \approx \Pr\{\chi^2(k) > c(k+1) - 1\}.$$

With $k = 3$, the rule $2p/n$ fires for 0.072 of the cases in large samples (0.067 when $n = 50$), and the rule $3p/n$ for 0.012. With $k = 10$ and $n = 500$, the rule $2p/n$ fires for only 0.020. “Twice the average” flags a different share of well-behaved cases for every p : it is a convention, not a test. [Figure 20.2.1\(a\)](#) checks the law against 4000 simulated designs.

```
import numpy as np
from scipy import stats

def leverages(X):
    Q, _ = np.linalg.qr(X)
    return np.sum(Q ** 2, axis=1)

print("Kolmogorov-Smirnov p-value against the Beta law:", stats.kstest(B, law.cdf).
pvalue)
```

20.2.2 Designed and observational data

In a designed experiment the analyst chooses the rows of $\mathbf{X}$. The largest leverage is at least the average p/n , with equality iff all are equal ([Exercise \(B2\)](#)), and many designs achieve it. If the columns are orthogonal with entries ± 1 , as in two-level factorials, then $\mathbf{X}^\top \mathbf{X} = n\mathbf{I}$ and $h_{ii} = \|\mathbf{x}_{(i)}\|^2/n = p/n$: a 2^3 factorial run twice ($n = 16$) with intercept, main effects and one interaction ($p = 5$) gives every case leverage $5/16 = 0.3125$. A balanced one-way layout gives every case $1/n_k = p/n$ ([Exercise \(B2\)](#)). Kiefer and Wolfowitz (1960) showed that, over a region of possible design points, the designs maximizing $\det(\mathbf{X}^\top \mathbf{X})$ are exactly those minimizing the largest leverage $\mathbf{x}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}$ over the region, with minimum p/n (for designs viewed as

probability measures). For D-optimal designs, good design and small maximum leverage are the same thing.

In observational data the rows are drawn, not chosen, and with light enough tails no case dominates in large samples.

Proposition 20.2.2 — Leverage vanishes in large samples

Let the rows $\mathbf{x}_{(1)}, \mathbf{x}_{(2)}, \dots$ be independent copies of a random vector $\mathbf{x}$ with $E\|\mathbf{x}\|^2 < \infty$ and $E(\mathbf{x}\mathbf{x}^\top)$ positive definite, and let $h_{ii}^{(n)}$ be the leverages of the first n rows. Then $\max_{i \leq n} h_{ii}^{(n)} \rightarrow 0$ in probability.

Proof. Write $\mathbf{S}_n = n^{-1}\mathbf{X}^\top\mathbf{X} = n^{-1}\sum_{i \leq n} \mathbf{x}_{(i)}\mathbf{x}_{(i)}^\top$ and let λ_n be its smallest eigenvalue. By the strong law of large numbers $\mathbf{S}_n \rightarrow E(\mathbf{x}\mathbf{x}^\top)$ with probability one, and eigenvalues are continuous functions of a symmetric matrix, so $\lambda_n \rightarrow \lambda > 0$, the smallest eigenvalue of $E(\mathbf{x}\mathbf{x}^\top)$. Hence with probability one $\mathbf{X}^\top\mathbf{X}$ is nonsingular for all large n , and the leverages are defined from then on. By Theorem 1.7.7 applied to $(\mathbf{X}^\top\mathbf{X})^{-1}$, whose largest eigenvalue is $1/(n\lambda_n)$,

$$\max_{i \leq n} h_{ii}^{(n)} = \max_{i \leq n} \mathbf{x}_{(i)}^\top (\mathbf{X}^\top\mathbf{X})^{-1} \mathbf{x}_{(i)} \leq \frac{\max_{i \leq n} \|\mathbf{x}_{(i)}\|^2}{n\lambda_n}.$$

It remains to show that $\max_{i \leq n} \|\mathbf{x}_{(i)}\|^2/n \rightarrow 0$ in probability. For $\epsilon > 0$, by the union bound and Markov's inequality,

$$\Pr\left\{\max_{i \leq n} \|\mathbf{x}_{(i)}\|^2 > \epsilon n\right\} \leq n \Pr\{\|\mathbf{x}\|^2 > \epsilon n\} \leq \frac{1}{\epsilon} E[\|\mathbf{x}\|^2 \mathbf{1}\{\|\mathbf{x}\|^2 > \epsilon n\}] \rightarrow 0,$$

by dominated convergence, since $E\|\mathbf{x}\|^2 < \infty$.

■

The condition matters for inference with non-normal errors. Huber (1973) showed that every fitted value $\mathbf{x}^\top \hat{\boldsymbol{\beta}}$ is asymptotically normal, for every error law with finite variance, iff the largest leverage tends to zero, and Theorem 19.3.2 of Chapter 19 rests on a condition of this Lindeberg type. A case that keeps a fixed share of the leverage keeps a fixed share of its own error in its fitted value, and no averaging makes that error normal.

Figure 20.2.1(b) shows the median, over 300 replications, of the largest leverage with two independent regressors. For normal regressors it falls from 0.322 at $n = 25$ to 0.0030 at $n = 6400$. For t_3 regressors, heavy-tailed but with finite variance, it falls much more slowly, to 0.066. For Cauchy regressors, which have no variance, it does not fall at all (0.857 at $n = 25$, 0.831 at $n = 6400$): one case keeps most of the pull however many are added.

Example. (Leverage in Engel's household budgets)

Engel's 1857 survey records the annual income and food expenditure of 235 Belgian working-class households. Income is strongly skewed (skewness 2.78): the median is 884 and the largest, row 138 of the file, is 4958. In the straight-line regression of food expenditure on income the average leverage is $2/235 = 0.0085$, and the richest household has leverage 0.255, about 30 times the average; the next largest is 0.058.

Figure 20.2.1: (a) Leverage of one case in 4000 Gaussian designs ($n = 30$, $p = 4$), the beta density of Proposition 20.2.1, and the cut-offs $2p/n$ (dashed) and $3p/n$ (dotted). (b) Median largest leverage for normal, t_3 and Cauchy regressors.

Since $h_{ii} - 1/n = (x_i - \bar{x})^2/S_{xx}$, this one household supplies a quarter (0.251) of the spread of income about its mean, and the fitted line will pass near it whatever it spends on food. On the logarithmic scale its leverage is 0.070, still the largest but no longer in a class of its own. Choosing the scale (Chapter 22) decides which cases the fit depends on.

```
import numpy as np
import statsmodels.api as sm
engel = sm.datasets.engel.load_pandas().data

income = engel["income"].to_numpy()
food = engel["foodexp"].to_numpy()
n = len(income)
for label, x in [("income", income), ("log income", np.log(income))]:
    X = np.column_stack([np.ones(n), x])
    Q, _ = np.linalg.qr(X)
    h = np.sum(Q ** 2, axis=1)
    top = np.argsort(h)[::-1][:3]
    print(f"{label:11s} average p/n = {2 / n:.4f}; largest:",
          ", ".join(f"row {i + 1}: h = {h[i]:.3f}" for i in top))
```

Leverage also depends on the model: adding a column never decreases a leverage (Exercise (B2)), and a case ordinary for a line can be extreme for a quadratic (Exercise (B3)). A new point inside the range of every regressor can have high leverage because its *combination* of values is unusual (Example (Hidden extrapolation)).

20.2.3 Partial leverage

The leverage h_{ii} measures the pull of case i on the whole fitted surface. The Frisch–Waugh–Lovell theorem isolates one coefficient. Let $\mathbf{M}_{(j)}$ project onto the span of the columns other than $\mathbf{x}_j$, and let $\tilde{\mathbf{x}}_j = (\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j$.

Definition 20.2.1 — Partial leverage

The **partial leverage** of case i for the coefficient of $\mathbf{x}_j$ is

$$\ell_{ij} = \frac{\tilde{x}_{ij}^2}{\|\tilde{\mathbf{x}}_j\|^2}.$$

Proposition 20.2.3 — Properties of partial leverage

Let $h_{ii}^{(j)}$ be the leverages of the model without $\mathbf{x}_j$. Then:

- (a) $h_{ii} = h_{ii}^{(j)} + \ell_{ij}$ for every i ;
- (b) $0 \leq \ell_{ij} \leq 1$ and $\sum_i \ell_{ij} = 1$;
- (c) ℓ_{ij} is the leverage of case i in the regression through the origin of $\tilde{\mathbf{y}} = (\mathbf{I} - \mathbf{M}_{(j)})\mathbf{y}$ on $\tilde{\mathbf{x}}_j$, the regression drawn in the added-variable plot for $\mathbf{x}_j$;
- (d) $\hat{\beta}_j = \sum_i (\tilde{x}_{ij}/\|\tilde{\mathbf{x}}_j\|^2)y_i$, so the weight of y_i in $\hat{\beta}_j$ has square $\ell_{ij}/\|\tilde{\mathbf{x}}_j\|^2 = \ell_{ij} \text{Var}(\hat{\beta}_j)/\sigma^2$.

Proof. By Lemma 6.6.1(c) with $\mathbf{X}_1 = \mathbf{x}_j$, $\mathbf{M} = \mathbf{M}_{(j)} + \tilde{\mathbf{x}}_j\tilde{\mathbf{x}}_j^\top/\|\tilde{\mathbf{x}}_j\|^2$. The diagonal entries give (a), and the second term is the hat matrix of the regression in (c). It is a rank-one projection, which gives (b). Part (d) is Theorem 6.6.2(a), together with $\text{Var}(\hat{\beta}_j) = \sigma^2/\|\tilde{\mathbf{x}}_j\|^2$ (Eq. 6.6.2). ■

A case can have high leverage and negligible partial leverage for the coefficient of interest, when its unusual position lies along the other regressors. Partial leverages average $1/n$, so a few times $1/n$ is already large.

Example. (Where the District of Columbia's leverage comes from)

In the murder-rate regression for the 51 jurisdictions, with poverty, single-parent households and urbanization as regressors, the District of Columbia has leverage 0.506 (Example (High-leverage states)) but partial leverage for poverty only 0.032: its leverage comes from its extreme single-parent and urban percentages, not from its poverty rate. The largest partial leverage for poverty is Alaska's, 0.141. Section 20.4 shows that the District nevertheless moves the poverty coefficient more than any other case, because influence also depends on the residual.

20.2.4 Exercises**20.2.4.1 A. Check your understanding****Exercise A1.**

For regression through the origin on one regressor, show that $h_{ii} = x_i^2/\sum_k x_k^2$. Give

data with $n = 10$ in which one leverage exceeds 0.99.

Solution. $\mathbf{M} = \mathbf{xx}^\top / \mathbf{x}^\top \mathbf{x}$, so $h_{ii} = x_i^2 / \mathbf{x}^\top \mathbf{x}$. With $x_1 = 100$ and $x_2 = \cdots = x_{10} = 1$, $h_{11} = 10^4 / (10^4 + 9) > 0.99$.

Exercise A2.

Show that with an intercept the leverages are unchanged when the regressors are replaced by $\mathbf{a} + \mathbf{Bx}$ with $\mathbf{B}$ nonsingular, but not under a nonlinear transformation (Example (Leverage in Engel's household budgets)). Use Proposition 6.8.2.

20.2.4.2 B. Practice

Exercise B1.

In the setting of Proposition 20.2.1, show that $n(h_{ii} - 1/n)$ converges in law to $\chi^2(k)$ as $n \rightarrow \infty$.

Solution. By the proof of Proposition 20.2.1, $h_{ii} - 1/n$ has the law of $(1 - 1/n)U/(U + V)$ with $U \sim \chi^2(k)$ and $V \sim \chi^2(n - 1 - k)$ independent. So $n(h_{ii} - 1/n)$ has the law of $(n - 1)U/(U + V) = U/[(U + V)/(n - 1)]$. By the law of large numbers $V/(n - 1) \rightarrow 1$ in probability, and $U/(n - 1) \rightarrow 0$, so the denominator tends to 1 in probability. Slutsky's theorem gives convergence in law to $U \sim \chi^2(k)$.

Exercise B2.

Show that $\max_i h_{ii} \geq p/n$, with equality iff all leverages equal p/n . Show that if $\mathbf{X}$ has orthogonal columns and every entry is ± 1 , then all leverages equal p/n .

Exercise B3.

Take $x = -3, -2, -1, 0, 1, 2, 3$. Compute the leverage of the case at $x = 0$ for the straight-line model and for the quadratic model $E(Y) = \beta_0 + \beta_1 x + \beta_2 x^2$. Explain the difference.

Solution. For the line, $h = 1/7 + 0^2/28 = 1/7$. For the quadratic, apply Proposition 20.2.3(a) with $\mathbf{x}_j$ the column of squares: $h = 1/7 + \ell$, where ℓ is the partial leverage of the quadratic term. The residual of x^2 on $(1, x)$ is $x^2 - 4$, because x^2 has mean 4 and $\sum_x x(x^2 - 4) = 0$ by symmetry. Its values are 5, 0, -3, -4, -3, 0, 5, with sum of squares 84. So $\ell = 16/84 = 4/21$ and $h = 1/7 + 4/21 = 1/3$. The case at $x = 0$ is the only one near the centre, and in a quadratic model the centre is where the curvature is pinned down.

20.2.4.3 C. Going deeper

Exercise C1.

Complete the proof of Proposition 20.2.1 by showing that if $\mathbf{Z}$ is $n \times k$ with indepen-

dent $N(0,1)$ entries and $n \geq k + 2$, then $\mathbf{CZ}$ has rank k with probability one. *Hint:* add columns one at a time, and use that a nonzero normal vector with a nonsingular covariance restricted to a subspace falls in a fixed proper subspace with probability zero.

20.3 Deletion diagnostics

A case cannot fairly judge itself, since its own response pulled the fit towards it. So set the case aside, fit the other $n - 1$ cases, and ask how well that fit predicts it and how far the fit moved. Chapter 10 showed that one regression gives all n answers (Proposition 10.6.2). This section collects the formulas and proves that the externally studentized residual has an exact t law, which turns it into a test for an outlier.

20.3.1 Leave-one-out formulas

Write $\hat{\boldsymbol{\beta}}_{(i)}$ for the least squares estimate from the cases other than i , $\hat{\mathbf{Y}}_{(i)} = \mathbf{X}\hat{\boldsymbol{\beta}}_{(i)}$ for the fitted values it gives at *all* n cases (including case i), $\text{SSE}_{(i)}$ for its residual sum of squares and $s_{(i)}^2 = \text{SSE}_{(i)}/(n - p - 1)$.

Theorem 20.3.1 — Leave-one-out formulas

Let $\mathbf{X}$ have full column rank, and let $\mathbf{X}_{(i)}$ be $\mathbf{X}$ without row i .

- (a) $\mathbf{X}_{(i)}$ has full column rank iff $h_{ii} < 1$. Assume this from now on.
- (b) $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} \hat{\varepsilon}_i / (1 - h_{ii})$.
- (c) $\hat{\mathbf{Y}} - \hat{\mathbf{Y}}_{(i)} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} \hat{\varepsilon}_i / (1 - h_{ii})$; that is, the fitted value of case j moves by $h_{ji} \hat{\varepsilon}_i / (1 - h_{ii})$. In particular case i 's own fitted value moves by $h_{ii} \hat{\varepsilon}_i / (1 - h_{ii})$.
- (d) The **prediction residual** of case i is $y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)} = \hat{\varepsilon}_i / (1 - h_{ii})$.
- (e) $(n - p - 1) s_{(i)}^2 = (n - p) s^2 - \hat{\varepsilon}_i^2 / (1 - h_{ii})$.

Proof.

- (a) $\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)} = \mathbf{X}^\top \mathbf{X} - \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$, whose determinant is $(1 - h_{ii}) \det(\mathbf{X}^\top \mathbf{X})$ by Example (Deleting an observation). So it is nonsingular iff $h_{ii} \neq 1$, and $h_{ii} \leq 1$ always. Parts (b), (d) and (e) are Proposition 10.6.2(a), (b) and (c), the last divided through by the degrees of freedom. Part (c) is (b) multiplied by $\mathbf{X}$; its j th entry is $\mathbf{x}_{(j)}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} \hat{\varepsilon}_i / (1 - h_{ii})$, and $\mathbf{x}_{(j)}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} = h_{ji}$.

■

Every quantity is a residual times a function of the design: a case with zero residual changes nothing when deleted, and high leverage magnifies a residual by $1/(1 - h_{ii})$. When $h_{ii} = 1$ the case determines one direction of $\mathcal{C}(\mathbf{X})$ by itself (Proposition 6.8.1(d)), and without it a parameter is not estimable; no diagnostic can check it.

20.3.2 Prediction residuals and PRESS

The prediction residual $\hat{\varepsilon}_i/(1 - h_{ii})$ is the error in predicting y_i by a fit that never saw it. Its variance is $\sigma^2/(1 - h_{ii})$, and dividing it by an estimate of $\sigma/\sqrt{1 - \bar{h}_{ii}}$ gives back r_i (with s) or t_i (with $s_{(i)}$). The sum of squares of the prediction residuals is the PRESS statistic of Allen (1974),

$$\text{PRESS} = \sum_{i=1}^n \left(\frac{\hat{\varepsilon}_i}{1 - h_{ii}} \right)^2, \quad (20.3.1)$$

a leave-one-out estimate of prediction error that [Chapter 29](#) uses for choosing between models ([Theorem 29.3.2](#)).

Proposition 20.3.2 — Expected PRESS

Under the second-moment model of [Section 20.1](#),

$$E(\text{PRESS}) = \sigma^2 \sum_{i=1}^n \frac{1}{1 - h_{ii}} \geq \sigma^2 \frac{n^2}{n - p},$$

with equality iff all leverages equal p/n . By comparison, the expected sum of squared errors in predicting new responses at the same n design points is $\sigma^2(n + p)$ ([Proposition 14.2.7\(a\)](#)), which is smaller than $\sigma^2 n^2/(n - p)$ by $\sigma^2 p^2/(n - p)$.

Proof. $E(\hat{\varepsilon}_i^2) = \text{Var}(\hat{\varepsilon}_i) = \sigma^2(1 - h_{ii})$, and dividing by $(1 - h_{ii})^2$ and summing gives the first identity. The function $u \mapsto 1/(1 - u)$ is strictly convex on $[0, 1)$, so by Jensen's inequality $n^{-1} \sum_i 1/(1 - h_{ii}) \geq 1/(1 - \bar{h})$ with $\bar{h} = p/n$, with equality iff all h_{ii} are equal. This gives the bound. Finally $n^2 - (n + p)(n - p) = p^2$. ■

So PRESS overcorrects the optimism of the in-sample error ([Proposition 14.2.7](#)) slightly, because each case is predicted from a design that lacks it. It also weights cases by $(1 - h_{ii})^{-2}$: at $h_{ii} = 0.5$, four times the squared raw residual. For the state regression with all 51 jurisdictions, $\text{SSE} = 142.53$ and $\text{PRESS} = 230.52$ ([Example \(Leaving out the District of Columbia\)](#)), and the District of Columbia alone contributes 9.066^2 , a share of 0.36. For this design $E(\text{PRESS})/(n\sigma^2) = 1.096$, against the bound $n/(n - p) = 1.085$ and $(n + p)/n = 1.078$: the District's residual, not the unequal leverages, inflates PRESS.

20.3.3 The externally studentized residual

As a test statistic, r_i is bounded by $\sqrt{n - p}$ and has a nonstandard law ([Proposition 20.1.1](#)). The externally studentized residual repairs both, and its law is clearest from the alternative it is meant to detect.

The **mean-shift outlier model** for case i is

$$\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \Delta \mathbf{e}_i + \boldsymbol{\varepsilon}, \quad \boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I}), \quad (20.3.2)$$

in which case i alone has its mean displaced by an unknown Δ , as by a misrecorded digit. Testing $\Delta = 0$ tests whether case i is an outlier.

Theorem 20.3.3 — Law of the externally studentized residual

Assume [Eq. 20.3.2](#) with $h_{ii} < 1$ and $n - p \geq 2$.

- (a) In the model with columns $[\mathbf{X}, \mathbf{e}_i]$, the least squares estimate of the shift is $\hat{\Delta} = \hat{\varepsilon}_i / (1 - h_{ii}) = y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)}$, the estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}}_{(i)}$, the residual mean square is $s_{(i)}^2$, and the t statistic for $\Delta = 0$ is t_i .
- (b) $t_i \sim t(n - p - 1, \Delta\sqrt{1 - h_{ii}}/\sigma)$. In particular, if $\Delta = 0$, then $t_i \sim t(n - p - 1)$.
- (c) $t_i = r_i \sqrt{(n - p - 1)/(n - p - r_i^2)}$, an increasing function of r_i that maps $(-\sqrt{n - p}, \sqrt{n - p})$ onto the whole real line.
- (d) (*Bonferroni outlier test.*) If no case is shifted, that is under [Eq. 7.3.1](#), and $h_{jj} < 1$ for every j , then

$$\Pr\left\{\max_j |t_j| > t_{n-p-1, \alpha/(2n)}\right\} \leq \alpha.$$

Equivalently, the adjusted p -value $\min(1, np_{(1)})$, where $p_{(1)}$ is the smallest of the single-case two-sided p -values from (b), is valid.

Proof.

- (a) Since $h_{ii} < 1$, $\mathbf{e}_i \notin \mathcal{C}(\mathbf{X})$ ([Proposition 6.8.1\(d\)](#)), so $[\mathbf{X}, \mathbf{e}_i]$ has full column rank $p + 1$. By [Exercise \(B1\)](#), $\hat{\Delta} = \hat{\varepsilon}_i / (1 - h_{ii})$, the enlarged fit reproduces y_i exactly, and its estimate of $\boldsymbol{\beta}$ is $\hat{\boldsymbol{\beta}}_{(i)}$. Its residuals are therefore zero at case i and equal to the residuals of the deletion fit elsewhere, so its residual sum of squares is $\text{SSE}_{(i)}$ on $n - p - 1$ degrees of freedom, and its residual mean square is $s_{(i)}^2$. By [Eq. 6.6.1](#), the diagonal entry of $([\mathbf{X}, \mathbf{e}_i]^\top [\mathbf{X}, \mathbf{e}_i])^{-1}$ belonging to $\mathbf{e}_i$ is $1/\|(\mathbf{I} - \mathbf{M})\mathbf{e}_i\|^2 = 1/(1 - h_{ii})$. So the standard error of $\hat{\Delta}$ is $s_{(i)}/\sqrt{1 - h_{ii}}$, and

$$\frac{\hat{\Delta}}{s_{(i)}/\sqrt{1 - h_{ii}}} = \frac{\hat{\varepsilon}_i}{(1 - h_{ii})} \cdot \frac{\sqrt{1 - h_{ii}}}{s_{(i)}} = t_i.$$

- (b) The enlarged model is a normal linear model of full rank $p + 1 < n$, and Δ is one of its coefficients. By [Theorem 11.6.1\(a\)](#) the t statistic for $\Delta = 0$ has the $t(n - p - 1, \delta)$ law with $\delta = \Delta/(\sigma\sqrt{1/(1 - h_{ii})}) = \Delta\sqrt{1 - h_{ii}}/\sigma$.
- (c) By [Theorem 20.3.1\(e\)](#) and $\hat{\varepsilon}_i^2/(1 - h_{ii}) = r_i^2 s^2$, $(n - p - 1)s_{(i)}^2 = s^2(n - p - r_i^2)$. Hence $t_i^2 = r_i^2 s^2 / s_{(i)}^2 = r_i^2(n - p - 1)/(n - p - r_i^2)$, and t_i has the sign of r_i . The map $r \mapsto r\sqrt{(n - p - 1)/(n - p - r^2)}$ is increasing on $(-\sqrt{n - p}, \sqrt{n - p})$ and tends to $\pm\infty$ at the ends.
- (d) By (b) with $\Delta = 0$, each event $A_j = \{|t_j| > t_{n-p-1, \alpha/(2n)}\}$ has probability exactly α/n . Apply [Theorem 13.4.1\(a\)](#) to their union. The p -value form is [Theorem 13.4.1\(c\)](#) with every $\alpha_j = \alpha/n$.

■

By (c), r_i and t_i carry the same information, but t_i is unbounded and has a standard law, so it is the one to report. [Exercise \(B1\)](#) gives a second proof of (b). Part (b) also shows how leverage hides outliers: the noncentrality is $\Delta\sqrt{1-h_{ii}}/\sigma$, because a shift at a high-leverage case is partly absorbed by the fit. At the state design, a shift of 4σ at the District of Columbia ($h_{ii} = 0.506$) gives noncentrality 2.81, and the Bonferroni test of (d) detects it with probability 0.258; at Missouri, the case of lowest leverage ($h_{ii} = 0.021$), the noncentrality is 3.96 and the probability 0.666.

20.3.4 Testing for an outlier

A case suspected in advance can be tested with [Theorem 20.3.3\(b\)](#). Usually the suspect is chosen *because* its residual is largest, and the question is whether $\max_i |t_i|$ is surprising under a model with no outliers. The t_i are dependent, but the Bonferroni test of [Theorem 20.3.3\(d\)](#) needs no joint law, and it is nearly exact because two cases rarely exceed the high cut-off together. At the state design ($n = 51$, $p = 4$), the simulated familywise level of the 5% test is 0.0497 (standard error 0.0005, from 200000 normal samples).

```
import numpy as np
import statsmodels.api as sm
from scipy import stats
data = sm.datasets.statelcrime.load_pandas().data
X = np.column_stack([np.ones(len(data)), data[["poverty", "single", "urban"]]])

def max_abs_t(X, Y):
    """max_i |t_i| for each column of Y (one simulated response vector per column).
    """
    n, p = X.shape
    Q, _ = np.linalg.qr(X)
    h = np.sum(Q ** 2, axis=1)[:, None]
    E = Y - Q @ (Q.T @ Y)
    sse = np.sum(E ** 2, axis=0)
    s2_del = (sse - E ** 2 / (1 - h)) / (n - p - 1)
    return np.max(np.abs(E) / np.sqrt(s2_del * (1 - h)), axis=0)

n, p = X.shape
alpha = 0.05
crit = stats.t.isf(alpha / (2 * n), n - p - 1)
rng = np.random.default_rng(51)
reps = 4000
T = max_abs_t(X, rng.normal(size=(n, reps))) # no outliers: errors N(0, 1)
print(f"Bonferroni bound {alpha}, simulated familywise level {np.mean(T > crit):.4f}")
    "
```

Example. (Is the District of Columbia an outlier?)

For the murder-rate regression with all 51 jurisdictions, the District of Columbia has raw residual 4.475, leverage 0.506, $r_i = 3.658$ and $t_i = 4.278$ (as in [Example \(Leaving out the District of Columbia\)](#)); deleting it lowers $s = 1.741$ to $s_{(i)} = 1.489$. Its single-case p -value is 9.4×10^{-5} , and the Bonferroni-adjusted value 0.0048 (critical value 3.522). The next case, Mississippi, has $t_i = -2.877$ and adjusted p -value 0.310. Among the 50 states alone the most extreme is Louisiana, $t_i = 3.299$, adjusted p -value 0.095; such sequential testing is not covered by [Theorem 20.3.3\(d\)](#), and [Section 20.5](#) shows it can

fail badly.

The test says that the District's murder rate is incompatible with the linear relation that holds for the states. It does not say the number is wrong or that the case should be dropped. The District is a city, with regressors outside the range of the states; a defensible analysis restricts the population to states and says so.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats
data = sm.datasets.statcrime.load_pandas().data           # District of Columbia
      kept
y = data["murder"].to_numpy()
X = np.column_stack([np.ones(len(y)), data[["poverty", "single", "urban"]]])
names = np.array(data.index)

n, p = X.shape
Q, R = np.linalg.qr(X)
beta = np.linalg.solve(R, Q.T @ y)
e = y - X @ beta                                         # raw residuals
h = np.sum(Q ** 2, axis=1)                               # leverages
s2 = e @ e / (n - p)
r = e / np.sqrt(s2 * (1 - h))                           # internally studentized
s2_del = (e @ e - e ** 2 / (1 - h)) / (n - p - 1)       # s^2 without case i
t = e / np.sqrt(s2_del * (1 - h))                       # externally studentized

    print(f"{names[i]:22s} h = {h[i]:.3f}  r = {r[i]:6.3f}  t = {t[i]:6.3f}"
          f"  Bonferroni p = {p_bonf[i]:.4f}")
print(f"critical value |t| > {crit:.3f}")
```

Warning. An outlier test tests *the model* at one case, including normality, constant variance and the mean function. A large $|t_i|$ can come from a gross error, from heavy-tailed errors, from variance that grows where case i lies, or from a wrong mean function there, and the test cannot tell these apart (Chapter 21, Chapter 22).

20.3.5 Exercises

20.3.5.1 A. Check your understanding

Exercise A1.

Use Theorem 20.3.3(c) to compute the District of Columbia's t_i from its $r_i = 3.658$, with $n = 51$ and $p = 4$.

Solution. $t_i = 3.658\sqrt{46/(47 - 3.658^2)} = 3.658\sqrt{46/33.62} = 3.658 \times 1.1697 \approx 4.279$, which agrees with the recorded 4.278 to the rounding of r_i .

Exercise A2.

A case has leverage 0.5 and residual 1. By how much does its own fitted value change when it is deleted, and what is its prediction residual? What is the prediction residual of a case with leverage 0.9 and the same raw residual?

20.3.5.2 B. Practice**Exercise B1.**

Prove [Theorem 20.3.3](#)(b) with $\Delta = 0$ directly. Show that $y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)}$ is independent of $s_{(i)}^2$, that its variance is $\sigma^2(1 + \mathbf{x}_{(i)}^\top (\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)})^{-1} \mathbf{x}_{(i)})$, and that this equals $\sigma^2/(1 - h_{ii})$.

Solution. The fit without case i is a normal linear model for the other $n - 1$ cases, and y_i is independent of those cases. So $y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)}$ is the error of predicting a new observation at $\mathbf{x}_{(i)}$, and by [Theorem 12.3.1](#)(a) it is normal with mean zero and variance $\sigma^2(1 + g)$, $g = \mathbf{x}_{(i)}^\top (\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)})^{-1} \mathbf{x}_{(i)}$, independent of $s_{(i)}^2$, with $(y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)}) / (s_{(i)} \sqrt{1 + g}) \sim t(n - p - 1)$. By [Example \(Deleting an observation\)](#), $(\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)})^{-1} = (\mathbf{X}^\top \mathbf{X})^{-1} + (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top (\mathbf{X}^\top \mathbf{X})^{-1} / (1 - h_{ii})$, so $g = h_{ii} + h_{ii}^2 / (1 - h_{ii}) = h_{ii} / (1 - h_{ii})$ and $1 + g = 1 / (1 - h_{ii})$. Using [Theorem 20.3.1](#)(d), the statistic is $[\hat{\varepsilon}_i / (1 - h_{ii})] \sqrt{1 - h_{ii}} / s_{(i)} = t_i$.

Exercise B2.

Show that $s_{(i)} < s$ iff $r_i^2 > 1$. Interpret.

Exercise B3.

In the setting of [Theorem 20.3.3](#), the shift at case i is detected by the single-case test with probability $\Pr\{|T| > c\}$, $T \sim t(n - p - 1, \Delta \sqrt{1 - h_{ii}} / \sigma)$. Show that for fixed Δ and c this probability decreases as h_{ii} increases. *Hint:* T^2 has a noncentral F law; use [Theorem 4.1.4](#).

20.3.5.3 C. Going deeper**Exercise C1.**

Suppose the errors are independent with a t distribution on 3 degrees of freedom and the design is that of the state data. By simulation, estimate the probability that the 5% Bonferroni outlier test rejects. Explain the result in terms of the warning at the end of this section.

20.4 Cook's distance, DFFITS and DFBETAS

An outlier is a case the model fits badly; an **influential** case is one whose removal would change the conclusions. A remote case that follows the trend of the others exactly has no influence, and a large residual near the centroid moves the fit little. Influence measures, all from [Theorem 20.3.1](#), quantify different consequences of deleting a case.

20.4.1 Four measures

Definition 20.4.1 — Cook's distance, DFFITS, DFBETAS

Let $h_{ii} < 1$, and let c_{jj} be the j th diagonal entry of $(\mathbf{X}^\top \mathbf{X})^{-1}$, so that $s^2 c_{jj}$ is the estimated variance of $\hat{\beta}_j$.

(a) **Cook's distance** is

$$D_i = \frac{(\hat{\beta}_{(i)} - \hat{\beta})^\top \mathbf{X}^\top \mathbf{X} (\hat{\beta}_{(i)} - \hat{\beta})}{p s^2}.$$

(b) **DFFITS** is the change in case i 's own fitted value in units of its standard error,

$$\text{DFFITS}_i = \frac{\hat{y}_i - \mathbf{x}_{(i)}^\top \hat{\beta}_{(i)}}{s_{(i)} \sqrt{h_{ii}}}.$$

(c) **DFBETAS** is the change in one coefficient in units of its standard error,

$$\text{DFBETAS}_{ij} = \frac{\hat{\beta}_j - \hat{\beta}_{j(i)}}{s_{(i)} \sqrt{c_{jj}}}.$$

(d) **COVRATIO** compares the generalized variances of the estimates with and without case i ,

$$\text{COVRATIO}_i = \frac{\det(s_{(i)}^2 (\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)})^{-1})}{\det(s^2 (\mathbf{X}^\top \mathbf{X})^{-1})}.$$

Cook (1977) proposed D_i ; DFFITS, DFBETAS and COVRATIO are from Belsley, Kuh and Welsch (1980). DFFITS and DFBETAS use $s_{(i)}$, for the same reason as t_i . None requires a refit.

Theorem 20.4.1 — Influence identities

Let $h_{ii} < 1$ and $n - p \geq 2$, and let $\tilde{\mathbf{x}}_j$ and ℓ_{ij} be as in [Definition 20.2.1](#).

$$(a) \quad D_i = \frac{\|\hat{\mathbf{Y}} - \hat{\mathbf{Y}}_{(i)}\|^2}{p s^2} = \frac{r_i^2}{p} \cdot \frac{h_{ii}}{1 - h_{ii}}.$$

$$(b) \quad \text{DFFITS}_i = t_i \sqrt{h_{ii}/(1 - h_{ii})}, \text{ and } D_i = \text{DFFITS}_i^2 s_{(i)}^2 / (p s^2).$$

(c) $\text{DFBETAS}_{ij} = t_i \frac{\tilde{x}_{ij}}{\|\tilde{\mathbf{x}}_j\| \sqrt{1 - h_{ii}}}$, so $\text{DFBETAS}_{ij}^2 = t_i^2 \ell_{ij} / (1 - h_{ii})$.

(d) For every $\boldsymbol{\lambda} \neq \mathbf{0}$,

$$\frac{(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} - \boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{(i)})^2}{s_{(i)}^2 \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda}} \leq \text{DFFITS}_i^2,$$

with equality at $\boldsymbol{\lambda} = \mathbf{x}_{(i)}$. In particular $|\text{DFBETAS}_{ij}| \leq |\text{DFFITS}_i|$ for every j .

(e) $\text{COVRATIO}_i = \frac{1}{1 - h_{ii}} \left(\frac{n - p}{n - p - 1 + t_i^2} \right)^p$.

Proof. Put $\mathbf{d} = \hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} g$ with $g = \hat{\varepsilon}_i / (1 - h_{ii})$ ([Theorem 20.3.1\(b\)](#)).

(a) $\hat{\mathbf{Y}} - \hat{\mathbf{Y}}_{(i)} = \mathbf{X} \mathbf{d}$, and $\|\mathbf{X} \mathbf{d}\|^2 = \mathbf{d}^\top \mathbf{X}^\top \mathbf{X} \mathbf{d} = g^2 \mathbf{x}_{(i)}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} = g^2 h_{ii}$. So $p D_i s^2 = \hat{\varepsilon}_i^2 h_{ii} / (1 - h_{ii})^2$, and dividing by s^2 and using $r_i^2 = \hat{\varepsilon}_i^2 / \{s^2(1 - h_{ii})\}$ gives (a).

(b) The numerator of DFFITS_i is $\mathbf{x}_{(i)}^\top \mathbf{d} = h_{ii} g$, so $\text{DFFITS}_i = \sqrt{h_{ii}} \hat{\varepsilon}_i / \{s_{(i)}(1 - h_{ii})\} = t_i \sqrt{h_{ii} / (1 - h_{ii})}$. Then $\text{DFFITS}_i^2 s_{(i)}^2 = \hat{\varepsilon}_i^2 h_{ii} / (1 - h_{ii})^2 = p D_i s^2$.

(c) By [Theorem 6.6.2\(a\)](#) the j th row of $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top$ is $\tilde{\mathbf{x}}_j^\top / \|\tilde{\mathbf{x}}_j\|^2$, so the j th entry of $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)}$, the i th column of that matrix, is $\tilde{x}_{ij} / \|\tilde{\mathbf{x}}_j\|^2$. By [Eq. 6.6.1](#), $c_{jj} = 1 / \|\tilde{\mathbf{x}}_j\|^2$. Hence

$$\text{DFBETAS}_{ij} = \frac{\tilde{x}_{ij} g \|\tilde{\mathbf{x}}_j\|^{-2}}{s_{(i)} \|\tilde{\mathbf{x}}_j\|^{-1}} = \frac{\tilde{x}_{ij} \hat{\varepsilon}_i}{s_{(i)} \|\tilde{\mathbf{x}}_j\| (1 - h_{ii})},$$

which is the stated form.

(d) $\boldsymbol{\lambda}^\top \mathbf{d} = g \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)}$. Let $\mathbf{K}^{1/2}$ be the symmetric square root of $\mathbf{K} = (\mathbf{X}^\top \mathbf{X})^{-1}$ ([Theorem 1.7.6](#)). The Cauchy–Schwarz inequality ([Proposition 1.1.1](#)) for $\mathbf{K}^{1/2} \boldsymbol{\lambda}$ and $\mathbf{K}^{1/2} \mathbf{x}_{(i)}$ gives $(\boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)})^2 \leq \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda} \cdot h_{ii}$, with equality when $\boldsymbol{\lambda}$ is a multiple of $\mathbf{x}_{(i)}$. So the ratio is at most $g^2 h_{ii} / s_{(i)}^2 = \text{DFFITS}_i^2$. Taking $\boldsymbol{\lambda} = \mathbf{e}_j$ gives DFBETAS_{ij}^2 .

(e) By [Example \(Deleting an observation\)](#), $\det(\mathbf{X}_{(i)}^\top \mathbf{X}_{(i)}) = (1 - h_{ii}) \det(\mathbf{X}^\top \mathbf{X})$, so $\text{COVRATIO}_i = (s_{(i)}^2 / s^2)^p / (1 - h_{ii})$. From the proof of [Theorem 20.3.3\(c\)](#), $s_{(i)}^2 / s^2 = (n - p - r_i^2) / (n - p - 1)$, and solving $t_i^2 = r_i^2 (n - p - 1) / (n - p - r_i^2)$ for r_i^2 gives $n - p - r_i^2 = (n - p)(n - p - 1) / (n - p - 1 + t_i^2)$. Substitute.

■

20.4.2 What the measures mean

Cook's distance has two readings. By (a) it is the squared distance the fitted vector moves when case i is deleted, in units of $p s^2$. By [Theorem 12.2.1](#) with $\boldsymbol{\Lambda} = \mathbf{I}$, the $100(1 - \alpha)\%$ confidence ellipsoid for $\boldsymbol{\beta}$ is $\{\mathbf{b} : (\mathbf{b} - \hat{\boldsymbol{\beta}})^\top \mathbf{X}^\top \mathbf{X} (\mathbf{b} - \hat{\boldsymbol{\beta}}) \leq p s^2 F_\alpha(p, n - p)\}$, so $\hat{\boldsymbol{\beta}}_{(i)}$ lies on the boundary of the ellipsoid of level $\Pr\{F(p, n - p) \leq D_i\}$.

By the second equality in (a), D_i is misfit, r_i^2 , times leverage, $h_{ii} / (1 - h_{ii})$: a case is influential only if it has both. DFFITS factors the same way with t_i . The **influence plot** of [Figure](#)

20.4.1 places each case by leverage and studentized residual, with the curves of constant D_i , $r^2 = pD(1 - h)/h$.

DFBETAS isolates one coefficient: by (c) the partial leverage ℓ_{ij} replaces the leverage in the product, but the factor $1/(1 - h_{ii})$ still involves the overall leverage. By (d), the largest standardized change in *any* linear combination $\lambda^\top \hat{\beta}$ is $|\text{DFFITS}_i|$, so a small DFFITS rules out a large change in every coefficient and contrast. **COVRATIO** measures precision rather than location: by (e) it exceeds one when h_{ii} is large and t_i small (the case adds precision) and falls below one when t_i is large (the case inflates s^2).

20.4.3 The null law of Cook's distance and the choice of cut-offs

How large must an influence measure be before it matters? Since D_i is a multiple of r_i^2 , its law under the model is known exactly.

Proposition 20.4.2 — Cook's distance under the model

Assume Eq. 7.3.1 with $n - p \geq 2$ and all leverages below one. Then $D_i = \frac{n - p}{p} \frac{h_{ii}}{1 - h_{ii}} B_i$ with $B_i \sim \text{Beta}(\frac{1}{2}, \frac{n - p - 1}{2})$, so

$$E(D_i) = \frac{h_{ii}}{p(1 - h_{ii})}, \quad \frac{1}{n} \sum_{i=1}^n E(D_i) \geq \frac{1}{n - p},$$

with equality in the last bound iff all leverages equal p/n .

Proof. Combine Theorem 20.4.1(a) with Proposition 20.1.1(a), and use $E(B_i) = 1/(n - p)$. For the bound, $u \mapsto u/(1 - u)$ is strictly convex on $[0, 1)$, so by Jensen's inequality the average of $h_{ii}/(1 - h_{ii})$ is at least $\bar{h}/(1 - \bar{h}) = p/(n - p)$, with equality iff the h_{ii} are equal. ■

So under the model a typical D_i is of order $1/n$, which explains the popular cut-off $4/n$. For the state design of Example (How much does the District of Columbia matter?) the average of $E(D_i)$ is 0.0240, against the bound $1/(n - p) = 0.0213$. Comparing D_i with the median of $F(p, n - p)$, which is near one, is far stricter: it flags only cases whose deletion moves the estimate to the edge of a 50% confidence region. The usual cut-offs are these.

Measure	Cut-off	Reasoning
h_{ii}	$2p/n$	twice the average leverage
D_i	$4/n$, or the median of $F(p, n - p)$	four times the typical value; or the edge of the 50% region
$ \text{DFFITS}_i $	$2\sqrt{p/n}$	$ t_i \approx 2$ at a case of average leverage p/n
$ \text{DFBETAS}_{ij} $	$2/\sqrt{n}$	$ t_i \approx 2$ at a case of average partial leverage $1/n$

Figure 20.4.1: Influence plot for the state regression: leverage against r_i , area proportional to Cook's distance, curves $D_i = 0.5$ (dotted) and $D_i = 1$ (dashed), and the line $h_{ii} = 2p/n$.

Measure	Cut-off	Reasoning
$ \text{COVRATIO}_i - 1 $	$3p/n$	first-order expansion of (e) at $ t_i \approx 2$ or $h_{ii} \approx 2p/n$

All are arbitrary in the same way: each puts a case with studentized residual about two and typical leverage near the line. Calibrating D_i exactly by [Proposition 20.4.2](#) would not help: for a fixed design D_i is a multiple of r_i^2 , so the resulting test is an outlier test with a case-dependent level, discarding the leverage factor that is the point of an influence measure. Influence is a consequence to be assessed, not a hypothesis: the right threshold is whether deleting the case changes a conclusion.

Example. (How much does the District of Columbia matter?)

In the murder-rate regression with all 51 jurisdictions, the District of Columbia has $D_i = 3.430$, seven times the next largest (Mississippi, 0.481); the median of $F(4, 47)$ is 0.851, and deleting the District moves $\hat{\beta}$ to the boundary of the 0.985 confidence ellipsoid. Its DFFITS is 4.333 (cut-off 0.560) and its DFBETAS for poverty -1.090 (cut-off 0.280). Its partial leverage for poverty is only 0.032 ([Example \(Where the District of Columbia's leverage comes from\)](#)), but by [Theorem 20.4.1\(c\)](#) it is multiplied by $t_i^2/(1 - h_{ii})$: $4.278^2 \times 0.032/(1 - 0.506) \approx 1.19$, so $|\text{DFBETAS}| \approx 1.09$. Alaska, with the largest partial leverage (0.141), has $t_i = -0.760$ and DFBETAS 0.315.

The consequences are substantive. With the District, the poverty coefficient is 0.1551 (standard error 0.1059, $t = 1.47$); without it, 0.2538 (standard error 0.0934, $t = 2.72$), the fit of [Example \(Poverty and murder rates\)](#). One jurisdiction decides whether poverty has a detectable association with murder rates given the other regressors, and the single-parent coefficient moves from 0.6256 to 0.3980. The cut-offs flag 2 cases by $D_i > 4/n = 0.078$, 3 by DFFITS, 5 by DFBETAS for poverty and 4 by leverage above $2p/n = 0.157$, but only the District changes a conclusion. Its COVRATIO is 0.578: it inflates the estimated generalized variance through its contribution to s^2 .

```

import numpy as np
import statsmodels.api as sm
from scipy import stats
data = sm.datasets.statelcrime.load_pandas().data           # District of Columbia

```

20.4.4 Exercises

20.4.4.1 A. Check your understanding

Exercise A1.

In a regression with $p = 3$, case i has $r_i = 2$. Compute D_i when $h_{ii} = 0.1$ and when $h_{ii} = 0.6$. Which case would you look at first, and why might neither be alarming?

Solution. By [Theorem 20.4.1\(a\)](#), $D_i = (4/3) h_{ii} / (1 - h_{ii})$: $(4/3)(1/9) = 4/27 \approx 0.15$ and $(4/3)(1.5) = 2$. The second moves the coefficient vector to about the edge of a high-level confidence region. Neither is alarming by itself if the change it produces in the estimates of interest is small relative to their uncertainty, or if the case is known to be correct and the model to hold in its region.

Exercise A2.

Show that $D_i = 0$ iff $\hat{\varepsilon}_i = 0$, whatever the leverage. Give an example of a case with leverage 0.9 and no influence.

20.4.4.2 B. Practice

Exercise B1.

Let $\mathbf{C} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top$. Show that the sum of squares of the j th row of $\mathbf{C}$ is c_{jj} , and deduce that $\sum_i \ell_{ij} = 1$ in a second way. Why does this suggest a cut-off of order $1/\sqrt{n}$ for DFBETAS?

Solution. $\mathbf{C}\mathbf{C}^\top = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1} = (\mathbf{X}^\top \mathbf{X})^{-1}$, whose j th diagonal entry is c_{jj} . The j th row of $\mathbf{C}$ is $\tilde{\mathbf{x}}_j^\top / \|\tilde{\mathbf{x}}_j\|^2$ (proof of [Theorem 20.4.1\(c\)](#)), so $\sum_i \ell_{ij} = \sum_i \tilde{x}_{ij}^2 / \|\tilde{\mathbf{x}}_j\|^2 = c_{jj} \|\tilde{\mathbf{x}}_j\|^2 = 1$. The partial leverages for a coefficient average $1/n$. With $|t_i| \approx 2$ and h_{ii} small, $|\text{DFBETAS}_{ij}| \approx 2\sqrt{\ell_{ij}} \approx 2/\sqrt{n}$ for a typical case.

Exercise B2.

For simple regression, show that the DFBETAS of case i for the slope is $t_i(x_i - \bar{x}) / \sqrt{S_{xx}(1 - h_{ii})}$. Which cases can change the slope most?

Exercise B3.

Use [Theorem 20.4.1\(e\)](#) to show that for large n and small p/n , $\text{COVRATIO}_i \approx 1 + h_{ii} - p(t_i^2 - 1)/n$. Deduce the cut-off $|\text{COVRATIO}_i - 1| > 3p/n$ from the two extreme cases $h_{ii} \approx 0$, $|t_i| = 2$ and $h_{ii} = 2p/n$, $t_i = 0$.

Solution. $1/(1 - h) \approx 1 + h$, and $((n - p)/(n - p - 1 + t^2))^p = (1 + (t^2 - 1)/(n - p))^{-p} \approx 1 - p(t^2 - 1)/n$. Multiplying, $\text{COVRATIO} \approx 1 + h - p(t^2 - 1)/n$ to first order. With $h \approx 0$ and $t^2 = 4$ this is $1 - 3p/n$: a case of no leverage and a residual of two standard errors lowers the precision by that much. With $t = 0$ and $h = 2p/n$ it is $1 + 3p/n$: a well-fitting case of high leverage raises it by the same amount. Deviations beyond $3p/n$ in either direction are more extreme than both.

20.5 Masking and swamping

Every diagnostic so far removes *one* case. But bad cases often come in groups: a batch of records in the wrong units, or a sensor that failed for an afternoon. **Masking** is when a bad case escapes detection because others hide it: deleting it alone leaves its companions to hold the fit in place. **Swamping** is when good cases are flagged because the bad ones have dragged the fit away from them. This section deletes sets of cases and proves how a cluster masks itself and swamps the rest.

20.5.1 Deleting a set of cases

Let $D \subset \{1, \dots, n\}$ be a set of d cases. Write $\mathbf{X}_D$ for the $d \times p$ matrix of their rows, $\mathbf{X}_{(D)}$ for $\mathbf{X}$ with those rows removed, $\hat{\mathbf{e}}_D$ for their residuals in the full fit, and

$$\mathbf{H}_D = \mathbf{X}_D (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}_D^\top$$

for the $d \times d$ block of the hat matrix that belongs to them. Let $\hat{\boldsymbol{\beta}}_{(D)}$ and $\text{SSE}_{(D)}$ come from the least squares fit to the cases not in D , and let $\mathbf{E}_D$ be the $n \times d$ matrix whose columns are the coordinate vectors $\mathbf{e}_i$, $i \in D$.

Theorem 20.5.1 — Deleting a set of cases

Let $\mathbf{X}$ and $\mathbf{X}_{(D)}$ have full column rank. Then $\mathbf{I} - \mathbf{H}_D$ is nonsingular, and

- (a) $\mathbf{y}_D - \mathbf{X}_D \hat{\boldsymbol{\beta}}_{(D)} = (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D$;
- (b) $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(D)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D$;
- (c) $\text{SSE}_{(D)} = \text{SSE} - \hat{\boldsymbol{\varepsilon}}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D$;
- (d) if $n - p - d \geq 1$, then under [Eq. 7.3.1](#)

$$F_D = \frac{\hat{\boldsymbol{\varepsilon}}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D / d}{\text{SSE}_{(D)} / (n - p - d)} \sim F(d, n - p - d),$$

and F_D is the F statistic for $\boldsymbol{\gamma} = \mathbf{0}$ in the mean-shift model $\mathbf{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta} + \mathbf{E}_D\boldsymbol{\gamma}$.

Proof. Let $\mathbf{Z} = [\mathbf{X}, \mathbf{E}_D]$. If $\mathbf{X}\mathbf{b} + \mathbf{E}_D\mathbf{c} = \mathbf{0}$, the rows outside D give $\mathbf{X}_{(D)}\mathbf{b} = \mathbf{0}$, so $\mathbf{b} = \mathbf{0}$, and then $\mathbf{c} = \mathbf{0}$. So $\mathbf{Z}$ has full column rank. By [Lemma 6.6.1\(b\)](#) with $\mathbf{X}_1 = \mathbf{E}_D$, the matrix $(\mathbf{I} - \mathbf{M})\mathbf{E}_D$ has full column rank, so its Gram matrix $\mathbf{E}_D^\top (\mathbf{I} - \mathbf{M})\mathbf{E}_D = \mathbf{I} - \mathbf{H}_D$ is nonsingular.

Fit the mean-shift model. By [Theorem 6.6.2\(a\)](#) with $\mathbf{X}_1 = \mathbf{E}_D$ and $\mathbf{X}_2 = \mathbf{X}$, the estimated shifts are

$$\hat{\boldsymbol{\gamma}} = (\mathbf{E}_D^\top (\mathbf{I} - \mathbf{M})\mathbf{E}_D)^{-1} \mathbf{E}_D^\top (\mathbf{I} - \mathbf{M})\mathbf{y} = (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D.$$

On the other hand, for any $\mathbf{b}$ the residual sum of squares $\sum_{i \notin D} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2 + \|\mathbf{y}_D - \mathbf{X}_D \mathbf{b} - \mathbf{c}\|^2$ is minimized over $\mathbf{c}$ by $\mathbf{c} = \mathbf{y}_D - \mathbf{X}_D \mathbf{b}$, which removes the second term. What remains is minimized by $\mathbf{b} = \hat{\boldsymbol{\beta}}_{(D)}$, uniquely because $\mathbf{X}_{(D)}$ has full column rank. So the mean-shift fit has coefficients $\hat{\boldsymbol{\beta}}_{(D)}$ and $\hat{\boldsymbol{\gamma}} = \mathbf{y}_D - \mathbf{X}_D \hat{\boldsymbol{\beta}}_{(D)}$, and its residual sum of squares is $\text{SSE}_{(D)}$. Comparing the two expressions for $\hat{\boldsymbol{\gamma}}$ gives (a). By [Theorem 6.6.2\(c\)](#), the coefficients of $\mathbf{X}$ in the mean-shift fit are $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top (\mathbf{y} - \mathbf{E}_D \hat{\boldsymbol{\gamma}}) = \hat{\boldsymbol{\beta}} - (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}_D^\top \hat{\boldsymbol{\gamma}}$, which gives (b). By [Lemma 6.6.1\(c\)](#) the projection onto $\mathcal{C}(\mathbf{Z})$ is $\mathbf{M}$ plus the projection onto $\mathcal{C}((\mathbf{I} - \mathbf{M})\mathbf{E}_D)$, so the fall in the residual sum of squares from the fit of $\mathbf{X}$ to the fit of $\mathbf{Z}$ is

$$\mathbf{y}^\top (\mathbf{I} - \mathbf{M})\mathbf{E}_D (\mathbf{I} - \mathbf{H}_D)^{-1} \mathbf{E}_D^\top (\mathbf{I} - \mathbf{M})\mathbf{y} = \hat{\boldsymbol{\varepsilon}}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\varepsilon}}_D,$$

which gives (c). Finally $\mathcal{C}(\mathbf{X}) \subseteq \mathcal{C}(\mathbf{Z})$ with dimensions p and $p+d$, and F_D is the statistic [Eq. 11.1.1](#) for this pair of nested models, so (d) is [Theorem 11.1.1\(d\)](#). ■

With $d = 1$ this is [Theorem 20.3.1](#), and $F_D = t_i^2$ ([Exercise \(A2\)](#)). Part (d) is exact only for a set chosen in advance; a Bonferroni correction over all $\binom{n}{d}$ subsets is valid but very conservative.

20.5.2 How a cluster masks itself

The simplest mechanism is a group of identical bad cases: n_0 clean cases plus m copies of one bad case.

Proposition 20.5.2 — Masking and swamping by a cluster

Let $\mathbf{X}_0$ ($n_0 \times p$, full column rank) and $\mathbf{y}_0$ be the clean cases, with least squares estimate $\hat{\boldsymbol{\beta}}_0$, residuals $\tilde{\epsilon}_j = y_j - \mathbf{x}_{(j)}^\top \hat{\boldsymbol{\beta}}_0$ and residual sum of squares SSE_0 . Add $m \geq 1$ cases, each with row $\mathbf{x}_\star^\top$ and response $y_\star$. Put $\mathbf{A} = \mathbf{X}_0^\top \mathbf{X}_0$,

$$h_\star = \mathbf{x}_\star^\top \mathbf{A}^{-1} \mathbf{x}_\star, \quad \delta = y_\star - \mathbf{x}_\star^\top \hat{\boldsymbol{\beta}}_0,$$

the leverage of $\mathbf{x}_\star$ relative to the clean design and the distance of the cluster from the clean fit. In the least squares fit to all $n_0 + m$ cases:

- (a) each cluster case has leverage $h = h_\star / (1 + mh_\star) < 1/m$;
- (b) each cluster case has residual $\delta / (1 + mh_\star)$;
- (c) deleting one cluster case gives it prediction residual $\delta / (1 + (m-1)h_\star)$ and changes the estimate by $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)} = \mathbf{A}^{-1} \mathbf{x}_\star \delta / [(1 + mh_\star)(1 + (m-1)h_\star)]$;
- (d) deleting the whole cluster gives each member prediction residual δ , and $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(D)} = m(1 + (m-1)h_\star)(\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)})$;
- (e) clean case j has residual $\tilde{\epsilon}_j - m\delta h_{j\star} / (1 + mh_\star)$, where $h_{j\star} = \mathbf{x}_{(j)}^\top \mathbf{A}^{-1} \mathbf{x}_\star$, and $\text{SSE} = \text{SSE}_0 + m\delta^2 / (1 + mh_\star)$.

Proof. Let D be the cluster. Then $\mathbf{X}^\top \mathbf{X} = \mathbf{A} + m\mathbf{x}_\star \mathbf{x}_\star^\top$, and $(\mathbf{A} + m\mathbf{x}_\star \mathbf{x}_\star^\top) \mathbf{A}^{-1} \mathbf{x}_\star = (1 + mh_\star) \mathbf{x}_\star$, so

$$(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_\star = \frac{\mathbf{A}^{-1} \mathbf{x}_\star}{1 + mh_\star}. \quad (20.5.1)$$

- (a) $h = \mathbf{x}_\star^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_\star = h_\star / (1 + mh_\star)$, and $mh = mh_\star / (1 + mh_\star) < 1$.
- (b) and (d) Deleting D leaves the clean cases, so $\hat{\boldsymbol{\beta}}_{(D)} = \hat{\boldsymbol{\beta}}_0$ and every cluster case has prediction residual δ . All rows of $\mathbf{X}_D$ equal $\mathbf{x}_\star^\top$, so $\mathbf{H}_D = h \mathbf{1} \mathbf{1}^\top$, and by Theorem 20.5.1(a) $\hat{\boldsymbol{\epsilon}}_D = (\mathbf{I} - h \mathbf{1} \mathbf{1}^\top) \delta \mathbf{1} = (1 - mh) \delta \mathbf{1} = \delta \mathbf{1} / (1 + mh_\star)$. By Theorem 20.5.1(b) and Eq. 20.5.1, $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_0 = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}_D^\top \delta \mathbf{1} = m\delta (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_\star = m\delta \mathbf{A}^{-1} \mathbf{x}_\star / (1 + mh_\star)$.
- (c) By Theorem 20.3.1(d) and (b), with $1 - h = (1 + (m-1)h_\star) / (1 + mh_\star)$, the prediction residual is $\delta / (1 + (m-1)h_\star)$. By Theorem 20.3.1(b) and Eq. 20.5.1, $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_{(i)} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_\star \cdot \delta / (1 + (m-1)h_\star)$, which is the stated vector. Comparing with the expression for $\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_0$ in the previous step gives the ratio in (d).
- (d) $y_j - \mathbf{x}_{(j)}^\top \hat{\boldsymbol{\beta}} = \tilde{\epsilon}_j - \mathbf{x}_{(j)}^\top (\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_0)$, and $\mathbf{x}_{(j)}^\top (\hat{\boldsymbol{\beta}} - \hat{\boldsymbol{\beta}}_0) = m\delta h_{j\star} / (1 + mh_\star)$. For the sum of squares, Theorem 20.5.1(c) gives $\text{SSE} = \text{SSE}_0 + \hat{\boldsymbol{\epsilon}}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\epsilon}}_D$, and $\hat{\boldsymbol{\epsilon}}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\boldsymbol{\epsilon}}_D = \delta^2 \mathbf{1}^\top (\mathbf{I} - h \mathbf{1} \mathbf{1}^\top)^{-1} \mathbf{1} = m\delta^2 (1 - mh)$, using $(\mathbf{I} - h \mathbf{1} \mathbf{1}^\top)^{-1} \hat{\boldsymbol{\epsilon}}_D = \delta \mathbf{1}$ from part (b). ■

Figure 20.5.1: Masking and swamping. (a) Clean cases, four identical bad records (diamond), and least squares lines with and without them. (b) Externally studentized residuals (bad records last) and the 5% Bonferroni cut-offs.

Each part is a way of hiding. **Leverage is masked** (a): however remote the cluster, each copy has leverage below $1/m$; a single copy would have $h_*/(1 + h_*)$, near one. **Residuals are masked** (b): each is only $1/(1 + mh_*)$ of the cluster's distance from the clean fit. **Deletion is masked** (c, d): deleting one copy leaves $m - 1$ to hold the fit, recovering only $1/(1 + (m - 1)h_*)$ of δ . **Good cases are swamped** (e): clean residuals shift in proportion to their cross-leverage with the cluster, and s^2 is inflated.

Example. (Four identical bad records)

Thirty clean cases have x uniform on $(0, 10)$ and $y = 2 + 0.5x + \varepsilon$, $\sigma = 0.5$. Four identical records are added at $x = 20$, $y = 2$, where the clean line predicts about 12 (Figure 20.5.1(a)). The slope drops from 0.514 (clean cases) to 0.007, and s rises from 0.608 to 1.632. Here $h_* = 1.126$ (it can exceed one, since $x = 20$ is outside the clean design, as in Proposition 12.3.2) and $\delta = -10.150$. Each bad case has leverage 0.205, below $1/m = 0.25$, where a single copy would have 0.530; residual -1.844 ; prediction residual -2.318 ; and $t_i = -1.28$. Deleting the group changes $\hat{\beta}$ 17.51 times as much as deleting one member.

The single-case diagnostics fail as predicted. The Bonferroni test (critical value 3.49) flags nothing, and the only case with $|t_i| > 2$ is a clean one: case 30, the clean case with largest x (9.86), has $t_i = 2.25$, because the dragged line passes below it. Cook's distance does a little better: each bad case has $D_i = 0.206$, above $4/n = 0.118$ (no clean case exceeds it; the largest is 0.100) but far below the median of $F(2, 32)$. A single bad record alone would have had $t_i = -11.45$ and $D_i = 13.46$. Deleting the four together tells the truth: their prediction residuals are all δ , and Theorem 20.5.1(d) gives $F = 50.6$ on 4 and 28 degrees of freedom, p -value 2.0×10^{-12} . The difficulty is not in testing the cluster but in finding it.

20.5.3 Finding the set

There are $\binom{n}{d}$ candidate sets of each size d , far too many to search. The natural shortcut, deleting the case with the largest $|t_i|$ and repeating, starts in the wrong place: in [Example \(Four identical bad records\)](#) it would first remove case 30, a clean case. Three ideas get around the combinatorics. First, **start from a fit the cluster cannot capture**, one determined by about half the data (the next section); the cases it flags form a candidate set to examine and test, remembering that it was chosen by looking. Second, **grow a clean subset**: the forward search of Atkinson and Riani (2000) adds cases one at a time in order of their residuals from a

robust start, and a cluster enters late and all at once, as a jump in the monitored residuals and estimates; Hadi and Simonoff (1993) proposed a related procedure. Third, **unmask leverage separately**: by [Proposition 20.5.2\(a\)](#) the hat matrix is fooled by clusters, since leverage is a Mahalanobis distance built from the sample covariance, which a cluster inflates in its own direction. Rousseeuw and van Zomeren (1990) replaced the mean and covariance by estimates that ignore up to half the cases.

Idea. Single-case diagnostics answer “what if this case alone were different?”, the wrong question when bad cases come in groups. Group deletion asks the right one, but only for a suspected group; finding the group needs a fit it cannot capture.

20.5.4 Exercises

20.5.4.1 A. Check your understanding

Exercise A1.

Check the leverage 0.205 and the residual -1.844 in [Example \(Four identical bad records\)](#) from $h_{\star} = 1.126$, $\delta = -10.150$ and $m = 4$.

Exercise A2.

Show that [Theorem 20.5.1](#) with $D = \{i\}$ gives parts (b), (d) and (e) of [Theorem 20.3.1](#), and that $F_D = t_i^2$.

Solution. With $d = 1$, $\mathbf{H}_D = h_{ii}$ and $\hat{\mathbf{e}}_D = \hat{\varepsilon}_i$, so (a) is the prediction residual $\hat{\varepsilon}_i/(1 - h_{ii})$, (b) is [Theorem 20.3.1\(b\)](#), and (c) is $\text{SSE}_{(i)} = \text{SSE} - \hat{\varepsilon}_i^2/(1 - h_{ii})$. Then $F_D = \hat{\varepsilon}_i^2/\{(1 - h_{ii})s_{(i)}^2\} = t_i^2$.

20.5.4.2 B. Practice

Exercise B1.

Show that for $\mathbf{H}_D = h\mathbf{1}\mathbf{1}^\top$ ($d \times d$) with $dh \neq 1$, $(\mathbf{I} - h\mathbf{1}\mathbf{1}^\top)^{-1} = \mathbf{I} + h\mathbf{1}\mathbf{1}^\top/(1 - dh)$, and use it to recompute the group term $\hat{\mathbf{e}}_D^\top(\mathbf{I} - \mathbf{H}_D)^{-1}\hat{\mathbf{e}}_D$ in the proof of [Proposition 20.5.2\(e\)](#) from $\hat{\mathbf{e}}_D = \delta\mathbf{1}/(1 + mh_{\star})$.

Exercise B2.

In simple regression with clean mean $\bar{x}_0$ and $S_0 = \sum(x_j - \bar{x}_0)^2$, show that $h_{j\star} = 1/n_0 + (x_j - \bar{x}_0)(x_{\star} - \bar{x}_0)/S_0$. In [Example \(Four identical bad records\)](#), with $x_{\star}$ far to the right and $\delta < 0$, which clean residuals does [Proposition 20.5.2\(e\)](#) push up, and which down? Explain why case 30 was flagged.

Solution. Use the centred rows $(1, x - \bar{x}_0)$, which span the same column space; then $\mathbf{A}^{-1} = \text{diag}(1/n_0, 1/S_0)$, so $h_{j\star} = 1/n_0 + (x_j - \bar{x}_0)(x_{\star} - \bar{x}_0)/S_0$. The shift in clean residual j is $-\delta h_{j\star}/(1 + mh_{\star})$, which has the sign of $h_{j\star}$ because $\delta < 0$. Since $x_{\star} - \bar{x}_0 > 0$, $h_{j\star}$

grows with x_j : positive on the right of the clean data and negative on the far left (once $(x_j - \bar{x}_0)(x_\star - \bar{x}_0)/S_0 < -1/n_0$). Residuals on the right are pushed up and those on the far left down. Case 30 is the clean case with the largest x , so it has the largest upward shift, and its studentized residual crosses two.

Exercise B3.

In the setting of [Proposition 20.5.2](#), delete $k < m$ of the cluster cases. Show that each deleted case has prediction residual $\delta/(1 + (m - k)h_\star)$. What does this say about searching for a cluster of unknown size by deleting sets of size k ?

20.5.4.3 C. Going deeper

Exercise C1.

Place two clusters of m identical bad cases at the two ends of a straight-line design, one above the clean line and one below. Describe, using [Theorem 20.5.1](#), what single-case deletion, deletion of one cluster, and deletion of both clusters report. Is it possible for each cluster to mask the other?

Exercise C2.

For a set D of cases, define $D_D = (\hat{\beta}_{(D)} - \hat{\beta})^\top \mathbf{X}^\top \mathbf{X} (\hat{\beta}_{(D)} - \hat{\beta}) / (p s^2)$. Using [Theorem 20.5.1\(b\)](#), show that $D_D = \hat{\epsilon}_D^\top (\mathbf{I} - \mathbf{H}_D)^{-1} \mathbf{H}_D (\mathbf{I} - \mathbf{H}_D)^{-1} \hat{\epsilon}_D / (p s^2)$.

20.6 Robust fitting as a diagnostic

Least squares hides bad cases by accommodating them. A fit that refuses to accommodate them leaves them with large residuals, visible without any deletion. That is the diagnostic use of robust regression, and this section develops only as much theory as that use needs: does a fit the bad cases cannot capture tell a different story, and which cases account for the difference?

20.6.1 M-estimators

Least squares minimizes $\sum_i \rho(y_i - \mathbf{x}_{(i)}^\top \mathbf{b})$ with $\rho(u) = u^2/2$, which lets one large residual outweigh many small ones. An M-estimator (Huber 1964) uses a ρ that grows more slowly.

Definition 20.6.1 — M-estimator of regression

Let $\rho : \mathbb{R} \rightarrow [0, \infty)$ be even, nondecreasing on $[0, \infty)$, differentiable, with $\rho(0) = 0$, and put $\psi = \rho'$ and $w(u) = \psi(u)/u$ (with $w(0) = \lim_{u \rightarrow 0} \psi(u)/u$). Given a scale $\hat{\sigma} > 0$, an

M-estimate $\hat{\mathbf{b}}_M$ minimizes

$$Q(\mathbf{b}) = \sum_{i=1}^n \rho\left(\frac{y_i - \mathbf{x}_{(i)}^\top \mathbf{b}}{\hat{\sigma}}\right).$$

Two choices of ρ are standard.

- (a) **Huber:** $\rho(u) = u^2/2$ for $|u| \leq k$ and $k|u| - k^2/2$ beyond, so $\psi(u) = \max(-k, \min(k, u))$ and $w(u) = \min(1, k/|u|)$.
- (b) **Bisquare** (Tukey's biweight): $\rho(u) = \frac{c^2}{6} [1 - (1 - u^2/c^2)^3]$ for $|u| \leq c$ and $c^2/6$ beyond, so $\psi(u) = u(1 - u^2/c^2)^2$ and $w(u) = (1 - u^2/c^2)^2$ for $|u| < c$, and $\psi(u) = w(u) = 0$ beyond.

Setting the gradient of Q to zero gives the estimating equations

$$\sum_{i=1}^n \psi\left(\frac{y_i - \mathbf{x}_{(i)}^\top \mathbf{b}}{\hat{\sigma}}\right) \mathbf{x}_{(i)} = \mathbf{0} \iff \mathbf{X}^\top \mathbf{W}(\mathbf{b})(\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{0}, \quad (20.6.1)$$

where $\mathbf{W}(\mathbf{b})$ is diagonal with entries $w((y_i - \mathbf{x}_{(i)}^\top \mathbf{b})/\hat{\sigma})$: the normal equations of weighted least squares (Section 6.9) with weights that depend on the fit. A residual beyond $k\hat{\sigma}$ has its Huber influence capped; a residual beyond $c\hat{\sigma}$ gets bisquare weight zero. The Huber ρ is convex; the bisquare ρ is not, and is called **redescending** because ψ falls back to zero.

A standard scale is $\hat{\sigma} = \text{median}_i |y_i - \mathbf{x}_{(i)}^\top \mathbf{b}| / 0.6745$, where $0.6745 = \Phi^{-1}(0.75)$ makes it consistent for σ under centred normal errors; software re-estimates it at each step. The constants $k = 1.345$ and $c = 4.685$ make the location efficiency $(E\psi'(Z))^2 / E\psi(Z)^2$, $Z \sim N(0, 1)$, equal to 0.950 for both (computed by numerical integration in the script). For convex ρ such as Huber's, with p fixed and under smoothness conditions on ψ , that this ratio governs the asymptotic variance of regression M-estimators when $\max_i h_{ii} \rightarrow 0$ is a theorem of Huber (1973) that this book does not prove; redescending estimators such as the bisquare also need a consistent starting value, as in the MM-estimator of Yohai (1987).

20.6.2 Iteratively reweighted least squares

Eq. 20.6.1 suggests **iteratively reweighted least squares** (IRLS), studied for robust regression by Holland and Welsch (1977): from $\mathbf{b}^{(t)}$, compute $w_i = w((y_i - \mathbf{x}_{(i)}^\top \mathbf{b}^{(t)})/\hat{\sigma})$ and let $\mathbf{b}^{(t+1)}$ be the weighted least squares estimate; repeat. With the scale fixed, it never goes uphill.

Proposition 20.6.1 — IRLS descends

Suppose $\rho(u) = g(u^2)$, where $g : [0, \infty) \rightarrow [0, \infty)$ is concave, nondecreasing, and differentiable on $(0, \infty)$ with a finite limit $g'(0^+)$. Then $w(u) = 2g'(u^2) \geq 0$. Hold $\hat{\sigma}$ fixed, and suppose $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ is nonsingular at every step. Then every IRLS step satisfies $Q(\mathbf{b}^{(t+1)}) \leq Q(\mathbf{b}^{(t)})$. The Huber and bisquare ρ satisfy the hypotheses.

Proof. Since $\rho(u) = g(u^2)$, $\psi(u) = 2ug'(u^2)$, so $w(u) = 2g'(u^2)$, which is nonnegative because g is nondecreasing. A concave function lies below each of its tangent lines: $g(v) \leq g(v_0) + g'(v_0)(v - v_0)$ for $v \geq 0$, $v_0 > 0$ (and for $v_0 = 0$ with $g'(0^+)$, by continuity).

With $v = u^2$ and $v_0 = u_0^2$,

$$\rho(u) \leq \rho(u_0) + \frac{1}{2}w(u_0)(u^2 - u_0^2).$$

Write $u_i(\mathbf{b}) = (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})/\hat{\sigma}$ and $w_i = w(u_i(\mathbf{b}^{(t)}))$. Summing over i ,

$$Q(\mathbf{b}) \leq G(\mathbf{b}) = Q(\mathbf{b}^{(t)}) + \frac{1}{2} \sum_i w_i(u_i(\mathbf{b})^2 - u_i(\mathbf{b}^{(t)})^2) \quad \text{for every } \mathbf{b},$$

with equality at $\mathbf{b} = \mathbf{b}^{(t)}$. Up to terms that do not involve $\mathbf{b}$, $G(\mathbf{b})$ is $\frac{1}{2\hat{\sigma}^2} \sum_i w_i(y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$, which the weighted least squares step minimizes. Hence $Q(\mathbf{b}^{(t+1)}) \leq G(\mathbf{b}^{(t+1)}) \leq G(\mathbf{b}^{(t)}) = Q(\mathbf{b}^{(t)})$.

For Huber, $g(v) = v/2$ for $v \leq k^2$ and $k\sqrt{v} - k^2/2$ beyond, so $g'(v) = \frac{1}{2}$ and then $k/(2\sqrt{v})$: continuous at $v = k^2$, nonincreasing, hence g is concave. For the bisquare, $g(v) = \frac{c^2}{6}[1 - (1 - v/c^2)^3]$ for $v \leq c^2$ and constant beyond, so $g'(v) = \frac{1}{2}(1 - v/c^2)^2$, falling to 0 at $v = c^2$, and 0 beyond: again nonincreasing and continuous.

■

This is majorization: Q is replaced by a quadratic that lies above it and touches it at the current point. For Huber's convex ρ , a fixed point of IRLS solves [Eq. 20.6.1](#) and is a global minimizer. For the bisquare, Q can have several local minima, and IRLS finds one near its start.

20.6.3 Breakdown

How many bad cases can an estimator tolerate? The finite-sample breakdown point of [Definition 19.4.1](#) counts the cases that must be replaced to make the estimate arbitrary, and least squares breaks down at a single case: changing y_i by Δ moves $\hat{\beta}$ by $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_{(i)} \Delta$ ([Proposition 19.4.2](#)).

Provided no single row dominates the design, a Huber estimate cannot be broken by changing y_i alone, since ψ is bounded; how much a y -outlier can do depends on the leverages. But one case bad in both $\mathbf{x}$ and y , a **bad leverage point**, breaks it: the fit turns towards the case, whose residual becomes moderate and whose large row then dominates the estimating equations ([Exercise \(C1\)](#)). This is masking again: M-estimates downweight by residual, and a high-leverage case controls its own residual. For regression M-estimates with monotone ψ the breakdown point is $1/n$ (Maronna, Martin and Yohai 2006). Added to the thirty clean cases of [Example \(Four identical bad records\)](#), one case at $x = 50$, $y = 0$ turns the least squares slope from 0.514 to -0.025 , and the Huber slope to -0.026 .

20.6.4 High-breakdown fits

Rousseeuw (1984) proposed estimators that fit a majority of the data and ignore the rest.

Definition 20.6.2 — Least trimmed squares

Let q be an integer with $n/2 \leq q \leq n$. For $\mathbf{b} \in \mathbb{R}^p$, let $r_{[1]}^2(\mathbf{b}) \leq \dots \leq r_{[n]}^2(\mathbf{b})$ be the ordered squared residuals $(y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$. The **least trimmed squares** (LTS) estimate minimizes

$$T(\mathbf{b}) = \sum_{k=1}^q r_{[k]}^2(\mathbf{b}),$$

the sum of the q smallest squared residuals. The **least median of squares** (LMS) estimate minimizes $r_{[\lceil n/2 \rceil]}^2(\mathbf{b})$ instead.

With $q = \lfloor (n + p + 1)/2 \rfloor$ the breakdown point of LTS is close to $1/2$ (see Rousseeuw and Leroy 1987): the fit follows the best-fitting half of the data. Computing it is combinatorial, since $\min T$ is the minimum over q -subsets of their least squares criteria ([Exercise \(B1\)](#)). The practical algorithm rests on the **concentration step** of Rousseeuw and Van Driessen (2006).

Proposition 20.6.2 — Concentration step

Let $\mathbf{b} \in \mathbb{R}^p$, let H be a set of q cases with the smallest squared residuals at $\mathbf{b}$, and suppose the rows of $\mathbf{X}$ in H have full column rank. Let $\mathbf{b}'$ be the least squares estimate computed from the cases in H . Then $T(\mathbf{b}') \leq T(\mathbf{b})$.

Proof. By the choice of H , $T(\mathbf{b}) = \sum_{i \in H} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$, and since $\mathbf{b}'$ minimizes the sum of squares over H , this is at least $\sum_{i \in H} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b}')^2$. Any q squared residuals at $\mathbf{b}'$ sum to at least the q smallest, $T(\mathbf{b}')$. ■

Repeated concentration steps give a nonincreasing sequence of values of T , constant after finitely many steps since there are finitely many q -subsets. The algorithm starts from many random **elemental** fits through p cases and keeps the best result. It needs only one start whose p cases are clean: with a fraction ϵ of bad cases, N starts all fail with probability about $(1 - (1 - \epsilon)^p)^N$, and with $\epsilon = 0.2$, $p = 4$, $N = 9$ starts push this below 1% ([Exercise \(B2\)](#)). LTS with $q \approx n/2$ is inefficient; the MM-estimator of Yohai (1987) uses a high-breakdown fit only to start a redescending M-estimate with a fixed robust scale, keeping the high breakdown point and recovering efficiency. A simplified version, bisquare IRLS from LTS with the scale fixed at the median absolute LTS residual over 0.6745, is used below.

```
def lts(X, y, q, n_starts=500, seed=0):
    """Least trimmed squares: minimize the sum of the q smallest squared residuals.

    Random elemental starts (p cases), each followed by concentration steps: fit
    least
    squares to the current q cases, then keep the q cases with the smallest
    residuals."""
    rng = np.random.default_rng(seed)
    n, p = X.shape
    best, best_obj = None, np.inf
    for _ in range(n_starts):
        idx = rng.choice(n, size=p, replace=False)
        if np.linalg.matrix_rank(X[idx]) < p:
            continue
        beta = np.linalg.solve(X[idx], y[idx])
        for _ in range(100): # concentration steps
            keep = np.argsort((y - X @ beta) ** 2)[:q]
            new, *_ = np.linalg.lstsq(X[keep], y[keep], rcond=None)
            if np.allclose(new, beta):
                break
            beta = new
        obj = np.sort((y - X @ beta) ** 2)[:q].sum()
        if obj < best_obj:
            best, best_obj = beta, obj
    return best, best_obj
```

20.6.5 Using a robust fit diagnostically

The procedure: (1) fit least squares and a high-breakdown or MM-type fit; (2) compare the coefficients, since a difference of more than a standard error means a minority of cases drives least squares; (3) standardize the robust residuals by the robust scale and list cases beyond about 2.5 or with small weights, plotting them against a robust leverage measure to separate outlying responses from bad leverage points (Rousseeuw and van Zomeren 1990); (4) examine the flagged set substantively, refit without it, and report both fits. [Theorem 20.5.1\(d\)](#) measures its incompatibility with the rest, with an optimistic p -value because the set was chosen from the data.

Example. (Robust fits on the masking data)

For the data of [Example \(Four identical bad records\)](#) ([Figure 20.6.1\(a\)](#)), least squares has slope 0.007, and the Huber fit 0.005, with Huber weight 1.000 for each bad record: they have captured the fit so completely that their residuals are not even downweighted. The bisquare fit started from least squares is captured too (slope 0.005). LTS with $q = 18$ of the 34 cases has slope 0.546 and robust scale 0.587; in that scale each bad record has standardized residual -18.6 , and no clean case exceeds 2.81. The bisquare fit started from LTS has slope 0.509 and intercept 1.930, close to the clean fit (0.514 and 1.862), and gives the four records weight zero.

```
rng = np.random.default_rng(20)
n0, m = 30, 4
x_clean = np.sort(rng.uniform(0, 10, n0))
y_clean = 2 + 0.5 * x_clean + rng.normal(0, 0.5, n0)
x = np.r_[x_clean, np.full(m, 20.0)]
y = np.r_[y_clean, np.full(m, 2.0)]
X = np.column_stack([np.ones(len(x)), x])
n, p = X.shape

b_ls, *_ = np.linalg.lstsq(X, y, rcond=None)
b_hub, w_hub, _ = irls(X, y, huber_weight)
b_lts, _ = lts(X, y, q=(n + p + 1) // 2)
s_lts = mad_scale(y - X @ b_lts)
b_bis, w_bis, _ = irls(X, y, bisquare_weight, beta=b_lts, scale=s_lts)
for name, b in [("least squares", b_ls), ("Huber", b_hub), ("LTS", b_lts), ("
    bisquare from LTS", b_bis)]:
    print(f"{name:18s} intercept {b[0]:6.3f} slope {b[1]:6.3f}")
print("scaled LTS residuals of the cluster:", ((y - X @ b_lts) / s_lts)[-m:].round
    (1))
```

Example. (Engel's budgets, robustly)

For food expenditure on income in Engel's data ([Example \(Leverage in Engel's household budgets\)](#)), least squares gives slope 0.485, Huber 0.537 and bisquare 0.553. The bisquare fit gives weight zero to 3 households, rows 59, 105, 138 ([Figure 20.6.1\(b\)](#)). Row 138, the case of highest leverage (income 4958, food 1827, far below the line through the others, Huber weight 0.117), pulls the least squares slope down; in the least squares fit its externally studentized residual is -8.39 and its Cook's distance 9.28.

But the spread of food expenditure grows with income. On the logarithmic scale the three fits nearly agree (slopes 0.856, 0.868, 0.871) and the smallest bisquare weight is 0.16: nobody is rejected. The robust fit correctly reported that a few cases disagree with a constant-variance line; whether the data or the scale is wrong no fit can decide ([Chapter 21](#), [Chapter 22](#)).

```
import statsmodels.api as sm
engel = sm.datasets.engel.load_pandas().data
inc = engel["income"].to_numpy()
food = engel["foodexp"].to_numpy()
XE = np.column_stack([np.ones(len(inc)), inc])
fits = {
    "least squares": sm.OLS(food, XE).fit(),
```

Figure 20.6.1: Robust fits. (a) The masking data: least squares and Huber are captured, LTS and bisquare from LTS are not. (b) Engel's budgets; circled points have bisquare weight zero.

```

"Huber": sm.RLM(food, XE, M=sm.robust.norms.HuberT()).fit(),
"bisquare": sm.RLM(food, XE, M=sm.robust.norms.TukeyBiweight()).fit(),
}
for name, f in fits.items():
    print(f"{name:14s} slope {f.params[1]:.4f}")
w = fits["bisquare"].weights
print("households with bisquare weight 0 (row numbers from 1):", np.where(w == 0)[0]
      + 1)

```

Warning. Deleting flagged cases and then reporting ordinary standard errors treats a data-driven choice as fixed in advance, and the intervals are too short. Report both analyses; [Chapter 23](#) discusses resampling that can include the selection step.

20.6.6 Exercises

20.6.6.1 A. Check your understanding

Exercise A1.

With $k = 1.345$, compute the Huber weights of standardized residuals 0.5, 2 and 10. With $c = 4.685$, compute the bisquare weights of the same residuals.

Exercise A2.

Show that least squares is the M-estimator with $\rho(u) = u^2/2$, that its weights are all one, and that IRLS started anywhere reaches it in one step.

20.6.6.2 B. Practice

Exercise B1.

Show that $\min_{\mathbf{b}} T(\mathbf{b}) = \min_H \text{SSE}_H$, where H ranges over the q -subsets of cases for which the rows of $\mathbf{X}$ in H have full column rank and SSE_H is the residual sum of squares of least squares on H (assume at least one such subset exists). Deduce that an LTS estimate is the least squares estimate on some q -subset.

Solution. For any $\mathbf{b}$ and any q -subset H , $T(\mathbf{b}) \leq \sum_{i \in H} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$, with equality when H consists of cases with the q smallest squared residuals. So $T(\mathbf{b}) = \min_H \sum_{i \in H} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$, and $\min_{\mathbf{b}} T(\mathbf{b}) = \min_H \min_{\mathbf{b}} \sum_{i \in H} (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2$, the order of minimization being interchangeable. For a subset of full rank the inner minimum is SSE_H , attained at the least squares estimate on H . (Subsets without full rank can be handled by a limiting argument or excluded, as the statement assumes.) An LTS estimate is therefore the least squares estimate on a minimizing H .

Exercise B2.

Find the smallest number N of elemental starts for which $(1 - (1 - \epsilon)^p)^N \leq 0.01$ when $\epsilon = 0.2$ and $p = 4$, and when $\epsilon = 0.4$ and $p = 10$. What does the second answer say about high-breakdown fitting with many regressors?

Exercise B3.

For the state murder-rate regression with all 51 jurisdictions, fit Huber and bisquare M-estimates with statsmodels and list the jurisdictions with the smallest weights. Compare the poverty coefficient with the least squares values with and without the District of Columbia ([Example \(How much does the District of Columbia matter?\)](#)).

20.6.6.3 C. Going deeper**Exercise C1.**

Consider regression through the origin, $E(Y) = \beta x$, and an M-estimate with fixed scale $\hat{\sigma} = 1$ and a continuous, nondecreasing, bounded, odd ψ with $\psi(u) > 0$ for $u > 0$. Add to fixed data (x_i, y_i) , $i < n$, one case $(x_n, y_n) = (L, aL)$. Show that as $L \rightarrow \infty$ every solution $\hat{\beta}_L$ of $\sum_i \psi(y_i - \hat{\beta}_L x_i) x_i = 0$ tends to a . Conclude that the breakdown point is $1/n$.

Solution. Let $B = \sup |\psi|$ and $S = \sum_{i < n} |x_i|$, so the first $n - 1$ terms contribute at most BS in absolute value, whatever $\hat{\beta}$. Fix $\eta > 0$. If $\hat{\beta} \leq a - \eta$, the last term is $\psi(L(a - \hat{\beta}))L \geq \psi(L\eta)L$, which exceeds BS once L is large, because $\psi(L\eta) \rightarrow \sup \psi > 0$ (as ψ is nondecreasing and positive on $(0, \infty)$). Then the sum is positive and $\hat{\beta}$ is not a solution. Symmetrically for $\hat{\beta} \geq a + \eta$. So for large L every solution lies in $(a - \eta, a + \eta)$. Since a is arbitrary, one case can place the estimate anywhere, and the breakdown point is $1/n$.

20.7 Summary and Notes

20.7.1 Summary

Idea.

1. Residuals are the projection of the errors onto $\mathcal{C}(\mathbf{X})^\perp$, with variances $\sigma^2(1 - h_{ii})$. The internally studentized residual r_i has a scaled beta law and is bounded by $\sqrt{n-p}$; the externally studentized residual t_i uses a scale estimated without case i (Definition 20.1.1 and Proposition 20.1.1).
2. Residual plots show only the part of a misspecified mean that is orthogonal to $\mathcal{C}(\mathbf{X})$: they can reveal wrong fitted values, not biased coefficients. The added-variable and component-plus-residual plots share their line and their residuals and differ in the horizontal axis (Proposition 20.1.2 and Proposition 20.1.3).
3. Leverage is potential influence. Under a Gaussian design $h_{ii} - 1/n$ is a scaled beta variable, so the $2p/n$ rule fires at a rate that depends on p . With finite second moments the largest leverage vanishes as n grows; with heavy-tailed regressors it need not (Proposition 20.2.1 and Proposition 20.2.2).
4. Partial leverage isolates the pull of a case on one coefficient, and h_{ii} is the leverage without $\mathbf{x}_j$ plus the partial leverage for $\mathbf{x}_j$ (Definition 20.2.1 and Proposition 20.2.3).
5. Deleting one case changes the coefficients, fitted values and residual variance by explicit formulas in $\hat{\varepsilon}_i$ and h_{ii} , and PRESS overestimates fixed-design prediction error slightly (Theorem 20.3.1 and Proposition 20.3.2).
6. t_i is the t statistic of the mean-shift outlier model and has the $t(n-p-1, \Delta\sqrt{1-h_{ii}}/\sigma)$ law; the maximum over cases, with a Bonferroni correction, is an outlier test of level at most α (Theorem 20.3.3).
7. Cook's distance, DFFITS and DFBETAS are products of a residual and a leverage factor. DFFITS is the largest standardized change in any linear combination of the coefficients. Their conventional cut-offs are scaled conventions, not tests (Definition 20.4.1, Theorem 20.4.1 and Proposition 20.4.2).
8. A set of cases can be deleted exactly, and the mean-shift F test checks a prespecified set (Theorem 20.5.1).
9. A cluster of m similar bad cases masks itself: each has leverage below $1/m$, its residual shrinks by $1 + mh_\star$, single deletion recovers a fraction $1/[m(1 + (m-1)h_\star)]$ of the group effect, and clean cases are swamped (Proposition 20.5.2).
10. Huber and bisquare M-estimates are computed by IRLS, which never increases the objective with a fixed scale. They resist outlying responses at cases of moderate leverage, but not bad leverage points. High-breakdown fits such as LTS, computed by concentration steps, expose clusters that least squares and M-estimates absorb (Proposition 20.6.1, Proposition 19.4.2 and Proposition 20.6.2).

20.7.2 Notes and sources

Sources. Seber and Lee (2003, sections 10.2 and 10.6) derive the studentized residuals and their laws, the leave-one-out diagnostics including COVRATIO and the Andrews–Pregibon statistic,

the mean-shift test for a set of cases, and brief accounts of masking, swamping and robust residuals. Christensen (2020, sections 12.1 and 12.5–12.6) develops leverage from the projection $\mathbf{M}$ and derives the updating formulae and predicted residuals. Sen and Srivastava (1990, chapter 8) and Rencher and Schaalje (2008, chapter 9) are briefer. The proofs here take the book's own route: the mean-shift model and the Frisch–Waugh–Lovell theorem for the law of t_i and for group deletion, orthogonal projections for the law of r_i , and partial leverage for DFBETAS.

Residuals and influence. Hoaglin and Welsch (1978) proposed the $2p/n$ rule. The t law of the externally studentized residual is due to Beckman and Trussell (1974). Cook (1977) introduced his distance and its ellipsoid reading, Belsley, Kuh and Welsch (1980) DFFITS, DFBETAS and COVRATIO with their size-adjusted cut-offs, and Andrews and Pregibon (1978) a determinant-based measure for sets of cases. Book-length treatments are Cook and Weisberg (1982), Atkinson (1985) and Chatterjee and Hadi (1988); the review of Beckman and Cook (1983) surveys outlier testing, including the Bonferroni approach. PRESS is from Allen (1974), and partial residual plots were popularized by Larsen and McCleary (1972). [Proposition 20.2.1](#) is the regression form of the classical beta law for the Mahalanobis distance of a normal observation from the sample mean. Kiefer and Wolfowitz (1960) founded optimal design, which this book does not develop.

Masking and robust fitting. Beckman and Cook (1983) discuss masking and swamping at length; [Proposition 20.5.2](#) is a formal version for the simplest configuration. Hadi and Simonoff (1993), Atkinson and Riani (2000) and Rousseeuw and van Zomeren (1990) give the procedures mentioned in [Section 20.5](#). M-estimation began with Huber (1964); Huber (1973) treated regression, under the leverage condition of [Proposition 20.2.2](#). The bisquare is from Beaton and Tukey (1974), IRLS for robust regression was studied by Holland and Welsch (1977), and the finite-sample breakdown point is from Donoho and Huber (1983). LMS and LTS are from Rousseeuw (1984), with Rousseeuw and Leroy (1987) the standard account and Rousseeuw and Van Driessen (2006) the concentration step. The MM-estimator is Yohai's (1987). Maronna, Martin and Yohai (2006) give the theory; median and quantile regression are the subject of [Chapter 45](#) ([Definition 45.2.1](#)).

Data. Engel's budgets were made widely available by Koenker and Bassett (1982) and are distributed with statsmodels; the state data are those of [Chapter 6](#).

Chapter 21

Non-Normality, Heteroscedasticity and Serial Correlation

The exact theory of Part III rests on three assumptions about the errors: they are normal, they have a common variance, and they are uncorrelated. [Chapter 19](#) worked out what least squares does when each of them fails. This chapter is about the data analyst's side of the same question: how to see a failure in the residuals, how large it must be before it matters, and what to do about it. The three assumptions do not matter equally. Coefficient inference survives non-normal errors in moderately large samples, but prediction intervals do not. Unequal variances leave least squares unbiased but make its usual standard errors wrong, sometimes by a factor of four or more, and they can be repaired either by weighting or by a variance estimator that does not trust the model. Serial correlation does the same damage in time-ordered data, and it often signals a mean function that is missing its dynamics. Every diagnostic in the chapter is computed from residuals, which are not the errors. How they differ is where the chapter starts.

What you need. Residuals, leverage and generalized least squares from [Chapter 6](#) ([Proposition 6.4.3](#), [Proposition 6.8.1](#), [Definition 6.9.1](#), [Theorem 6.9.1](#)), the Gauss–Markov and Aitken theorems and the normal sampling theory of [Chapter 7](#) ([Theorem 7.2.1](#), [Corollary 7.2.3](#), [Theorem 7.5.1](#)), the moments of quadratic forms from [Chapter 2](#) ([Theorem 2.3.1](#), [Theorem 2.3.3](#)) and their normal distribution theory from [Chapter 4](#) ([Theorem 4.2.1](#), [Corollary 4.3.3](#)), the deletion formulas of [Chapter 10](#) ([Proposition 10.6.2](#)), and prediction intervals from [Chapter 12](#) ([Theorem 12.3.1](#)) and their large-sample coverage under non-normal errors ([Proposition 12.3.3](#)). From [Chapter 19](#) we use the covariance of least squares under a general error covariance ([Theorem 19.2.2](#)) and its large-sample behaviour under non-normal errors ([Theorem 19.3.2](#)). From [Chapter 20](#) we use studentized residuals ([Definition 20.1.1](#), [Theorem 20.3.3](#)). The limit theorems of probability that the chapter needs are gathered, or pointed to, in [Section 21.2](#).

21.1 Checking normality

Normality turns the first two moments of least squares into exact distributions. How much of Part III needs it? [Chapter 19](#) answered the question for coefficients. When no observation carries much leverage, $\hat{\boldsymbol{\beta}}$ is approximately normal whatever the error law, and the t and F tests keep their nominal levels in large samples ([Theorem 19.3.2](#)). Two kinds of inference are not protected in this way. The interval for σ^2 of [Section 12.1](#) depends on the fourth moment of the errors ([Proposition 7.5.4](#)). A prediction interval is a statement about a single new error, and no averaging makes a single error normal. So the error distribution is worth checking mainly when the analysis will predict individual responses, when the sample is small, or when a few observations may be of a different kind from the rest.

The errors are never observed, so the first task is to say how well the residuals stand in for them.

21.1.1 Residuals are not the errors

If $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ and $\mathbf{M}$ is the hat matrix, the residual vector is $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$ ([Proposition 6.4.3](#)). Write m_{ij} for the entries of $\mathbf{M}$, so that $h_{ii} = m_{ii}$ are the leverages, and c_{ij} for the entries of $\mathbf{I} - \mathbf{M}$. Each residual is a weighted sum of all n errors,

$$\hat{\varepsilon}_i = (1 - h_{ii})\varepsilon_i - \sum_{j \neq i} m_{ij}\varepsilon_j,$$

so even when the errors are independent and identically distributed the residuals are neither. They are correlated, and their variances $\sigma^2(1 - h_{ii})$ differ.

Proposition 21.1.1 — What residuals reveal about the errors

Let $\varepsilon_1, \dots, \varepsilon_n$ be independent and identically distributed with mean 0 and variance σ^2 , and let $\text{rank}(\mathbf{X}) = p$.

- $\hat{\varepsilon}_i - \varepsilon_i = -(\mathbf{M}\boldsymbol{\varepsilon})_i$, which has mean 0 and variance $\sigma^2 h_{ii}$. The total $E\|\hat{\boldsymbol{\varepsilon}} - \boldsymbol{\varepsilon}\|^2$ equals $\sigma^2 p$.
- Let $\hat{\varepsilon}_{(1)} \leq \dots \leq \hat{\varepsilon}_{(n)}$ and $\varepsilon_{(1)} \leq \dots \leq \varepsilon_{(n)}$ be the ordered residuals and ordered errors. Then

$$\frac{1}{n} \sum_{i=1}^n (\hat{\varepsilon}_{(i)} - \varepsilon_{(i)})^2 \leq \frac{1}{n} \|\mathbf{M}\boldsymbol{\varepsilon}\|^2,$$

and the right-hand side has expectation $\sigma^2 p/n$.

- Suppose the errors have skewness $\gamma_1 = E\varepsilon^3/\sigma^3$ and excess kurtosis $\gamma_2 = E\varepsilon^4/\sigma^4 - 3$. If $h_{ii} < 1$, the standardized residual $\hat{\varepsilon}_i/(\sigma\sqrt{1 - h_{ii}})$ has skewness $a_i\gamma_1$ and excess kurtosis $b_i\gamma_2$, where

$$a_i = \frac{\sum_j c_{ij}^3}{(1 - h_{ii})^{3/2}}, \quad b_i = \frac{\sum_j c_{ij}^4}{(1 - h_{ii})^2},$$

with $|a_i| \leq 1$ and $(1 - h_{ii})^2 \leq b_i \leq 1$.

Proof.

- (a) $\hat{\varepsilon} - \varepsilon = -\mathbf{M}\varepsilon$, with mean zero and covariance $\sigma^2\mathbf{M}\mathbf{M}^\top = \sigma^2\mathbf{M}$ (Theorem 2.2.1), whose diagonal is $\sigma^2 h_{ii}$ and whose trace is $\sigma^2 p$.
- (b) Let $\mathbf{u}, \mathbf{v} \in \mathbb{R}^n$. Pairing the sorted values gives $\sum_i u_{(i)} v_{(i)} \geq \sum_i u_i v_{\pi(i)}$ for every permutation π : if a pairing matches $u_{(i)} < u_{(j)}$ with v -values $b > b'$ respectively, exchanging the two partners changes the sum by $(u_{(j)} - u_{(i)})(b - b') \geq 0$, and finitely many such exchanges reach the sorted pairing. Since sorting does not change $\|\mathbf{u}\|$ or $\|\mathbf{v}\|$, it follows that $\sum_i (u_{(i)} - v_{(i)})^2 \leq \|\mathbf{u} - \mathbf{v}\|^2$. Take $\mathbf{u} = \hat{\varepsilon}$ and $\mathbf{v} = \varepsilon$ and use (a).
- (c) Row i of $\mathbf{I} - \mathbf{M}$ has $\sum_j c_{ij}^2 = (\mathbf{I} - \mathbf{M})_{ii} = 1 - h_{ii}$ because $\mathbf{I} - \mathbf{M}$ is symmetric and idempotent. Expand $\hat{\varepsilon}_i = \sum_j c_{ij} \varepsilon_j$. By independence and $E \varepsilon_j = 0$, every cross term with an index appearing once vanishes, so $E \hat{\varepsilon}_i^3 = E \varepsilon^3 \sum_j c_{ij}^3$ and

$$\begin{aligned} E \hat{\varepsilon}_i^4 &= E \varepsilon^4 \sum_j c_{ij}^4 + 3\sigma^4 \sum_{j \neq k} c_{ij}^2 c_{ik}^2 \\ &= (E \varepsilon^4 - 3\sigma^4) \sum_j c_{ij}^4 + 3\sigma^4(1 - h_{ii})^2. \end{aligned}$$

Dividing by $\sigma^3(1 - h_{ii})^{3/2}$ and $\sigma^4(1 - h_{ii})^2$ gives the skewness and the excess kurtosis. For the bounds, $\max_j c_{ij}^2 \leq \sum_j c_{ij}^2 = 1 - h_{ii}$, so $|\sum_j c_{ij}^3| \leq (1 - h_{ii})^{1/2}(1 - h_{ii})$ and $\sum_j c_{ij}^4 \leq (1 - h_{ii})^2$, while $\sum_j c_{ij}^4 \geq c_{ii}^4 = (1 - h_{ii})^4$. ■

Parts (a) and (b) say that the residuals are good proxies for the errors when p/n is small. Part (b) is the statement that matters for plots, because a normal probability plot shows sorted values: on average the sorted residuals lie within $\sigma\sqrt{p/n}$ of the sorted errors, in root mean square. Part (c) describes what happens when p/n is not small. Each residual is an average of many errors, and averaging pushes a distribution towards normality, so residuals look *more* normal than the errors that produced them. This is sometimes called **supernormality**. The factor b_i measures it exactly.

Example. (How much non-normality survives)

Take $n = 30$ observations, an intercept, and $p - 1$ columns of standard normal regressors. Averaged over the observations, the share of the errors' excess kurtosis that survives in the standardized residuals is 0.873 for $p = 2$, 0.467 for $p = 10$ and 0.162 for $p = 20$. The share of skewness is 0.898, 0.532 and 0.162. With centred exponential errors (skewness 2, excess kurtosis 6) and $p = 10$, the residual with the largest leverage, $h_{ii} = 0.57$, has predicted excess kurtosis 1.23, against 1.26 in 200,000 simulated data sets. For the ordered values, the average squared distance between sorted residuals and sorted errors was 0.133, while the bound in (b) averaged 0.330, close to its expectation $p/n = 1/3$.

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(2101)
```

```

n = 30
designs = {}
for p in (2, 10, 20):
    X = np.column_stack([np.ones(n), rng.normal(size=(n, p - 1))])
    Q, _ = np.linalg.qr(X)
    M = Q @ Q.T                                # the hat matrix
    designs[p] = (M, np.diag(M).copy())

for p, (M, h) in designs.items():
    # residual i = (row i of C) @ errors
    C = np.eye(n) - M
    # excess kurtosis of residual i / that of an error
    kurt_kept = (C**4).sum(axis=1) / (1 - h) ** 2
    # skewness of residual i / that of an error
    skew_kept = (C**3).sum(axis=1) / (1 - h) ** 1.5
    print(f"p = {p:2d}: max leverage {h.max():.2f}, "
          f"average share of skewness kept {skew_kept.mean():.3f}, "
          f"of excess kurtosis kept {kurt_kept.mean():.3f}")

```

21.1.2 Normal probability plots

A **normal probability plot** graphs the sorted values of a sample against the corresponding quantiles of the standard normal distribution. If $U_1, \dots, U_n$ are independent $N(\mu, \tau^2)$, the i th smallest is close to $\mu + \tau q_i$, where q_i approximates the expected i th order statistic of a standard normal sample. A common choice, due to Blom (1958), is

$$q_i = \Phi^{-1}\left(\frac{i - 3/8}{n + 1/4}\right).$$

Normal data give points near a straight line with intercept μ and slope τ . Heavy tails bend both ends away from the line, into an S shape. Skewness bends the plot into a curve that is convex for a long right tail, and isolated points at either end suggest outliers.

For residuals, the unequal variances $\sigma^2(1 - h_{ii})$ should be removed first. The natural choice is the externally studentized residual t_i , which divides $\hat{\varepsilon}_i$ by $s_{(i)}\sqrt{1 - h_{ii}}$, where $s_{(i)}^2$ is the error variance estimate without observation i ([Definition 20.1.1](#)). Under normal errors every t_i has the $t(n - p - 1)$ distribution ([Theorem 20.3.3](#)), so the t_i share a common marginal law and their sorted values can be compared with one reference. They are not independent, and that makes it hard to judge by eye how much wiggle is normal.

A simulated **envelope** answers that. Under normal errors the vector $(t_1, \dots, t_n)$ is a function of $\hat{\varepsilon}/\|\hat{\varepsilon}\| = (\mathbf{I} - \mathbf{M})\varepsilon/\|(\mathbf{I} - \mathbf{M})\varepsilon\|$ alone, so its joint distribution depends on the design but not on β or σ ([Exercise \(B1\)](#)). We can therefore simulate it exactly: generate normal errors, compute the sorted studentized residuals, repeat, and plot pointwise percentiles (Atkinson 1981). The envelope is pointwise, so a few points outside it are expected even for normal data. A run of consecutive points outside it, or an end of the plot leaving it, is the signal.

Example. (Three error laws)

[Figure 21.1.1](#) shows plots for one simulated data set of $n = 60$ observations with an intercept and two regressors ($p = 3$), with three error laws of variance one. The normal case stays inside its envelope except for 3 scattered points, and the Shapiro–Wilk test described below gives $p = 0.519$. Errors from a $t(3)$ distribution give the S shape of

Figure 21.1.1: Normal probability plots of externally studentized residuals, $n = 60$, $p = 3$, with pointwise 95% envelopes from 1999 data sets simulated with normal errors (shaded) and their pointwise median (line). Points outside the envelope are drawn in the second colour. (a) Normal errors. (b) Errors from $t(3)$. (c) Centred exponential errors.

heavy tails, with the largest residual far above the envelope (Shapiro–Wilk $p < 0.001$). Centred exponential errors give a curved plot whose left end is too short and whose right end is too long ($p = 0.001$).

```
import numpy as np
from scipy import stats

rng = np.random.default_rng(2104)
n, p = 60, 3
X = np.column_stack([np.ones(n), rng.normal(size=(n, 2))])
Q, _ = np.linalg.qr(X)
h = np.sum(Q**2, axis=1) # leverages

def ext_studentized(y):
    """Externally studentized residuals  $t_i = e_i / (s_{-i} \sqrt{1 - h_{ii}})$ ."""
    e = y - Q @ (Q.T @ y)
    s2 = e @ e / (n - p)
    # squared internally studentized residuals
    r2 = e**2 / (s2 * (1 - h))
    return np.sign(e) * np.sqrt(r2 * (n - p - 1) / (n - p - r2))

# plotting positions
blom = stats.norm.ppf((np.arange(1, n + 1) - 0.375) / (n + 0.25))
sims = np.sort([ext_studentized(rng.normal(size=n)) for _ in range(1999)],
                axis=1)
# pointwise envelope
lower, upper = np.percentile(sims, [2.5, 97.5], axis=0)

laws = {
    "normal": rng.normal(size=n),
    "t(3)": rng.standard_t(3, size=n) / np.sqrt(3.0),
    "centred exponential": rng.exponential(size=n) - 1.0,
}
beta = np.array([1.0, 2.0, -1.0])
for name, eps in laws.items():
```

```
t = np.sort(ext_studentized(X @ beta + eps))
outside = np.sum((t < lower) | (t > upper))
print(f"{name:20s}: {outside} of {n} points outside the envelope, "
      f"Shapiro-Wilk p = {stats.shapiro(t).pvalue:.3f}")
```

21.1.3 Formal tests

Many tests of normality exist. Four kinds are in common use for residuals.

- The **Shapiro–Wilk** statistic (Shapiro and Wilk 1965) is $W = (\sum_i a_i u_{(i)})^2 / \sum_i (u_i - \bar{u})^2$. The weights a_i come from the means and the covariance matrix of standard normal order statistics, and they make the numerator the square of the best linear unbiased estimate of the standard deviation from the ordered sample, up to a constant. So W compares two estimates of scale, one that is efficient only under normality and one that is always valid. It lies in $(0, 1]$, and small values reject. Its null distribution has no closed form and is computed numerically.
- The **Shapiro–Francia** statistic (Shapiro and Francia 1972) replaces the weights by the plotting positions, which makes it the squared correlation between the sorted sample and the q_i . It is a one-number summary of how straight the normal probability plot is.
- **Moment tests** use the sample skewness $\sqrt{b_1}$ and kurtosis b_2 . The Jarque–Bera statistic $n\{b_1/6 + (b_2 - 3)^2/24\}$ is approximately $\chi^2(2)$ for large normal samples (Jarque and Bera 1980). These tests are directed at the two departures that matter most for inference.
- **Distance tests** compare the empirical and fitted normal distribution functions: Kolmogorov–Smirnov with estimated parameters (Lilliefors 1967) and Anderson–Darling (Anderson and Darling 1952). They are usually less powerful than Shapiro–Wilk.

Applied to residuals, none of these has its nominal null distribution, because the residuals are not a sample. The effect on the level is small. In the design of [Example \(How much non-normality survives\)](#) with $p = 20$ and normal errors, the 5% Shapiro–Wilk test applied to the raw residuals rejected in 0.045 of 4000 simulated data sets, and applied to the internally studentized residuals in 0.035. The effect on power is not small. Supernormality hides the non-normality that the test is looking for.

Example. (Power lost to supernormality)

In the same designs ($n = 30$), the 5% Shapiro–Wilk test applied to the unobservable centred exponential errors rejects in 0.96 to 0.97 of simulated data sets. Applied to the residuals it rejects in 0.92 for $p = 2$, 0.45 for $p = 10$ and only 0.07 for $p = 20$. For errors from $t(5)$, rescaled to variance one, the rates are 0.24 to 0.25 for the errors and 0.23, 0.14 and 0.05 for the residuals.

```
def errors(kind, size, rng):
    """Mean-zero, variance-one errors."""
    if kind == "exp":
        return rng.exponential(size=size) - 1.0
    return rng.standard_t(5, size=size) / np.sqrt(5 / 3)

def power_table(reps, rng):
    """Rejection rates of the 5% Shapiro-Wilk test on errors and on residuals."""
    table = {}
```

```

for kind in ("exp", "t5"):
    for p, (M, h) in designs.items():
        E = errors(kind, (reps, n), rng)
        # residual vectors (M is symmetric)
        R = E - E @ M
        rej_err = np.mean([stats.shapiro(e).pvalue < 0.05 for e in E])
        rej_res = np.mean([stats.shapiro(r).pvalue < 0.05 for r in R])
        table[kind, p] = (rej_err, rej_res)
    print(f"{kind:3s} p = {p:2d}: Shapiro-Wilk rejects "
          f"errors {rej_err:.2f}, "
          f"residuals {rej_res:.2f}")
return table

# a quick version (the book uses 4000 replications)
quick = power_table(400, rng)

```

A test of normality also answers the wrong question. In small samples it passes error laws that would distort a prediction interval badly; in large ones it rejects departures too small to matter. The useful question is whether the departure is large enough to affect the inference at hand. For coefficient tests without high-leverage points it rarely is. For prediction intervals it can be, as the next result shows.

21.1.4 What non-normality does to prediction intervals

Under normal errors the interval $\hat{Y}_0 \pm t_{n-p, \alpha/2} s \sqrt{1 + h_0}$ covers a new response $Y_0 = \mathbf{x}_0^\top \boldsymbol{\beta} + \varepsilon_0$ with probability exactly $1 - \alpha$, where $h_0 = \mathbf{x}_0^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_0$ (Theorem 12.3.1). Without normality its coverage does not tend to $1 - \alpha$ as the sample grows. By Proposition 12.3.3, when $h_0 \rightarrow 0$ and the errors are independent and identically distributed with a continuous distribution function F , the coverage tends to $\Pr(|\varepsilon_0| \leq z\sigma) = F(z\sigma) - F(-z\sigma)$, where $z = \Phi^{-1}(1 - \alpha/2)$, and the probabilities of missing above and below tend to $1 - F(z\sigma)$ and $F(-z\sigma)$.

The limit is the probability that a single error falls within z standard deviations of zero, and it depends on the whole shape of F . Section 12.3 evaluated it for centred exponential and uniform errors at the 80% and 95% levels. Table 21.1.1 extends that comparison to heavy-tailed laws and to the 99% level, and splits the misses between the two tails.

Table 21.1.1. Limiting coverage of the usual prediction interval (Proposition 12.3.3) when the errors are not normal, with the limiting probabilities of missing below and above in parentheses. All five laws have mean zero and variance one.

error law	nominal 80%	nominal 95%	nominal 99%
normal	0.800 (0.100, 0.100)	0.950 (0.025, 0.025)	0.990 (0.005, 0.005)
$t(5)$	0.841 (0.079, 0.079)	0.947 (0.026, 0.026)	0.979 (0.010, 0.010)
$t(3)$	0.887 (0.057, 0.057)	0.957 (0.021, 0.021)	0.979 (0.010, 0.010)
uniform	0.740 (0.130, 0.130)	1.000 (0.000, 0.000)	1.000 (0.000, 0.000)
centred exponential	0.898 (0.000, 0.102)	0.948 (0.000, 0.052)	0.972 (0.000, 0.028)

Heavy tails make a 99% interval too short and an 80% interval too long. The 95% level lies near

the crossing point, so checking a 95% interval alone would miss the problem. For the skewed law every miss is above the interval, since a centred exponential error is never below $-\sigma$; at the 99% level it misses above 0.028 of the time, more than five times the nominal 0.005 in that tail.

```
import numpy as np
from scipy import stats

laws = {
    "normal": stats.norm(),
    "t(5)": stats.t(5, scale=np.sqrt(3 / 5)),
    "t(3)": stats.t(3, scale=np.sqrt(1 / 3)),
    "uniform": stats.uniform(loc=-np.sqrt(3), scale=2 * np.sqrt(3)),
    "centred exponential": stats.expon(loc=-1.0),
}
for name, law in laws.items():
    assert abs(law.var() - 1) < 1e-9 and abs(law.mean()) < 1e-9
    row = []
    for level in (0.80, 0.95, 0.99):
        z = stats.norm.ppf(0.5 + level / 2)
        below, above = law.cdf(-z), law.sf(z)          # miss low, miss high
        row.append(f"{1 - below - above:.3f} ({below:.3f}, {above:.3f})")
    print(f"{name:20s}", " ".join(row))
```

The remedy is to use the residuals for what they are good at, estimating the error distribution: empirical quantiles of the residuals in place of $\pm z\sigma$ give intervals whose coverage tends to the nominal level, and [Chapter 23](#) refines this by resampling. A transformation of the response ([Chapter 22](#)) can remove skewness at its source.

21.1.5 Exercises

21.1.5.1 A. Check your understanding

Exercise A1.

In simple regression with $n = 5$ and $x = (1, 2, 3, 4, 10)$, compute the leverages and the variances of the five residuals when $\sigma^2 = 1$. Which residual is least like its error, in the sense of [Proposition 21.1.1\(a\)](#)?

21.1.5.2 B. Practice

Exercise B1.

Assume $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$. Show that the internally and externally studentized residuals are functions of $\mathbf{g} = \hat{\boldsymbol{\varepsilon}}/\|\hat{\boldsymbol{\varepsilon}}\|$, and that the law of $\mathbf{g}$ does not depend on $\boldsymbol{\beta}$ or σ . Conclude that the simulated envelope of this section is exact, whatever $\boldsymbol{\beta}$ and σ are used in the simulation.

Solution. $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$, and $\boldsymbol{\varepsilon}/\sigma \sim N_n(\mathbf{0}, \mathbf{I})$ whatever $\boldsymbol{\beta}$ and σ are, so $\mathbf{g} = (\mathbf{I} - \mathbf{M})(\boldsymbol{\varepsilon}/\sigma)/\|(\mathbf{I} - \mathbf{M})(\boldsymbol{\varepsilon}/\sigma)\|$ has a fixed law. The internally studentized residual is $r_i = \hat{\varepsilon}_i/(s\sqrt{1 - h_{ii}})$ with $s = \|\hat{\boldsymbol{\varepsilon}}\|/\sqrt{n - p}$, so $r_i = \sqrt{n - p} g_i / \sqrt{1 - h_{ii}}$. The externally studentized residual is the monotone function $t_i = r_i \sqrt{(n - p - 1)/(n - p - r_i^2)}$ of r_i ([Def-](#)

inition 20.1.1). Hence the whole vector of sorted t_i has a law that depends only on $\mathbf{M}$, and it can be simulated with any $\boldsymbol{\beta}$ and σ .

Exercise B2.

For centred exponential errors, $\varepsilon = E - 1$ with E standard exponential, show that the limit in Proposition 12.3.3 at the 95% level is $1 - e^{-2.96}$, and find the probabilities of missing below and above.

Solution. Here $\sigma = 1$ and $z = 1.96$. The event $|E - 1| \leq 1.96$ is $E \leq 2.96$, since $E \geq 0 > -0.96$ always. Its probability is $1 - e^{-2.96} = 1 - 0.0518 = 0.948$. The interval never misses below, and it misses above with probability $e^{-2.96} = 0.0518$.

Exercise B3.

In a one-way layout in which every group has m observations, show that the kurtosis factor of Proposition 21.1.1(c) is the same for every residual and equals

$$b = \frac{(1 - 1/m)^4 + (m - 1)/m^4}{(1 - 1/m)^2}.$$

Evaluate it for $m = 2$ and $m = 5$, and explain why residual plots from small groups say little about the tails of the errors.

21.1.5.3 C. Going deeper

Exercise C1.

Under the assumptions of Proposition 21.1.1, suppose $p/n \rightarrow 0$ along a sequence of designs. Let $\hat{F}_n$ and F_n be the empirical distribution functions of the residuals and of the errors. Show that $\hat{F}_n(x) - F_n(x) \rightarrow 0$ in probability at every continuity point x of F .

21.2 Detecting heteroscedasticity

The errors are **heteroscedastic** when their variances differ, $\text{Var}(\varepsilon_i) = \sigma_i^2$. Least squares remains unbiased, but its covariance becomes $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \boldsymbol{\Sigma} \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1}$ with $\boldsymbol{\Sigma} = \text{diag}(\sigma_1^2, \dots, \sigma_n^2)$, and $s^2(\mathbf{X}^\top \mathbf{X})^{-1}$ no longer estimates it (Theorem 19.2.2). Least squares also stops being the best linear unbiased estimator. How far the usual standard errors go wrong depends on how the variances line up with the regressors: the damage is greatest when the observations with the most influence on a coefficient also have the largest variances. Chapter 15 showed the same thing for the one-way layout, where unequal variances bias the F test only in unbalanced designs (Theorem 15.5.2).

Unequal variances have familiar sources. A response that is an average of m_i observations has variance proportional to $1/m_i$. Counts, sizes and amounts of money tend to vary more when they are larger. And if a coefficient itself varies from unit to unit, $y_i = \mathbf{x}_{(i)}^\top (\boldsymbol{\beta} + \mathbf{u}_i)$ with random

$\mathbf{u}_i$, the variance of y_i is a quadratic function of $\mathbf{x}_{(i)}$ ([Exercise \(B1\)](#)).

21.2.1 Residual plots

Under heteroscedasticity the residuals $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$ have covariance $(\mathbf{I} - \mathbf{M})\boldsymbol{\Sigma}(\mathbf{I} - \mathbf{M})$, so

$$E \hat{\varepsilon}_i^2 = (1 - h_{ii})^2 \sigma_i^2 + \sum_{j \neq i} m_{ij}^2 \sigma_j^2. \quad (21.2.1)$$

When h_{ii} is small the first term dominates, and the squared residual tracks the variance of its own observation. At high leverage it does not: a point with h_{ii} near one has a small residual whatever its variance. Even with constant variance the residuals have unequal variances $\sigma^2(1 - h_{ii})$, so plots for heteroscedasticity should use the studentized residuals $r_i = \hat{\varepsilon}_i / (s\sqrt{1 - h_{ii}})$, which have constant variance under the model.

The standard displays are:

- r_i against the fitted values. A fan that opens to the right says that variance grows with the mean.
- r_i against each regressor, and against variables outside the model that might affect precision, such as time, the instrument or the interviewer.
- $|r_i|$, or $\log|r_i|$, against the same variables. Absolute values fold the two halves of the fan onto each other and make a trend in spread easier to see.

The logarithmic plot also estimates a power law. If $\sigma_i = \sigma v_i^\theta$ for a positive variable v_i , then $\varepsilon_i = \sigma v_i^\theta \zeta_i$ with ζ_i of constant law, and $\log|\varepsilon_i| = \log \sigma + \theta \log v_i + \log|\zeta_i|$. So the slope of $\log|r_i|$ on $\log v_i$ estimates θ , with the residuals standing in for the errors.

Example. (Engel's food expenditure data)

[Section 6.9](#) fitted Engel's data on the annual income and food expenditure of 235 Belgian households, and noted that the spread of expenditure grows with income. The least squares slope is 0.4852. [Figure 21.2.1](#) shows the residual plots. Panel (a) is a fan. Panel (b) plots $|r_i|$ against income on logarithmic scales. The slope of the fitted line, 0.96, suggests a standard deviation roughly proportional to income, the weighting used in [Example \(Engel's food expenditure data\)](#). The most extreme point, at the far right of panel (a), is the household with the largest income. Its leverage is 0.255, about thirty times the average p/n , and its residual is large and negative.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

df = sm.datasets.engel.load_pandas().data
income, food = df["income"].to_numpy(), df["foodexp"].to_numpy()
n = len(food)
X = np.column_stack([np.ones(n), income])
beta, *_ = np.linalg.lstsq(X, food, rcond=None)
fitted = X @ beta
e = food - fitted
Q, _ = np.linalg.qr(X)

# OLS residuals
```

Figure 21.2.1: Residuals from the least squares fit to Engel's data. (a) Residuals against fitted values. (b) Absolute studentized residuals against income, both on logarithmic scales, with the least squares line.

```
h = np.sum(Q**2, axis=1)
s2 = e @ e / (n - 2)
# internally studentized residuals
r = e / np.sqrt(s2 * (1 - h))
```

Plots show the form of the variance function, which weighting will need. A formal test helps when the pattern is unclear or many models must be screened.

21.2.2 Limit theorems we need

Most results in the rest of the chapter are large-sample results. Three standard limit theorems, the central limit theorem, Slutsky's lemma and the delta method, were stated in [Section 14.4](#), and [Section 19.3](#) recalled three more: the Lindeberg–Feller central limit theorem, the Cramér–Wold device and the continuous mapping theorem. We add two pieces of notation and one law of large numbers.

Remark (Orders in probability and the weak law). A sequence T_n is **bounded in probability**, written $T_n = O_p(1)$, if for every $\eta > 0$ there is a K with $\Pr(|T_n| > K) < \eta$ for all n . If $E|T_n|$ is bounded, then $T_n = O_p(1)$ by Markov's inequality. We write $T_n = o_p(1)$ if $T_n \rightarrow 0$ in probability. Products and sums obey $O_p(1)o_p(1) = o_p(1)$ and $O_p(1) + o_p(1) = O_p(1)$. The *weak law of large numbers* says that if $W_1, W_2, \dots$ are independent copies of a random variable with finite mean, then $\bar{W}_n \rightarrow EW_1$ in probability. Proofs are in van der Vaart (1998, chapter 2).

The regression version of the central limit theorem concerns a weighted sum $\mathbf{c}^\top \boldsymbol{\xi}$ of independent variables, with weights determined by the design. It holds as long as no single weight dominates. [Lemma 19.3.1](#) proved it for identically distributed variables. The sandwich estimators of [Section 21.4](#) also need it for variables whose variances differ, and for that a moment slightly higher than the second must be bounded, in the form due to Lyapunov.

Lemma 21.2.1 — A central limit theorem for weighted sums

For each n let $\xi_1, \dots, \xi_n$ be independent with mean zero, and let $\mathbf{c} = \mathbf{c}_n \in \mathbb{R}^n$ be nonzero weights with

$$\max_i \frac{c_i^2}{\|\mathbf{c}\|^2} \rightarrow 0. \quad (21.2.2)$$

Suppose either (a) the ξ_i have a common distribution, not depending on n , with variance $\tau^2 \in (0, \infty)$, or (b) for some constants $\delta, K, \tau_{\min} > 0$, $\text{Var } \xi_i \geq \tau_{\min}^2$ and $\text{E}|\xi_i|^{2+\delta} \leq K$ for all i and n . Then

$$\frac{\sum_i c_i \xi_i}{(\sum_i c_i^2 \text{Var } \xi_i)^{1/2}} \rightarrow N(0, 1) \quad \text{in distribution.}$$

Proof. Case (a) is the lemma on weighted sums of errors in [Section 19.3](#), applied with ξ_i in place of the errors and the unit weights $\mathbf{c}/\|\mathbf{c}\|$. For case (b), let $v_n = \sum_i c_i^2 \text{Var } \xi_i$ and $X_{ni} = c_i \xi_i / \sqrt{v_n}$, so that $\sum_i \text{Var } X_{ni} = 1$, and write $\mu_n = \max_i |c_i|/\|\mathbf{c}\| \rightarrow 0$. We check Lindeberg's condition. Here $v_n \geq \tau_{\min}^2 \|\mathbf{c}\|^2$, and on $\{|X_{ni}| > \eta\}$ we have $X_{ni}^2 \leq |X_{ni}|^{2+\delta}/\eta^\delta$. Hence the Lindeberg sum satisfies

$$\begin{aligned} \sum_i \text{E}[X_{ni}^2 \mathbf{1}\{|X_{ni}| > \eta\}] &\leq \frac{K \sum_i |c_i|^{2+\delta}}{\eta^\delta v_n^{1+\delta/2}} \\ &\leq \frac{K \mu_n^\delta \|\mathbf{c}\|^2 \|\mathbf{c}\|^\delta}{\eta^\delta \tau_{\min}^{2+\delta} \|\mathbf{c}\|^{2+\delta}} = \frac{K \mu_n^\delta}{\eta^\delta \tau_{\min}^{2+\delta}} \rightarrow 0, \end{aligned}$$

using $\sum_i |c_i|^{2+\delta} \leq \max_i |c_i|^\delta \sum_i c_i^2$. The Lindeberg–Feller theorem gives the conclusion. ■

For the coefficient vector $\mathbf{c} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\lambda}$ of a linear function $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}$, the condition [Eq. 21.2.2](#) is implied by $\max_i h_{ii} \rightarrow 0$, since $c_i^2 \leq h_{ii} \|\mathbf{c}\|^2$, as the proof of [Theorem 19.3.2](#) shows. This is the condition behind that theorem.

21.2.3 The Breusch–Pagan score test

To test for heteroscedasticity we need an alternative. A **variance function** model supposes that

$$\sigma_i^2 = h(\alpha_0 + \mathbf{z}_i^\top \boldsymbol{\alpha}), \quad (21.2.3)$$

where $\mathbf{z}_i \in \mathbb{R}^q$ is a vector of observed variables, possibly some or all of the regressors, and h is a positive function. Constant variance is the hypothesis $\boldsymbol{\alpha} = \mathbf{0}$. Common choices are $h(t) = e^t$, which keeps variances positive, and $h(t) = t$. The score test of [Section 11.4](#) needs only the fit under the hypothesis, which is ordinary least squares, and it turns out not to depend on h at all.

Write $\tilde{\sigma}^2 = \|\hat{\boldsymbol{\epsilon}}\|^2/n$ for the maximum likelihood estimate of σ^2 under the hypothesis, $u_i = \hat{\epsilon}_i^2/\tilde{\sigma}^2$

for the scaled squared residuals, and $\tilde{\mathbf{Z}}$ for the $n \times q$ matrix whose rows are $(\mathbf{z}_i - \bar{\mathbf{z}})^\top$. Let R^2 be the coefficient of determination from regressing $\hat{\varepsilon}_i^2$ on an intercept and $\mathbf{z}_i$, and let $\hat{\kappa} = n \sum_i \hat{\varepsilon}_i^4 / (\sum_i \hat{\varepsilon}_i^2)^2$ be the sample kurtosis of the residuals. In this section κ denotes the raw kurtosis μ_4/σ^4 , which equals 3 for normal errors; [Section 19.3](#) used the same letter for the excess kurtosis $\mu_4/\sigma^4 - 3$.

Theorem 21.2.2 — Breusch–Pagan and Koenker

Let $\tilde{\mathbf{Z}}$ have full column rank q .

- (a) (*Score statistic.*) Suppose $\varepsilon_i \sim N(0, \sigma_i^2)$ independently, with [Eq. 21.2.3](#), h continuously differentiable, and $h' \neq 0$ at the null value of α_0 . The score statistic for $\alpha = \mathbf{0}$ is

$$\text{BP} = \frac{1}{2}(\mathbf{u} - \mathbf{1})^\top \tilde{\mathbf{Z}}(\tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}})^{-1} \tilde{\mathbf{Z}}^\top (\mathbf{u} - \mathbf{1}),$$

half the explained sum of squares from regressing u_i on an intercept and $\mathbf{z}_i$. It does not depend on h .

- (b) (*Studentized form.*) Let $K = nR^2$. Then $\text{BP} = \frac{1}{2}(\hat{\kappa} - 1)K$.
- (c) (*Null distributions.*) Suppose instead only that the errors are independent and identically distributed with mean 0, variance σ^2 , finite fourth moment μ_4 and kurtosis $\kappa = \mu_4/\sigma^4 > 1$, that $\text{rank}(\mathbf{X}) = p$ and q are fixed, that the $\mathbf{z}_i$ are bounded, and that $n^{-1}\tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}} \rightarrow \mathbf{Q}_z$, positive definite. Then, as $n \rightarrow \infty$,

$$K \rightarrow \chi^2(q), \quad \text{BP} \rightarrow \frac{1}{2}(\kappa - 1)\chi^2(q) \quad \text{in distribution.}$$

Proof.

- (a) The log-likelihood is $\ell = -\frac{1}{2} \sum_i \log(2\pi\sigma_i^2) - \frac{1}{2} \sum_i (y_i - \mathbf{x}_{(i)}^\top \boldsymbol{\beta})^2 / \sigma_i^2$. Put $\boldsymbol{\theta} = (\alpha_0, \boldsymbol{\alpha}^\top)^\top$, $\mathbf{z}_i^* = (1, \mathbf{z}_i^\top)^\top$ and $\eta_i = \alpha_0 + \mathbf{z}_i^\top \boldsymbol{\alpha}$. Since $\partial\ell/\partial\sigma_i^2 = (\varepsilon_i^2/\sigma_i^2 - 1)/(2\sigma_i^2)$ and $\partial\sigma_i^2/\partial\boldsymbol{\theta} = h'(\eta_i)\mathbf{z}_i^*$,

$$\begin{aligned} \frac{\partial\ell}{\partial\boldsymbol{\theta}} &= \sum_i \frac{h'(\eta_i)}{2\sigma_i^2} \left(\frac{\varepsilon_i^2}{\sigma_i^2} - 1 \right) \mathbf{z}_i^*, \\ \frac{\partial\ell}{\partial\boldsymbol{\beta}} &= \sum_i \frac{\varepsilon_i}{\sigma_i^2} \mathbf{x}_{(i)}. \end{aligned}$$

Under normality $\varepsilon_i^2/\sigma_i^2$ has variance 2, and $E\varepsilon_i(\varepsilon_i^2 - \sigma_i^2) = 0$, so the information matrix is block diagonal between $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$, and its $\boldsymbol{\theta}$ block is $\sum_i h'(\eta_i)^2 \mathbf{z}_i^* \mathbf{z}_i^{*\top} / (2\sigma_i^4)$. Under the hypothesis $\eta_i = \alpha_0$ for all i , the restricted maximum likelihood estimates are $\hat{\boldsymbol{\beta}}$ and $\tilde{\sigma}^2$, and $h(\hat{\alpha}_0) = \tilde{\sigma}^2$. Write $g = h'(\hat{\alpha}_0)$, let $\mathbf{Z}$ be the $n \times q$ matrix with rows $\mathbf{z}_i^\top$, and put $\mathbf{Z}^* = [\mathbf{1}, \mathbf{Z}]$. At the restricted estimate the $\boldsymbol{\beta}$ score vanishes, and

$$\mathbf{S}_\theta = \frac{g}{2\tilde{\sigma}^2} \mathbf{Z}^{*\top} (\mathbf{u} - \mathbf{1}), \quad \mathcal{I}_{\theta\theta} = \frac{g^2}{2\tilde{\sigma}^4} \mathbf{Z}^{*\top} \mathbf{Z}^*.$$

By block diagonality the score statistic is $\mathbf{S}_\theta^\top \mathcal{I}_{\theta\theta}^{-1} \mathbf{S}_\theta = \frac{1}{2}(\mathbf{u} - \mathbf{1})^\top \mathbf{Z}^* (\mathbf{Z}^{*\top} \mathbf{Z}^*)^{-1} \mathbf{Z}^{*\top} (\mathbf{u} - \mathbf{1})$, in which g has cancelled. The matrix here is the projection onto $\mathcal{C}(\mathbf{Z}^*) = \mathcal{C}(\mathbf{1}) \oplus \mathcal{C}(\tilde{\mathbf{Z}})$, and $\mathbf{1}^\top (\mathbf{u} - \mathbf{1}) = 0$ because $\sum_i u_i = n$, so only the projection onto $\mathcal{C}(\tilde{\mathbf{Z}})$ contributes ([Lemma 6.6.1](#)).

- (b) Let $\mathbf{w}$ have entries $\hat{\varepsilon}_i^2$. Its explained sum of squares on $[\mathbf{1}, \mathbf{Z}]$ is $\text{ESS}_w = (\mathbf{w} - \tilde{\sigma}^2 \mathbf{1})^\top \tilde{\mathbf{M}} (\mathbf{w} - \tilde{\sigma}^2 \mathbf{1})$, where $\tilde{\mathbf{M}}$ projects onto $\mathcal{C}(\tilde{\mathbf{Z}})$, and its total sum of squares is

$\text{TSS}_w = \sum_i (\hat{\varepsilon}_i^2 - \tilde{\sigma}^2)^2 = \sum_i \hat{\varepsilon}_i^4 - n\tilde{\sigma}^4$. Since $\mathbf{u} - \mathbf{1} = (\mathbf{w} - \tilde{\sigma}^2 \mathbf{1})/\tilde{\sigma}^2$, (a) gives $\text{BP} = \text{ESS}_w/(2\tilde{\sigma}^4)$, while $K = n \text{ESS}_w/\text{TSS}_w$. Their ratio is $\text{TSS}_w/(2n\tilde{\sigma}^4) = (\hat{\kappa} - 1)/2$.

- (c) Put $\mathbf{a} = \mathbf{M}\boldsymbol{\varepsilon}$, so that $\hat{\varepsilon}_i = \varepsilon_i - a_i$ and $E\|\mathbf{a}\|^2 = \sigma^2 p$ (Proposition 21.1.1). Let $|\tilde{z}_{ik}| \leq C$. By (b),

$$K = \frac{\mathbf{T}_n^\top (n^{-1} \tilde{\mathbf{Z}}^\top \tilde{\mathbf{Z}})^{-1} \mathbf{T}_n}{\text{TSS}_w/n},$$

$$\mathbf{T}_n = n^{-1/2} \tilde{\mathbf{Z}}^\top \mathbf{w} = n^{-1/2} \tilde{\mathbf{Z}}^\top (\mathbf{w} - \sigma^2 \mathbf{1}),$$

using $\tilde{\mathbf{Z}}^\top \mathbf{1} = \mathbf{0}$. We show three things.

The leading term. Let $\mathbf{T}_n^0 = n^{-1/2} \sum_i \tilde{\mathbf{z}}_i (\varepsilon_i^2 - \sigma^2)$. The $\xi_i = \varepsilon_i^2 - \sigma^2$ are independent and identically distributed with variance $\mu_4 - \sigma^4 > 0$. For fixed $\mathbf{b} \in \mathbb{R}^q$ the weights $c_i = \mathbf{b}^\top \tilde{\mathbf{z}}_i$ are bounded and $\|\mathbf{c}\|^2/n \rightarrow \mathbf{b}^\top \mathbf{Q}_z \mathbf{b} > 0$, so Eq. 21.2.2 holds, and Lemma 21.2.1(a) shows that $\mathbf{b}^\top \mathbf{T}_n^0 \rightarrow N(0, (\mu_4 - \sigma^4) \mathbf{b}^\top \mathbf{Q}_z \mathbf{b})$. By the Cramér–Wold device, $\mathbf{T}_n^0 \rightarrow N_q(\mathbf{0}, (\mu_4 - \sigma^4) \mathbf{Q}_z)$.

The residuals do not matter. $\hat{\varepsilon}_i^2 - \varepsilon_i^2 = a_i^2 - 2a_i \varepsilon_i$, so the k th coordinate of $\mathbf{T}_n - \mathbf{T}_n^0$ is $n^{-1/2} \sum_i \tilde{z}_{ik} a_i^2 - 2n^{-1/2} \boldsymbol{\varepsilon}^\top \mathbf{B} \boldsymbol{\varepsilon}$, with $\mathbf{B} = \frac{1}{2}(\mathbf{D}\mathbf{M} + \mathbf{M}\mathbf{D})$ and $\mathbf{D} = \text{diag}(\tilde{z}_{1k}, \dots, \tilde{z}_{nk})$. The first term is at most $Cn^{-1/2} \|\mathbf{a}\|^2$, whose mean $C\sigma^2 p/\sqrt{n}$ tends to zero. For the second, $|E \boldsymbol{\varepsilon}^\top \mathbf{B} \boldsymbol{\varepsilon}| = \sigma^2 |\text{tr}(\mathbf{D}\mathbf{M})| \leq C\sigma^2 p$ (Theorem 2.3.1), and by Theorem 2.3.3

$$\begin{aligned} \text{Var}(\boldsymbol{\varepsilon}^\top \mathbf{B} \boldsymbol{\varepsilon}) &\leq |\mu_4 - 3\sigma^4| \sum_i b_{ii}^2 + 2\sigma^4 \text{tr}(\mathbf{B}^2) \\ &\leq (|\mu_4 - 3\sigma^4| + 2\sigma^4) C^2 p, \end{aligned}$$

because $b_{ii} = \tilde{z}_{ik} h_{ii}$, $\sum_i h_{ii}^2 \leq \sum_i h_{ii} = p$, and $\text{tr}(\mathbf{B}^2) \leq \|\mathbf{D}\mathbf{M}\|_F^2 = \text{tr}(\mathbf{M}\mathbf{D}^2\mathbf{M}) \leq C^2 \text{tr} \mathbf{M}$. So $n^{-1/2} \boldsymbol{\varepsilon}^\top \mathbf{B} \boldsymbol{\varepsilon}$ has mean and variance tending to zero, and $\mathbf{T}_n - \mathbf{T}_n^0 = o_p(1)$.

The denominator. $\tilde{\sigma}^2 = (\|\boldsymbol{\varepsilon}\|^2 - \|\mathbf{a}\|^2)/n \rightarrow \sigma^2$ by the weak law and $\|\mathbf{a}\|^2 = O_p(1)$. For the fourth powers, Minkowski's inequality in the norm $\|\mathbf{v}\|_4 = (\sum_i v_i^4)^{1/4}$ gives $|\|\hat{\boldsymbol{\varepsilon}}\|_4 - \|\boldsymbol{\varepsilon}\|_4| \leq \|\mathbf{a}\|_4 \leq \|\mathbf{a}\| = O_p(1)$, while $n^{-1} \|\boldsymbol{\varepsilon}\|_4^4 \rightarrow \mu_4$ by the weak law. Hence $n^{-1} \sum_i \hat{\varepsilon}_i^4 \rightarrow \mu_4$, $\text{TSS}_w/n \rightarrow \mu_4 - \sigma^4$ and $\hat{\kappa} \rightarrow \kappa$.

Combining these by Slutsky's lemma and continuous mapping, K converges in distribution to $\mathbf{T}^\top \mathbf{Q}_z^{-1} \mathbf{T}/(\mu_4 - \sigma^4)$ with $\mathbf{T} \sim N_q(\mathbf{0}, (\mu_4 - \sigma^4) \mathbf{Q}_z)$, which is $\chi^2(q)$ by Corollary 4.3.3. The statement about BP follows from (b). ■

Part (a) is the test of Breusch and Pagan (1979). Cook and Weisberg (1983) derived the same statistic, and used the regression of u_i on $\mathbf{z}_i$ as a diagnostic plot. Part (c) exposes a weakness. BP is calibrated for normal errors, which have $\kappa = 3$. With heavier tails its null distribution is inflated by the factor $(\kappa - 1)/2$, and the test rejects too often, detecting kurtosis rather than heteroscedasticity. Koenker (1981) proposed the studentized form nR^2 , whose null limit is the same for every error law with a fourth moment. It is the version to use.

Example. (Size of the two tests)

Take a straight-line regression with $n = 100$ equally spaced values of x , constant variance, and $\mathbf{z}_i = x_i$. In 40,000 simulated data sets the 5% tests rejected as follows:

error law	κ	Breusch–Pagan	its limit	Koenker
normal	3	0.048	0.050	0.050
Laplace	6	0.185	0.215	0.047
uniform	1.8	0.003	0.002	0.049

The Laplace law makes the Breusch–Pagan test reject nearly four times too often; the uniform law makes it almost never reject. The studentized test holds its level in all three cases.

```
import numpy as np

```

White's test. For the least squares standard errors, what matters is whether σ_i^2 is correlated with the entries of $\mathbf{x}_{(i)}\mathbf{x}_{(i)}^\top$, the terms of $\mathbf{X}^\top\mathbf{\Sigma}\mathbf{X}$ (White 1980). White's test is Koenker's statistic with $\mathbf{z}_i$ the regressors, their squares and their cross products; with many regressors it has many degrees of freedom and low power.

Example. (Testing Engel's data)

With $z_i = \text{income}_i$, the Breusch–Pagan statistic is 636.0 and Koenker's is 109.3, on one degree of freedom. Their ratio is $5.820 = (\hat{\kappa} - 1)/2$, since the residuals have sample kurtosis 12.64. The heavy tails of the residuals inflate BP about sixfold, but the evidence is overwhelming either way: Koenker's p-value is 1.4×10^{-25} . White's test, with income and its square, gives 181.1 on two degrees of freedom.

21.2.4 An exact test: Goldfeld–Quandt

When the variance is suspected to change monotonically with one variable v that does not depend on the responses, there is an exact test under normality. Sort the observations by v , set aside a block in the middle, and fit the model separately to the n_1 observations with the smallest values of v and the n_2 with the largest.

Proposition 21.2.3 — Goldfeld–Quandt

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$, let the two groups be chosen without reference to $\mathbf{Y}$, and let $\mathbf{X}_1$ and $\mathbf{X}_2$, their rows of $\mathbf{X}$, have rank $p < n_k$. If SSE_1 and SSE_2 are the residual sums of squares of the separate fits, then

$$F_{\text{GQ}} = \frac{\text{SSE}_2/(n_2 - p)}{\text{SSE}_1/(n_1 - p)} \sim F(n_2 - p, n_1 - p).$$

Proof. Each group is a normal linear model with error variance σ^2 , so $\text{SSE}_k/\sigma^2 \sim \chi^2(n_k - p)$ by [Theorem 7.5.1\(b\)](#). The two sums of squares are functions of disjoint sets of independent errors, so they are independent, and the ratio has the stated law by [Definition 4.1.2](#) with $\gamma = 0$. ■

Dropping the middle block sharpens the contrast between the groups at the cost of degrees of freedom, and how much to drop is a matter of judgement; here we omit a fifth of the data. For Engel's data, with the middle 47 households omitted and 94 in each group, $F_{\text{GQ}} = 10.22$ on $(92, 92)$ degrees of freedom, with p-value 1.7×10^{-24} . The test is exact only under normality. Like every comparison of variances, it is sensitive to the tails of the error law. When the observations fall into groups, a more robust comparison is Levene's test (Levene 1960), the one-way analysis of variance of the absolute residuals $|\hat{\varepsilon}_i|$, or its version with deviations from group medians (Brown and Forsythe 1974). Box (1953) showed how badly the classical normal-theory test of equal group variances, Bartlett's, is affected by kurtosis.

21.2.5 Exercises**21.2.5.1 A. Check your understanding****Exercise A1.**

Derive [Eq. 21.2.1](#). Show that under constant variance $E \hat{\varepsilon}_i^2 = \sigma^2(1 - h_{ii})$, and give an example in which σ_i^2 is the largest variance but $E \hat{\varepsilon}_i^2$ is the smallest.

21.2.5.2 B. Practice**Exercise B1.**

Let $y_i = \mathbf{x}_{(i)}^\top(\boldsymbol{\beta} + \mathbf{u}_i) + \varepsilon_i$, where $\mathbf{u}_i$ has mean $\mathbf{0}$ and covariance $\boldsymbol{\Omega}$, ε_i has variance σ^2 , and all are independent. Show that $\text{Var}(y_i)$ is a linear function of the squares and cross products of the regressors. Which test of this section is the score-type test for $\boldsymbol{\Omega} = \mathbf{0}$?

Solution. $y_i - \mathbf{x}_{(i)}^\top \boldsymbol{\beta} = \mathbf{x}_{(i)}^\top \mathbf{u}_i + \varepsilon_i$ has variance $\sigma^2 + \mathbf{x}_{(i)}^\top \boldsymbol{\Omega} \mathbf{x}_{(i)} = \sigma^2 + \sum_{j,k} \omega_{jk} x_{ij} x_{ik}$, linear in the products $x_{ij} x_{ik}$ with coefficients ω_{jk} . This is [Eq. 21.2.3](#) with $h(t) = t$ and $\mathbf{z}_i$ the distinct squares and cross products (the squares of the intercept column merge with the

intercept). The score test is the Breusch–Pagan test with these $\mathbf{z}_i$, whose studentized form is White’s test.

Exercise B2.

Under the assumptions of [Proposition 21.2.3](#), suppose the observations are sorted by their fitted values $\hat{Y}_i$ instead of by a fixed variable. Show that F_{GQ} still has the $F(n_2 - p, n_1 - p)$ distribution. Show by an example that sorting by $|\hat{\varepsilon}_i|$ destroys the result.

Solution. Fix a partition, with selection matrices $\mathbf{S}_1, \mathbf{S}_2$, and let $\mathbf{M}_k$ project onto $\mathcal{C}(\mathbf{X}_k)$. The group residuals $(\mathbf{I} - \mathbf{M}_k)\mathbf{S}_k\boldsymbol{\varepsilon}$ and the fitted values $\mathbf{M}\boldsymbol{\varepsilon}$ are jointly normal with cross-covariance $\sigma^2(\mathbf{I} - \mathbf{M}_k)\mathbf{S}_k\mathbf{M} = \sigma^2(\mathbf{I} - \mathbf{M}_k)\mathbf{X}_k(\mathbf{X}^\top\mathbf{X})^{-1}\mathbf{X}^\top = \mathbf{0}$, since $\mathbf{S}_k\mathbf{X} = \mathbf{X}_k$. So, for every fixed partition, $(\text{SSE}_1, \text{SSE}_2)$ is independent of $\mathbf{M}\mathbf{Y}$, and it has the law of [Proposition 21.2.3](#). Sorting by fitted values makes the partition a function of $\mathbf{M}\mathbf{Y}$, so given $\mathbf{M}\mathbf{Y}$ the statistic has the F law, and therefore also unconditionally. Sorting by $|\hat{\varepsilon}_i|$ puts the largest residuals in the second group: with $p = 1$, $\mathbf{X} = \mathbf{1}$ and $n = 4$, no middle block, the second group contains the two observations farthest from $\bar{y}$, and F_{GQ} exceeds one with probability one.

21.2.5.3 C. Going deeper

Exercise C1.

Suppose the observations fall into g groups and $\mathbf{z}_i$ consists of $g - 1$ group indicators. Show that Koenker’s statistic is n times the R^2 of a one-way analysis of variance of the squared residuals, and compare it with Levene’s test.

21.3 Weighted least squares

Once heteroscedasticity has been found, one can transform the response ([Chapter 22](#)), keep least squares and correct its standard errors ([Section 21.4](#)), or give the noisier observations less weight. This section is about weighting. With known variances it is optimal and its theory is already in place. With estimated variances the gain is real but the theory is asymptotic, and a careless implementation can do worse than no weighting at all.

21.3.1 Known weights

Suppose $\text{Var}(\varepsilon_i) = \sigma^2/w_i$, with the $w_i > 0$ known and σ^2 unknown, and the errors uncorrelated. With $\mathbf{W} = \text{diag}(w_1, \dots, w_n)$ this is $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2\mathbf{W}^{-1}$. The generalized least squares estimate of [Definition 6.9.1](#) with $\mathbf{V} = \mathbf{W}^{-1}$ minimizes

$$\sum_{i=1}^n w_i (y_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2, \quad \text{so} \quad \hat{\boldsymbol{\beta}}_W = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{y}. \quad (21.3.1)$$

This is the **weighted least squares** (WLS) estimate. [Section 6.9](#) described its geometry: it is

ordinary least squares after each row of $\mathbf{X}$ and $\mathbf{y}$ is multiplied by $\sqrt{w_i}$, which turns the errors into $\sqrt{w_i}\varepsilon_i$ with common variance σ^2 . Aitken's theorem ([Corollary 7.2.3](#)) makes it the best linear unbiased estimator. Everything in Part III then applies to the rescaled data. The error variance is estimated by

$$s_w^2 = \frac{1}{n-p} \sum_{i=1}^n w_i (y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_W)^2,$$

the covariance of $\hat{\boldsymbol{\beta}}_W$ by $s_w^2(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$, and under normality the t and F procedures are exact. The residuals to plot are the rescaled ones, $\sqrt{w_i}(y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_W)$, studentized with the leverages of the weighted fit. The raw residuals $y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_W$ should still fan out, since their variances still differ.

Known weights arise when y_i is the mean of m_i observations ($w_i = m_i$), a total ($w_i = 1/m_i$), or a measurement from an instrument of known precision. The weights are then fixed by the design, not by the data.

21.3.2 Estimating the weights

More often the variances are unknown, and the weights must come from the data. There are three common routes.

1. **Replicates.** If there are several observations at each distinct row of $\mathbf{X}$, or in each of a few groups known to differ in precision, the sample variance within each group estimates its σ_g^2 .
2. **A variance function in other variables.** Model $\sigma_i^2 = \sigma^2 \exp(\mathbf{z}_i^\top \boldsymbol{\gamma})$, as in [Eq. 21.2.3](#), and estimate $\boldsymbol{\gamma}$ by regressing $\log \hat{\varepsilon}_i^2$ on an intercept and $\mathbf{z}_i$. The intercept of that regression is biased, because $E \log \chi^2(1) \neq 0$, but weights are needed only up to a common factor, so the intercept does not matter.
3. **A variance function of the mean.** Model $\sigma_i = \sigma |\mu_i|^\theta$ with $\mu_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, estimate θ from the slope of $\log |\hat{\varepsilon}_i|$ on $\log |\hat{Y}_i|$, and weight by $|\hat{Y}_i|^{-2\theta}$. Since the weights depend on the fit, the estimate is usually iterated.

The resulting estimate $\hat{\boldsymbol{\beta}}_{\hat{W}}$ is called **feasible** (or estimated) weighted least squares.

Example. (Engel's data, reweighted)

Regressing $\log \hat{\varepsilon}_i^2$ on an intercept and $\log \text{income}_i$ gives slope $\hat{\gamma} = 1.90$, so the fitted variance is proportional to $\text{income}^{1.90}$, close to the square law suggested by [Figure 21.2.1](#). Weighting by $\text{income}^{-1.90}$ changes the slope from 0.4852 to 0.5711. The model-based standard error $s_w \{(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}\}_{22}^{1/2}$ of the weighted slope is 0.0149. The sandwich standard error of [Section 21.4](#), which does not trust the variance model, is 0.0172 for the weighted slope and 0.0664 for the unweighted one. So weighting has cut the standard error by a factor of nearly four.

The variance function is not sharply determined by these data. Re-estimating γ from the residuals of the weighted fit, and repeating until it settles (10 iterations), moves $\hat{\gamma}$ to 2.52 and the slope to 0.5875, about one standard error away. Reporting the weighted estimate with the sandwich standard error protects against this uncertainty in the weights.

```

21.3.3 What feasible weighting achieves

The weights in $\hat{\beta}_W$ are random and depend on the same data as the fit, so none of the finite-sample results for known weights carries over directly. The next theorem collects what can be said in general. Part (b) shows that weighting with the wrong weights is harmless for bias. Part (c) is an exact finite-sample result, and part (d) is the large-sample justification in the setting of replicated groups.

Theorem 21.3.1 — Weighted least squares with known and estimated weights

Let $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $E\boldsymbol{\varepsilon} = \mathbf{0}$ and $\text{rank}(\mathbf{X}) = p$.

- (a) (*Known weights.*) If $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{W}^{-1}$ with $\mathbf{W}$ known, then $\hat{\beta}_W$ is the best linear unbiased estimator of $\boldsymbol{\beta}$, $\text{Cov}(\hat{\beta}_W) = \sigma^2 (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$ and $E s_w^2 = \sigma^2$. If $\boldsymbol{\varepsilon}$ is normal, $\hat{\beta}_W \sim N_p(\boldsymbol{\beta}, \sigma^2 (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1})$ independently of $(n - p) s_w^2 / \sigma^2 \sim \chi^2(n - p)$.

- (b) (*Wrong weights.*) If $\text{Cov}(\boldsymbol{\varepsilon}) = \boldsymbol{\Sigma}$ is arbitrary and $\mathbf{W}$ is any fixed positive diagonal matrix, then $\hat{\boldsymbol{\beta}}_W$ is unbiased with

$$\text{Cov}(\hat{\boldsymbol{\beta}}_W) = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \boldsymbol{\Sigma} \mathbf{W} \mathbf{X} (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}.$$

- (c) (*Estimated weights, symmetric errors.*) Let $\hat{\mathbf{W}} = \mathbf{W}(\hat{\boldsymbol{\varepsilon}})$ be a positive diagonal matrix that depends on the data only through the ordinary least squares residuals, with $\mathbf{W}(-\mathbf{e}) = \mathbf{W}(\mathbf{e})$. If $-\boldsymbol{\varepsilon}$ has the same distribution as $\boldsymbol{\varepsilon}$ and $E\|\hat{\boldsymbol{\beta}}_{\hat{\mathbf{W}}}\| < \infty$, then $E\hat{\boldsymbol{\beta}}_{\hat{\mathbf{W}}} = \boldsymbol{\beta}$.
- (d) (*Estimated weights from groups.*) Suppose the observations form G groups, fixed in advance, that the errors are independent, and that within group g they are identically distributed with variance $\sigma_g^2 > 0$. Let $n_g \rightarrow \infty$ for each g with $n^{-1} \mathbf{X}_g^\top \mathbf{X}_g \rightarrow \mathbf{A}_g$, where $\mathbf{X}_g$ holds the rows of group g , and let $\mathbf{A}_w = \sum_g \mathbf{A}_g / \sigma_g^2$ be positive definite. Let $\mathbf{W}$ have entries $1/\sigma_g^2$, and $\hat{\mathbf{W}}$ have entries $1/\hat{\sigma}_g^2$, where $\hat{\sigma}_g^2 = \|\hat{\boldsymbol{\varepsilon}}_g\|^2/n_g$ is the mean squared ordinary least squares residual in group g . Then

$$\sqrt{n}(\hat{\boldsymbol{\beta}}_{\hat{\mathbf{W}}} - \hat{\boldsymbol{\beta}}_W) \rightarrow \mathbf{0} \quad \text{and} \quad n(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} \rightarrow \mathbf{A}_w^{-1}$$

in probability, while $n \text{Cov}(\hat{\boldsymbol{\beta}}_W) = n(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \rightarrow \mathbf{A}_w^{-1}$.

Proof.

- (a) Multiply Eq. 21.3.1 through by $\mathbf{W}^{1/2}$: the model $\mathbf{W}^{1/2} \mathbf{Y} = \mathbf{W}^{1/2} \mathbf{X} \boldsymbol{\beta} + \mathbf{W}^{1/2} \boldsymbol{\varepsilon}$ satisfies $\text{Cov}(\mathbf{W}^{1/2} \boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$, and $\hat{\boldsymbol{\beta}}_W$ is its least squares estimate. The claims are Corollary 7.2.3, Theorem 5.5.1, Theorem 5.6.1 and Theorem 7.5.1 applied to the rescaled model.
- (b) $\hat{\boldsymbol{\beta}}_W - \boldsymbol{\beta} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \boldsymbol{\varepsilon}$ is a fixed linear map of $\boldsymbol{\varepsilon}$; apply Theorem 2.2.1.
- (c) The residuals $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M}) \boldsymbol{\varepsilon}$ do not involve $\boldsymbol{\beta}$, and they change sign with $\boldsymbol{\varepsilon}$. So $\hat{\boldsymbol{\beta}}_{\hat{\mathbf{W}}} - \boldsymbol{\beta} = \mathbf{g}(\boldsymbol{\varepsilon})$ with $\mathbf{g}(\boldsymbol{\varepsilon}) = (\mathbf{X}^\top \mathbf{W}(\hat{\boldsymbol{\varepsilon}}) \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W}(\hat{\boldsymbol{\varepsilon}}) \boldsymbol{\varepsilon}$, and $\mathbf{g}(-\boldsymbol{\varepsilon}) = -\mathbf{g}(\boldsymbol{\varepsilon})$ because $\mathbf{W}(-\hat{\boldsymbol{\varepsilon}}) = \mathbf{W}(\hat{\boldsymbol{\varepsilon}})$. If $-\boldsymbol{\varepsilon}$ has the law of $\boldsymbol{\varepsilon}$, then $\mathbf{g}(\boldsymbol{\varepsilon})$ has the law of $\mathbf{g}(-\boldsymbol{\varepsilon}) = -\mathbf{g}(\boldsymbol{\varepsilon})$, and its mean, which exists, equals its negative.
- (d) *Consistency of the group variances.* Write $\mathbf{a} = \mathbf{M} \boldsymbol{\varepsilon}$, so $\hat{\boldsymbol{\varepsilon}}_g = \boldsymbol{\varepsilon}_g - \mathbf{a}_g$. By the weak law, $\|\boldsymbol{\varepsilon}_g\|^2/n_g \rightarrow \sigma_g^2$. Also $E\|\mathbf{a}\|^2 = \text{tr}(\mathbf{M} \boldsymbol{\Sigma}) \leq p \max_g \sigma_g^2$, so $\|\mathbf{a}_g\|^2/n_g \leq \|\mathbf{a}\|^2/n_g \rightarrow 0$ in probability. The triangle inequality $|\|\hat{\boldsymbol{\varepsilon}}_g\| - \|\boldsymbol{\varepsilon}_g\|| \leq \|\mathbf{a}_g\|$ gives $\hat{\sigma}_g^2 \rightarrow \sigma_g^2$, hence $\hat{w}_g = 1/\hat{\sigma}_g^2 \rightarrow w_g = 1/\sigma_g^2$.

Comparison. Put $\mathbf{A}_n(\mathbf{v}) = n^{-1} \sum_g v_g \mathbf{X}_g^\top \mathbf{X}_g$ for weights $\mathbf{v} = (v_1, \dots, v_G)$, and $\mathbf{b}_g = n^{-1/2} \mathbf{X}_g^\top \boldsymbol{\varepsilon}_g$. Then

$$\sqrt{n}(\hat{\boldsymbol{\beta}}_{\hat{\mathbf{W}}} - \boldsymbol{\beta}) = \mathbf{A}_n(\hat{\mathbf{w}})^{-1} \sum_g \hat{w}_g \mathbf{b}_g,$$

$$\sqrt{n}(\hat{\boldsymbol{\beta}}_W - \boldsymbol{\beta}) = \mathbf{A}_n(\mathbf{w})^{-1} \sum_g w_g \mathbf{b}_g.$$

Each $\mathbf{b}_g$ has mean zero and $E\|\mathbf{b}_g\|^2 = \sigma_g^2 \text{tr}(n^{-1} \mathbf{X}_g^\top \mathbf{X}_g)$, which is bounded, so $\mathbf{b}_g = O_p(1)$. Both $\mathbf{A}_n(\hat{\mathbf{w}})$ and $\mathbf{A}_n(\mathbf{w})$ converge in probability to $\mathbf{A}_w$, which is invertible, and matrix inversion is continuous there. The difference of the two displays is

$$\{\mathbf{A}_n(\hat{\mathbf{w}})^{-1} - \mathbf{A}_n(\mathbf{w})^{-1}\} \sum_g \hat{w}_g \mathbf{b}_g + \mathbf{A}_n(\mathbf{w})^{-1} \sum_g (\hat{w}_g - w_g) \mathbf{b}_g,$$

a sum of products of $o_p(1)$ and $O_p(1)$ terms, so it is $o_p(1)$. Finally $n(\mathbf{X}^\top \hat{\mathbf{W}} \mathbf{X})^{-1} =$

Figure 21.3.1: Feasible weighted least squares with m replicates at each of ten design points and standard deviation proportional to x (20,000 simulated data sets for each m). (a) Variance of the slope estimate relative to weighted least squares with the true weights. (b) Coverage of the nominal 95% interval computed as if the within-group weights were known.

$$\mathbf{A}_n(\hat{\mathbf{w}})^{-1} \rightarrow \mathbf{A}_w^{-1}, \text{ and } n(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} = \mathbf{A}_n(\mathbf{w})^{-1} \rightarrow \mathbf{A}_w^{-1}.$$

Part (c) is exact but covers only weights computed from the least squares residuals, not those computed from fitted values ([Exercise \(B3\)](#)). Part (d) says that with enough replicates estimating the weights costs nothing in large samples. The scaled errors $\sqrt{n}(\hat{\beta}_{\hat{W}} - \beta)$ and $\sqrt{n}(\hat{\beta}_W - \beta)$ differ by $o_p(1)$, so whatever limiting distribution the optimal estimator has, the feasible one has the same; it is normal when, for instance, the rows of $\mathbf{X}$ are bounded, by [Lemma 21.2.1\(a\)](#) applied within each group. The model-based covariance estimate is consistent as well. Carroll and Ruppert (1988) prove the same conclusion for smooth parametric variance functions, including functions of the mean, under conditions we do not reproduce. What (d) does not say is how many replicates are “enough”. A simulation shows that the answer can be surprisingly many.

Example. (Weights from a few replicates)

Take ten design points $x = 1, \dots, 10$, m replicates at each, a straight-line mean, and normal errors with standard deviation proportional to x . [Figure 21.3.1](#) compares four slope estimates by their variance relative to weighted least squares with the true weights. Ordinary least squares has 2.44 times the optimal variance when $m = 2$, and about the same for every m . Weights $1/s_g^2$ from the within-group sample variances are a disaster for small groups: with $m = 2$ their variance is 5.44 times the optimum, twice that of the unweighted fit, and with $m = 3$ it is still 2.67, worse than no weighting. They approach the optimum only slowly (1.22 for $m = 10$, 1.05 for $m = 30$). Worse, the model-based interval, which treats the estimated weights as known, covers the true slope in only 0.47 of the data sets for $m = 2$, 0.65 for $m = 3$ and 0.80 for $m = 5$. Weights from a fitted variance function, the regression of $\log s_g^2$ on $\log x_g$, are far better: 1.41 times the optimum for $m = 2$, 1.12 for $m = 3$ and 1.04 for $m = 5$.

    rel, cover = replicate_study(m, 2000)
    print(f"m = {m:2d}: variance relative to WLS  OLS {rel[0]:.2f} "
          f"group weights {rel[2]:.2f}  fitted weights {rel[3]:.2f}; "
          f"coverage {cover:.2f}")

```

The failure of the group weights has a simple cause. With $m = 2$ each s_g^2 is $\sigma_g^2 \chi^2(1)$, which is often tiny, and $1/s_g^2$ then gives one group an enormous weight on the strength of two nearly equal responses. In fact $E(1/s_g^2) = \infty$ (Exercise (C1)). A fitted variance function pools the information from all groups into a few parameters and cannot be fooled by one lucky pair. The general lessons are to estimate a smooth variance function whenever possible, and to report feasible weighted estimates with standard errors that do not depend on the variance model being right. Part (b) of the theorem shows what those are: the sandwich form with Σ estimated from the residuals, which is the subject of the next section.

21.3.4 Exercises

21.3.4.1 A. Check your understanding

Exercise A1.

Under [Theorem 21.3.1\(a\)](#), show that $E \sum_i w_i (Y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_W)^2 = \sigma^2(n - p)$, and that the raw residual $Y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_W$ has variance $\sigma^2(1 - g_{ii})/w_i$, where g_{ii} is the i th leverage of the weighted fit.

Exercise A2.

A laboratory reports only the mean $\bar{y}_i$ of m_i replicate measurements at each of k settings $\mathbf{x}_{(i)}$, where the individual measurements have common variance σ^2 . Which weights should be used? What does s_w^2 then estimate, and why is it not the replicate variance σ^2 unless the model for the means is correct?

21.3.4.2 B. Practice**Exercise B1.**

In the model $y_i = \beta x_i + \varepsilon_i$ with $x_i > 0$ and $\text{Var}(\varepsilon_i) = \sigma^2 x_i^2$, show that the weighted estimate is the mean of the ratios y_i/x_i , and that the efficiency of ordinary least squares relative to it is $(\sum_i x_i^2)^2 / (n \sum_i x_i^4) \leq 1$. Evaluate the efficiency for $x = 1, \dots, 10$.

Solution. With $w_i = x_i^{-2}$, $\hat{\beta}_W = \sum_i w_i x_i y_i / \sum_i w_i x_i^2 = n^{-1} \sum_i y_i / x_i$, with variance σ^2/n . Ordinary least squares gives $\sum_i x_i y_i / \sum_i x_i^2$, with variance $\sigma^2 \sum_i x_i^4 / (\sum_i x_i^2)^2$. The ratio is $(\sum_i x_i^2)^2 / (n \sum_i x_i^4)$, at most one by the Cauchy–Schwarz inequality applied to the vectors (x_i^2) and (1) . For $x = 1, \dots, 10$, $\sum x_i^2 = 385$ and $\sum x_i^4 = 25,333$, so the efficiency is $148,225/253,330 = 0.585$.

Exercise B2.

Some programs implement integer weights w_i by repeating row i of the data w_i times and running ordinary least squares. Show that this gives the correct $\hat{\boldsymbol{\beta}}_W$ but divides the weighted residual sum of squares by $\sum_i w_i - p$ instead of $n - p$. Which standard errors are then wrong, and in which direction?

Exercise B3.

Weights $\hat{w}_i = |\hat{Y}_i|^{-2\theta}$ depend on the fitted values. Show that they are not functions of $\hat{\boldsymbol{\varepsilon}}$ alone, and find where the symmetry argument of [Theorem 21.3.1\(c\)](#) fails. What happens for a single regressor through the origin, $Y_i = \beta x_i + \varepsilon_i$ with every $x_i \neq 0$?

Solution. $\hat{\mathbf{Y}} = \mathbf{X}\boldsymbol{\beta} + \mathbf{M}\boldsymbol{\varepsilon}$ depends on $\boldsymbol{\beta}$, and replacing $\boldsymbol{\varepsilon}$ by $-\boldsymbol{\varepsilon}$ turns it into $\mathbf{X}\boldsymbol{\beta} - \mathbf{M}\boldsymbol{\varepsilon}$, which does not have the same absolute entries. So $\hat{\mathbf{W}}$ is not an even function of $\boldsymbol{\varepsilon}$, and $\mathbf{g}(-\boldsymbol{\varepsilon}) \neq -\mathbf{g}(\boldsymbol{\varepsilon})$ in general. The feasible estimate then need not be unbiased in finite samples, and the argument of [Theorem 21.3.1\(c\)](#) gives no guarantee.

The single regressor through the origin is an exception. There $\hat{Y}_i = \hat{\beta} x_i$, so $\hat{w}_i = |\hat{\beta}|^{-2\theta} |x_i|^{-2\theta}$ whenever $\hat{\beta} \neq 0$, an event of probability one for continuously distributed errors. The random factor $|\hat{\beta}|^{-2\theta}$ is common to all the weights and cancels from $\hat{\beta}_{\hat{\mathbf{W}}} =$

$\sum_i \hat{w}_i x_i Y_i / \sum_i \hat{w}_i x_i^2$. So the feasible estimate equals weighted least squares with the fixed weights $|x_i|^{-2\theta}$. It is unbiased by [Theorem 21.3.1\(b\)](#), and if $\text{Var}(\varepsilon_i)$ is proportional to $|x_i|^{2\theta}$ it is the best linear unbiased estimator by [Theorem 21.3.1\(a\)](#); for $\theta = 1$ this is the ratio-type case of variance proportional to x_i^2 . With two or more regressors the ratios $\hat{w}_i/\hat{w}_j = |\hat{Y}_j/\hat{Y}_i|^{2\theta}$ depend on the data, and the argument fails again.

21.3.4.3 C. Going deeper

Exercise C1.

Show that $E(1/U) = \infty$ if $U \sim \chi^2(1)$, and that $E(1/U) = 1/(k-2)$ if $U \sim \chi^2(k)$ with $k \geq 3$. Explain what this implies for weights $1/s_g^2$ computed from m replicates.

Solution. The density of $\chi^2(k)$ is proportional to $u^{k/2-1}e^{-u/2}$, so $E(1/U)$ is proportional to $\int_0^\infty u^{k/2-2}e^{-u/2} du$, which diverges at zero when $k/2 - 2 \leq -1$, that is, for $k \leq 2$. For $k \geq 3$ the integral is a gamma integral and gives $E(1/U) = \Gamma(k/2 - 1)/\{2\Gamma(k/2)\} = 1/(k-2)$. With m normal replicates, $(m-1)s_g^2/\sigma_g^2 \sim \chi^2(m-1)$, so $1/s_g^2$ has infinite mean for $m \leq 3$ and mean $(m-1)/\{(m-3)\sigma_g^2\}$ for $m \geq 4$. The group weights are both inflated and wildly variable in small groups.

21.4 Heteroscedasticity-consistent covariance estimators

Weighting needs a model for the variances. Often there is none worth trusting, and the analyst would rather keep ordinary least squares, which is unbiased whatever the variances are, and fix its standard errors. The covariance of $\hat{\beta}$ under $\text{Cov}(\varepsilon) = \Sigma = \text{diag}(\sigma_1^2, \dots, \sigma_n^2)$ is

$$\text{Cov}(\hat{\beta}) = (\mathbf{X}^\top \mathbf{X})^{-1} \left(\sum_{i=1}^n \sigma_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right) (\mathbf{X}^\top \mathbf{X})^{-1} \quad (21.4.1)$$

This is the covariance given by [Theorem 19.2.2](#). The n variances cannot be estimated, one observation each. The idea of Eicker (1963), Huber (1967) and White (1980) is that they do not need to be. Only the $p \times p$ matrix in the middle is needed, and a sum of n terms can be estimated consistently even when its terms cannot. The matrix is sandwiched between two copies of $(\mathbf{X}^\top \mathbf{X})^{-1}$, which gives the estimators their name.

21.4.1 The estimators

Definition 21.4.1 — Heteroscedasticity-consistent covariance estimators

Let $\hat{\varepsilon}_i$ and h_{ii} be the least squares residuals and leverages, with $h_{ii} < 1$. For weights ω_i ,

put

$$\hat{\mathbf{V}}_{\omega} = (\mathbf{X}^{\top} \mathbf{X})^{-1} \left(\sum_{i=1}^n \omega_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^{\top} \right) (\mathbf{X}^{\top} \mathbf{X})^{-1}.$$

The estimators **HC0** to **HC3** take

$$\omega_i = \hat{\varepsilon}_i^2, \quad \frac{n}{n-p} \hat{\varepsilon}_i^2, \quad \frac{\hat{\varepsilon}_i^2}{1-h_{ii}}, \quad \frac{\hat{\varepsilon}_i^2}{(1-h_{ii})^2}.$$

HC0 is White's estimator. HC1 applies the degrees-of-freedom correction of s^2 . HC2 and HC3, proposed by MacKinnon and White (1985), correct each squared residual for its own leverage. Their finite-sample properties follow from [Eq. 21.2.1](#) and from the deletion formulas of [Chapter 10](#).

Proposition 21.4.1 — Finite-sample properties

Let $\boldsymbol{\lambda} \in \mathbb{R}^p$ and $\mathbf{c} = \mathbf{X}(\mathbf{X}^{\top} \mathbf{X})^{-1} \boldsymbol{\lambda}$, so that $\boldsymbol{\lambda}^{\top} \hat{\boldsymbol{\beta}} - \boldsymbol{\lambda}^{\top} \boldsymbol{\beta} = \mathbf{c}^{\top} \boldsymbol{\varepsilon}$ and $\boldsymbol{\lambda}^{\top} \hat{\mathbf{V}}_{\omega} \boldsymbol{\lambda} = \sum_i c_i^2 \omega_i$.

- (a) Under constant variance σ^2 , $E(\boldsymbol{\lambda}^{\top} \hat{\mathbf{V}}_{\text{HC2}} \boldsymbol{\lambda}) = \text{Var}(\boldsymbol{\lambda}^{\top} \hat{\boldsymbol{\beta}})$, while $E(\boldsymbol{\lambda}^{\top} \hat{\mathbf{V}}_{\text{HC0}} \boldsymbol{\lambda}) = \text{Var}(\boldsymbol{\lambda}^{\top} \hat{\boldsymbol{\beta}}) - \sigma^2 \sum_i c_i^2 h_{ii} \leq \text{Var}(\boldsymbol{\lambda}^{\top} \hat{\boldsymbol{\beta}})$ and $E(\boldsymbol{\lambda}^{\top} \hat{\mathbf{V}}_{\text{HC3}} \boldsymbol{\lambda}) \geq \text{Var}(\boldsymbol{\lambda}^{\top} \hat{\boldsymbol{\beta}})$.
- (b) In general, $E(\boldsymbol{\lambda}^{\top} \hat{\mathbf{V}}_{\text{HC0}} \boldsymbol{\lambda}) = \sum_i c_i^2 \sum_j (\mathbf{I} - \mathbf{M})_{ij}^2 \sigma_j^2$.
- (c) $\hat{\mathbf{V}}_{\text{HC0}} \preceq \hat{\mathbf{V}}_{\text{HC2}} \preceq \hat{\mathbf{V}}_{\text{HC3}}$ in the order of nonnegative definiteness.
- (d) $\hat{\mathbf{V}}_{\text{HC3}} = \sum_{i=1}^n (\hat{\boldsymbol{\beta}}_{(i)} - \hat{\boldsymbol{\beta}})(\hat{\boldsymbol{\beta}}_{(i)} - \hat{\boldsymbol{\beta}})^{\top}$, where $\hat{\boldsymbol{\beta}}_{(i)}$ is the estimate with observation i deleted.

Proof.

- (a) and (b). $E \hat{\varepsilon}_i^2 = \sum_j (\mathbf{I} - \mathbf{M})_{ij}^2 \sigma_j^2$ by [Eq. 21.2.1](#), which proves (b). Under constant variance it is $\sigma^2(1-h_{ii})$, so the HC2 weights have expectation σ^2 and $E \sum_i c_i^2 \omega_i = \sigma^2 \|\mathbf{c}\|^2 = \text{Var}(\mathbf{c}^{\top} \boldsymbol{\varepsilon})$. The HC0 weights have expectation $\sigma^2(1-h_{ii})$ and the HC3 weights $\sigma^2/(1-h_{ii}) \geq \sigma^2$.
- (b) The HC weights satisfy $\hat{\varepsilon}_i^2 \leq \hat{\varepsilon}_i^2/(1-h_{ii}) \leq \hat{\varepsilon}_i^2/(1-h_{ii})^2$ term by term, and each difference $\hat{\mathbf{V}}_{\omega'} - \hat{\mathbf{V}}_{\omega}$ with $\omega'_i \geq \omega_i$ is $(\mathbf{X}^{\top} \mathbf{X})^{-1} \{ \sum_i (\omega'_i - \omega_i) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^{\top} \} (\mathbf{X}^{\top} \mathbf{X})^{-1}$, a nonnegative definite matrix.
- (c) By [Proposition 10.6.2\(a\)](#), $\hat{\boldsymbol{\beta}}_{(i)} - \hat{\boldsymbol{\beta}} = -(\mathbf{X}^{\top} \mathbf{X})^{-1} \mathbf{x}_{(i)} \hat{\varepsilon}_i / (1-h_{ii})$. The sum of the outer products of these vectors is $\hat{\mathbf{V}}_{\text{HC3}}$. ■

Part (d) says that HC3 measures how much the estimate moves when single observations are left out. This is the jackknife idea: the variability of an estimate is judged from its sensitivity to the data, not from a model for the errors. Part (a) makes HC0 biased downward when the model is right, and the bias is concentrated where $c_i^2 h_{ii}$ is large, at high-leverage points that dominate the coefficient. Part (b) shows the same effect under heteroscedasticity: a high-leverage observation's squared residual understates its own variance, precisely when that variance matters most.

      np.allclose(jack, covs["HC3"]))

```

Example. (Standard errors for Engel's slope)

For the least squares slope of food expenditure on income, the classical standard error $s\{(\mathbf{X}^\top \mathbf{X})^{-1}\}_{22}^{1/2}$ is 0.0144. The heteroscedasticity-consistent standard errors are 0.0518 (HC0), 0.0520 (HC1), 0.0585 (HC2) and 0.0664 (HC3). The classical value is too small by a factor of 4.6 relative to HC3. Evidently the high-income households, which pin down the slope, are the noisy ones, so the classical formula, which averages the noise over all households, understates the uncertainty. The second listing above checks the jackknife identity of [Proposition 21.4.1\(d\)](#).

21.4.2 Consistency

The estimators are justified by a large-sample argument. We give it under simple conditions that make every step elementary: bounded regressors, errors with bounded fourth moments, and variances bounded away from zero. The theorem covers every $\hat{\mathbf{V}}_\omega$ of [Definition 21.4.1](#).

Theorem 21.4.2 — Consistency of the sandwich estimators

Let $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with p fixed. Assume that

- (H1) the errors are independent with mean zero and variances σ_i^2 , with $\sigma_i^2 \geq \sigma_{\min}^2 > 0$ and $E\varepsilon_i^4 \leq K$ for all i ;
- (H2) the rows satisfy $\|\mathbf{x}_{(i)}\| \leq C$ for all i ;
- (H3) $n^{-1}\mathbf{X}^\top\mathbf{X} \rightarrow \mathbf{A}$, a positive definite matrix.

Let $\hat{\mathbf{V}}$ be any of HC0–HC3, and $\mathbf{V} = \text{Cov}(\hat{\boldsymbol{\beta}})$ as in Eq. 21.4.1. Then:

- (a) $n(\hat{\mathbf{V}} - \mathbf{V}) \rightarrow \mathbf{0}$ in probability;
- (b) for every fixed $\boldsymbol{\lambda} \neq \mathbf{0}$, $(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}} - \boldsymbol{\lambda}^\top \boldsymbol{\beta})/(\boldsymbol{\lambda}^\top \hat{\mathbf{V}} \boldsymbol{\lambda})^{1/2} \rightarrow N(0, 1)$ in distribution;
- (c) for every fixed $p \times q$ matrix $\boldsymbol{\Lambda}$ of rank q ,

$$W = (\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}} - \boldsymbol{\Lambda}^\top \boldsymbol{\beta})^\top (\boldsymbol{\Lambda}^\top \hat{\mathbf{V}} \boldsymbol{\Lambda})^{-1} (\boldsymbol{\Lambda}^\top \hat{\boldsymbol{\beta}} - \boldsymbol{\Lambda}^\top \boldsymbol{\beta})$$

tends to $\chi^2(q)$ in distribution.

Proof. Write $\mathbf{G}_n = n^{-1}\mathbf{X}^\top\mathbf{X}$, and let $\mathbf{B}_n = n^{-1} \sum_i \sigma_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ and $\hat{\mathbf{B}}_n = n^{-1} \sum_i \omega_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ be the true and estimated middle matrices, so that $n\mathbf{V} = \mathbf{G}_n^{-1} \mathbf{B}_n \mathbf{G}_n^{-1}$ and $n\hat{\mathbf{V}} = \mathbf{G}_n^{-1} \hat{\mathbf{B}}_n \mathbf{G}_n^{-1}$. Note $\sigma_i^2 \leq (E\varepsilon_i^4)^{1/2} \leq K^{1/2}$. By (H3), $\mathbf{G}_n^{-1} \rightarrow \mathbf{A}^{-1}$, and $\lambda_{\min}(\mathbf{X}^\top\mathbf{X}) \geq cn$ for some $c > 0$ and all large n .

Step 1: $\hat{\boldsymbol{\beta}}$ is consistent. $E\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 = \text{tr } \mathbf{V} \leq K^{1/2} \text{tr}(\mathbf{X}^\top\mathbf{X})^{-1} \leq K^{1/2}p/(cn) \rightarrow 0$.

Step 2: the errors estimate the middle. Each entry of $n^{-1} \sum_i (\varepsilon_i^2 - \sigma_i^2) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ is a sum of independent mean-zero terms with variance at most $n^{-2} \sum_i KC^4 = KC^4/n$, so it tends to zero in probability by Chebyshev's inequality.

Step 3: the residuals estimate the middle. Let $d_i = \mathbf{x}_{(i)}^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})$, so $\hat{\varepsilon}_i = \varepsilon_i - d_i$ and $|d_i| \leq C\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|$. Then, in the spectral norm,

$$\begin{aligned} \left\| n^{-1} \sum_i (\hat{\varepsilon}_i^2 - \varepsilon_i^2) \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right\| &\leq \frac{C^2}{n} \sum_i (d_i^2 + 2|d_i||\varepsilon_i|) \\ &\leq C^4 \|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 + 2C^3 \|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\| \frac{1}{n} \sum_i |\varepsilon_i|, \end{aligned}$$

which tends to zero because $\hat{\boldsymbol{\beta}} - \boldsymbol{\beta} = o_p(1)$ and $E n^{-1} \sum_i |\varepsilon_i| \leq K^{1/4}$. With Step 2, $\hat{\mathbf{B}}_n - \mathbf{B}_n \rightarrow \mathbf{0}$ for HC0.

Step 4: the leverage corrections vanish. $h_{ii} \leq C^2/\lambda_{\min}(\mathbf{X}^\top\mathbf{X}) \leq C^2/(cn)$, so $\delta_n = (1 - \max_i h_{ii})^{-2} - 1 \rightarrow 0$. For HC1–HC3, $\hat{\varepsilon}_i^2 \leq \omega_i \leq (1 + \delta_n)\varepsilon_i^2$ for large n (with δ_n replaced by $p/(n-p)$ for HC1), so $\mathbf{0} \leq \hat{\mathbf{B}}_n - \hat{\mathbf{B}}_n^{\text{HC0}} \leq \delta_n \hat{\mathbf{B}}_n^{\text{HC0}}$, which tends to zero because $\delta_n \rightarrow 0$ and $\hat{\mathbf{B}}_n^{\text{HC0}} = \mathbf{B}_n + o_p(1)$ is bounded in probability, since $\mathbf{0} \leq \mathbf{B}_n \leq K^{1/2}\mathbf{G}_n$ and $\mathbf{G}_n$ converges. This proves (a), since $n(\hat{\mathbf{V}} - \mathbf{V}) = \mathbf{G}_n^{-1}(\hat{\mathbf{B}}_n - \mathbf{B}_n)\mathbf{G}_n^{-1}$.

- (c) Let $\mathbf{V}_\Lambda = \boldsymbol{\Lambda}^\top \mathbf{V} \boldsymbol{\Lambda}$ and $\mathbf{T}_n = \mathbf{V}_\Lambda^{-1/2} \boldsymbol{\Lambda}^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})$, so that $\text{Cov}(\mathbf{T}_n) = \mathbf{I}_q$. For fixed $\mathbf{a} \in \mathbb{R}^q$, $\mathbf{a}^\top \mathbf{T}_n = \mathbf{c}^\top \boldsymbol{\varepsilon}$ with $\mathbf{c} = \mathbf{X}(\mathbf{X}^\top\mathbf{X})^{-1}\boldsymbol{\lambda}$ and $\boldsymbol{\lambda} = \boldsymbol{\Lambda} \mathbf{V}_\Lambda^{-1/2} \mathbf{a}$. By the Cauchy–Schwarz inequality in the metric $(\mathbf{X}^\top\mathbf{X})^{-1}$, $c_i^2 \leq h_{ii}\|\mathbf{c}\|^2$, so $\max_i c_i^2/\|\mathbf{c}\|^2 \leq$

$\max_i h_{ii} \rightarrow 0$. [Lemma 21.2.1](#)(b), with $\delta = 2$, shows that $\mathbf{a}^\top \mathbf{T}_n / \|\mathbf{a}\| \rightarrow N(0, 1)$ for $\mathbf{a} \neq \mathbf{0}$. By the Cramér–Wold device, $\mathbf{T}_n \rightarrow N_q(\mathbf{0}, \mathbf{I}_q)$. Next, $n\mathbf{V}_\Lambda = \mathbf{\Lambda}^\top \mathbf{G}_n^{-1} \mathbf{B}_n \mathbf{G}_n^{-1} \mathbf{\Lambda} \succeq \sigma_{\min}^2 \mathbf{\Lambda}^\top \mathbf{G}_n^{-1} \mathbf{\Lambda}$, whose limit $\sigma_{\min}^2 \mathbf{\Lambda}^\top \mathbf{A}^{-1} \mathbf{\Lambda}$ is positive definite; and $n\mathbf{V}_\Lambda$ is bounded because $\mathbf{B}_n \preceq K^{1/2} \mathbf{G}_n$. So $(n\mathbf{V}_\Lambda)^{-1/2}$ is bounded, and by (a)

$$\begin{aligned} \mathbf{V}_\Lambda^{-1/2} (\mathbf{\Lambda}^\top \hat{\mathbf{V}} \mathbf{\Lambda}) \mathbf{V}_\Lambda^{-1/2} &= \mathbf{I}_q + (n\mathbf{V}_\Lambda)^{-1/2} \mathbf{\Lambda}^\top \\ &\quad \times n(\hat{\mathbf{V}} - \mathbf{V}) \mathbf{\Lambda} (n\mathbf{V}_\Lambda)^{-1/2} \rightarrow \mathbf{I}_q. \end{aligned}$$

Since $W = \mathbf{T}_n^\top \{ \mathbf{V}_\Lambda^{-1/2} (\mathbf{\Lambda}^\top \hat{\mathbf{V}} \mathbf{\Lambda}) \mathbf{V}_\Lambda^{-1/2} \}^{-1} \mathbf{T}_n$, continuous mapping and Slutsky’s lemma give $W \rightarrow \mathbf{T}^\top \mathbf{T}$ with $\mathbf{T} \sim N_q(\mathbf{0}, \mathbf{I}_q)$, which is $\chi^2(q)$. Part (b) is the case $q = 1$, with the sign kept. ■

The theorem does not assume that the errors are normal, that their variances follow any model, or that they are identically distributed. It does assume independence, which the next two sections relax. The bounded regressors of (H2) are stronger than needed. Eicker (1967) and White (1980) replace them by conditions that amount to $\max_i h_{ii} \rightarrow 0$ together with moment bounds, and White’s version allows random regressors drawn independently from a common distribution, which covers most observational data. We do not prove these extensions.

In practice the statistic in (b) is compared with the $t(n-p)$ distribution rather than the normal. That choice has no exact justification, but it costs nothing asymptotically and helps in small samples. A heteroscedasticity-robust test of $\mathbf{\Lambda}^\top \boldsymbol{\beta} = \mathbf{d}$ compares W/q with $F(q, n-p)$.

21.4.3 Finite-sample behaviour

Consistency says nothing about how large n must be. The answer depends on the leverages, as [Proposition 21.4.1](#) suggests, and it can be sobering.

Example. (Coverage in a skewed design)

Let the regressor values be the n quantiles $x_i = \exp\{\Phi^{-1}((i-1/2)/n)\}$ of a standard lognormal distribution, a design with a long right tail like incomes. The largest leverage is 0.58 for $n = 25$ and still 0.15 for $n = 1000$. [Figure 21.4.1](#) shows the coverage of nominal 95% intervals for the slope, with normal errors, over 20,000 simulated data sets for each n .

With constant variance (panel a) the classical interval is exact, and the robust intervals pay a price for their robustness: at $n = 25$ they cover 0.852 (HC0), 0.866 (HC1), 0.895 (HC2) and 0.932 (HC3). With standard deviation proportional to x (panel b) the classical interval fails badly. Its coverage is 0.456 at $n = 25$ and falls to 0.287 at $n = 1000$, because the growing right tail of the design gives ever more influence to the noisiest observations. The robust intervals improve with n , but slowly. At $n = 25$ they cover 0.631 (HC0), 0.650 (HC1), 0.760 (HC2) and 0.853 (HC3); at $n = 1000$, 0.912, 0.912, 0.924 and 0.935. HC3 is the best of the four throughout, as Long and Ervin (2000) found in a wide range of designs.

```
rng = np.random.default_rng(2107)
```

Figure 21.4.1: Coverage of nominal 95% intervals for the slope in a design with lognormal quantiles as regressor values. (a) Constant error variance. (b) Error standard deviation proportional to x . HC1 is omitted; it lies just above HC0.

```
def coverage(n, hetero, reps):
    """Coverage of nominal 95% slope intervals, classical and HC0-HC3."""
    # lognormal quantiles
    x = np.exp(stats.norm.ppf((np.arange(1, n + 1) - 0.5) / n))
    Xs = np.column_stack([np.ones(n), x])
    Qs, Rs = np.linalg.qr(Xs)
    hs = np.sum(Qs**2, axis=1)
    # slope estimate - slope = c @ errors
    c = Qs @ np.linalg.inv(Rs).T[:, 1]
    E = rng.normal(size=(reps, n)) * (x if hetero else 1.0)
    err = E @ c
    res = E - (E @ Qs) @ Qs.T
    var = {"classical": (res**2).sum(axis=1) / (n - 2) * (c @ c),
          "HC0": (res**2) @ c**2,
          "HC1": (res**2) @ c**2 * n / (n - 2),
          "HC2": (res**2 / (1 - hs)) @ c**2,
          "HC3": (res**2 / (1 - hs) ** 2) @ c**2}
    q = stats.t.ppf(0.975, n - 2)
    cover = {k: np.mean(np.abs(err) <= q * np.sqrt(v)) for k, v in var.items()}
    return cover, hs.max()

for n_sim in (25, 100, 400):
    cov, hmax = coverage(n_sim, hetero=True, reps=2000)
    print(f"n = {n_sim:3d} (max leverage {hmax:.2f}):",
          {k: round(v, 3) for k, v in cov.items()})
```

21.4.4 Leverage and the sandwich

The poor small-sample behaviour has a simple source. The variance estimate $\sum_i c_i^2 \omega_i$ is a weighted sum of squared residuals, and when a few weights c_i^2 dominate, it behaves like a variance estimate with very few degrees of freedom, however large n is. A $t(n-p)$ reference distribution then has tails that are far too light.

Example. (One household carries the standard error)

In Engel's data the household with the largest income has leverage 0.255. Its term $c_i^2 \hat{\varepsilon}_i^2 / (1 - h_{ii})^2$ makes up 0.85 of the HC3 variance of the slope. The robust standard error of [Example \(Standard errors for Engel's slope\)](#) is, in effect, an estimate of one household's error variance. That is not a reason to go back to the classical standard error, which is far worse. It is a reason to look at that household (the influence measures of [Chapter 20](#), such as [Definition 20.4.1](#), are the tools), to report how the conclusions change without it, and to prefer weighting, which here gives that household much less influence ([Example \(Engel's data, reweighted\)](#)).

Several refinements address the degrees-of-freedom problem. Bell and McCaffrey's (2002) adjustment, as recommended by Imbens and Kolesár (2016), combines HC2 with a Satterthwaite approximation to the degrees of freedom of $\sum_i c_i^2 \omega_i$. The wild bootstrap of [Chapter 23](#) ([Definition 23.2.1](#)) resamples the residuals with random signs, keeping each one attached to its own row, and often gives better calibrated intervals than any of the HC formulas.

21.4.5 Exercises

21.4.5.1 A. Check your understanding

Exercise A1.

Take the two-group model $y_{gj} = \mu_g + \varepsilon_{gj}$, $g = 1, 2$, $j = 1, \dots, n_g$. Show that HC2 for $\hat{\mu}_1 - \hat{\mu}_2$ equals $s_1^2/n_1 + s_2^2/n_2$, the variance estimate of Welch's test, where s_g^2 is the sample variance of group g . What does HC0 give?

Solution. Here $h_{ii} = 1/n_g$, $\hat{\varepsilon}_{gj} = y_{gj} - \bar{y}_g$, and $\mathbf{c}$ has entries $1/n_1$ in group 1 and $-1/n_2$ in group 2. HC2 is $\sum_g \sum_j \hat{\varepsilon}_{gj}^2 / \{(1 - 1/n_g)n_g\} = \sum_g \sum_j (y_{gj} - \bar{y}_g)^2 / \{(n_g - 1)n_g\} = \sum_g s_g^2/n_g$. HC0 gives $\sum_g (n_g - 1)s_g^2/n_g^2$, which is smaller.

Exercise A2.

What happens to HC0, HC2 and HC3 if some observation has $h_{ii} = 1$? Explain why no estimator built from residuals can estimate that observation's contribution to $\text{Var}(\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}})$.

21.4.5.2 B. Practice

Exercise B1.

In simple regression with an intercept and constant variance, show that the relative bias of HC0 for the slope variance is $-\sum_i (x_i - \bar{x})^2 h_{ii} / S_{xx}$. Evaluate it for $x = (1, 2, 3, 4, 10)$ of [Exercise \(A1\)](#).

Solution. For the slope, $c_i = (x_i - \bar{x}) / S_{xx}$ and $\|\mathbf{c}\|^2 = 1/S_{xx}$, so [Proposition 21.4.1\(a\)](#) gives relative bias $-\sum_i c_i^2 h_{ii} / \|\mathbf{c}\|^2 = -\sum_i (x_i - \bar{x})^2 h_{ii} / S_{xx}$. With $S_{xx} = 50$ and the leverages $(0.38, 0.28, 0.22, 0.20, 0.92)$, the sum is $9(0.38) + 4(0.28) + 1(0.22) + 0 + 36(0.92) =$

37.88, and the relative bias is $-37.88/50 = -0.76$. HC0 estimates the slope variance at a quarter of its true value, on average, because the point $x = 10$ dominates the slope and has a tiny residual.

Exercise B2.

Using [Theorem 21.3.1\(b\)](#), write down a sandwich estimator of the covariance of a weighted least squares estimate with fixed weights $\mathbf{W}$, and show that it reduces to HC0 applied to the rescaled data $(\mathbf{W}^{1/2}\mathbf{X}, \mathbf{W}^{1/2}\mathbf{y})$.

Exercise B3.

White's test compares $s^2\mathbf{X}^\top\mathbf{X}$ with $\sum_i \hat{\varepsilon}_i^2 \mathbf{x}_{(i)}\mathbf{x}_{(i)}^\top$. Show that the difference of these matrices, divided by n , has entries $n^{-1} \sum_i (\hat{\varepsilon}_i^2 - s^2) x_{ij}x_{ik}$, and explain why Koenker's statistic with $\mathbf{z}_i$ the distinct products $x_{ij}x_{ik}$ tests whether these are jointly zero.

21.4.5.3 C. Going deeper

Exercise C1.

Suppose the rows $(\mathbf{x}_{(i)}, \varepsilon_i)$ are independent copies of a random pair with $E(\varepsilon | \mathbf{x}) = 0$, $E\|\mathbf{x}\|^4 < \infty$, $E\varepsilon^4 < \infty$ and $E\mathbf{x}\mathbf{x}^\top$ positive definite. Adapt the proof of [Theorem 21.4.2](#) to show that HC0 is consistent in the sense of part (a), replacing Chebyshev's inequality by the weak law of large numbers.

Exercise C2.

The usual jackknife variance is $\frac{n-1}{n} \sum_i (\hat{\beta}_{(i)} - \mathbf{m})(\hat{\beta}_{(i)} - \mathbf{m})^\top$, where $\mathbf{m}$ is the mean of the $\hat{\beta}_{(i)}$. Express it in terms of $\hat{\mathbf{V}}_{\text{HC3}}$ and the vector $\sum_i \mathbf{x}_{(i)} \hat{\varepsilon}_i / (1 - h_{ii})$, and show that the two agree to first order when $\max_i h_{ii} \rightarrow 0$.

21.5 Serial correlation and the Durbin–Watson test

When observations are taken in sequence, over time or along a transect, neighbouring errors are often alike. A shock to the economy lasts more than one quarter, a drifting instrument affects consecutive readings, and a variable missing from the model usually changes slowly, so its effect appears in the errors as a slow wave. Errors that are correlated with their neighbours are **serially correlated** or **autocorrelated**. As with heteroscedasticity, least squares stays unbiased and its usual standard errors become wrong ([Theorem 19.2.2](#)). The error is typically in the dangerous direction: with positive autocorrelation and a slowly varying regressor, the true variance of a slope can be many times its nominal value. [Section 21.6](#) measures this. This section is about detection.

21.5.1 Looking at residuals in time order

Three displays are standard. The residuals plotted against time show runs of the same sign when the autocorrelation is positive, and rapid alternation when it is negative. The **lag plot** of $\hat{\varepsilon}_t$ against $\hat{\varepsilon}_{t-1}$ shows the lag-one dependence as a tilt. And the **residual autocorrelations**

$$r_k = \frac{\sum_{t=k+1}^n \hat{\varepsilon}_t \hat{\varepsilon}_{t-k}}{\sum_{t=1}^n \hat{\varepsilon}_t^2}, \quad k = 1, 2, \dots,$$

summarize dependence at each lag. Under the model the residuals are themselves slightly correlated, with covariance $\sigma^2(\mathbf{I} - \mathbf{M})$, so the r_k are not exactly centred at zero, but for large n they are approximately independent with standard deviation $n^{-1/2}$.

Example. (A quarterly Okun's-law regression)

Okun's law, named after the economist Arthur Okun, relates changes in unemployment to output growth. The statsmodels macroeconomic data give US quarterly series from 1959 to 2009. Regress the change in the unemployment rate (percentage points per quarter) on real GDP growth (percent, at an annual rate) for the $n = 202$ quarters from the second quarter of 1959. The fitted line is

$$\widehat{\Delta u}_t = 0.227 - 0.0671 g_t,$$

so unemployment is stable when output grows at about $0.227/0.0671 \approx 3.4$ percent a year, and each extra percentage point of growth lowers it by about 0.07 points per quarter. Figure 21.5.1(a,b) shows the residuals. They wander in long swings, and the lag plot tilts, with $r_1 = 0.300$.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats
from scipy.integrate import quad
from scipy.optimize import brentq

macro = sm.datasets.macrodatab.load_pandas().data
# change in unemployment rate
du = np.diff(macro["unemp"].to_numpy())
# GDP growth, % a year
growth = 400 * np.diff(np.log(macro["realgdp"].to_numpy()))
year = (macro["year"] + (macro["quarter"] - 1) / 4).to_numpy()[1:]
n = len(du)
X = np.column_stack([np.ones(n), growth])
beta, *_ = np.linalg.lstsq(X, du, rcond=None)
e = du - X @ beta
# Durbin-Watson statistic
d = np.sum(np.diff(e) ** 2) / np.sum(e ** 2)
# lag-one residual autocorrelation
r1 = np.sum(e[1:] * e[:-1]) / np.sum(e ** 2)
print(f"n = {n}, slope {beta[1]:.4f}, d = {d:.3f}, r1 = {r1:.3f}, "
      f"2(1 - r1) = {2 * (1 - r1):.3f}")
```

21.5.2 The Durbin–Watson statistic

Definition 21.5.1 — Durbin–Watson statistic

For residuals $\hat{\varepsilon}_1, \dots, \hat{\varepsilon}_n$ in time order,

$$d = \frac{\sum_{t=2}^n (\hat{\varepsilon}_t - \hat{\varepsilon}_{t-1})^2}{\sum_{t=1}^n \hat{\varepsilon}_t^2} = \frac{\hat{\mathbf{\varepsilon}}^\top \mathbf{A} \hat{\mathbf{\varepsilon}}}{\hat{\mathbf{\varepsilon}}^\top \hat{\mathbf{\varepsilon}}}, \quad \mathbf{A} = \mathbf{D}^\top \mathbf{D},$$

where $\mathbf{D}$ is the $(n-1) \times n$ first-difference matrix, with rows $(\dots, 0, -1, 1, 0, \dots)$.

Expanding the numerator gives $d = 2(1 - r_1) - (\hat{\varepsilon}_1^2 + \hat{\varepsilon}_n^2) / \sum_t \hat{\varepsilon}_t^2$, so $d \approx 2(1 - r_1)$. Values near 2 indicate no lag-one correlation, values towards 0 positive correlation, and values towards 4 negative correlation. For the Okun regression $d = 1.386$, against $2(1 - r_1) = 1.401$.

The matrix $\mathbf{A}$ is tridiagonal with diagonal $(1, 2, \dots, 2, 1)$ and off-diagonal entries -1 . Its spectrum is known exactly, and that is what makes the Durbin–Watson theory work.

Lemma 21.5.1 — Eigenvalues of the difference matrix

The eigenvalues of $\mathbf{A}$ are

$$\lambda_j = 4 \sin^2 \left(\frac{\pi(j-1)}{2n} \right), \quad j = 1, \dots, n,$$

with eigenvectors $\mathbf{v}_j = (\cos(\theta_j/2), \cos(3\theta_j/2), \dots, \cos((2n-1)\theta_j/2))^\top$, where $\theta_j = \pi(j-1)/n$. In particular $0 = \lambda_1 < \lambda_2 < \dots < \lambda_n < 4$, and $\mathbf{v}_1 = \mathbf{1}$.

Proof. Let $\theta = \theta_j$ and $v_t = \cos((t - \frac{1}{2})\theta)$, and extend the sequence by $v_0 = \cos(-\theta/2) = v_1$ and $v_{n+1} = \cos((n + \frac{1}{2})\theta)$. Since $n\theta = \pi(j-1)$, $v_{n+1} = \cos(\pi(j-1) + \theta/2) = \cos(\pi(j-1) - \theta/2) = v_n$. With these boundary values every row of $\mathbf{A}\mathbf{v}$ has the interior form $(\mathbf{A}\mathbf{v})_t = 2v_t - v_{t-1} - v_{t+1}$, because the first row $v_1 - v_2$ equals $2v_1 - v_0 - v_2$ and similarly for the last. By the identity $\cos(a - \theta) + \cos(a + \theta) = 2 \cos a \cos \theta$, $2v_t - v_{t-1} - v_{t+1} = 2(1 - \cos \theta)v_t = 4 \sin^2(\theta/2) v_t$. The n values $\theta_j \in [0, \pi)$ give n distinct eigenvalues, so these are all of them. ■

The distribution theory also needs a classical fact about eigenvalues of compressed matrices.

Lemma 21.5.2 — Interlacing

Let $\mathbf{B}$ be $N \times N$ symmetric with eigenvalues $\beta_1 \leq \dots \leq \beta_N$, and let $\mathbf{U}$ be $N \times m$ with orthonormal columns. If $\mu_1 \leq \dots \leq \mu_m$ are the eigenvalues of $\mathbf{U}^\top \mathbf{B} \mathbf{U}$, then $\beta_k \leq \mu_k \leq \beta_{k+N-m}$ for $k = 1, \dots, m$.

Proof. Let $\mathbf{f}_1, \dots, \mathbf{f}_m$ be orthonormal eigenvectors of $\mathbf{U}^\top \mathbf{B} \mathbf{U}$ and $\mathbf{q}_1, \dots, \mathbf{q}_N$ those of $\mathbf{B}$. The subspaces $\mathcal{S} = \text{span}\{\mathbf{U}\mathbf{f}_1, \dots, \mathbf{U}\mathbf{f}_m\}$, of dimension m , and $\mathcal{T} = \text{span}\{\mathbf{q}_k, \dots, \mathbf{q}_N\}$, of dimension $N - k + 1$, have dimensions adding to $N + 1$, so they share a nonzero vector $\mathbf{x} = \mathbf{U}\mathbf{f}$. Since $\mathbf{U}$ preserves lengths, $\mathbf{x}^\top \mathbf{B} \mathbf{x} / \mathbf{x}^\top \mathbf{x} = \mathbf{f}^\top \mathbf{U}^\top \mathbf{B} \mathbf{U} \mathbf{f} / \mathbf{f}^\top \mathbf{f} \leq \mu_k$, because $\mathbf{f} \in \text{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$; and $\mathbf{x}^\top \mathbf{B} \mathbf{x} / \mathbf{x}^\top \mathbf{x} \geq \beta_k$, because $\mathbf{x} \in \mathcal{T}$. Both bounds are [Theo-](#)

rem 1.7.7 applied to the restriction of the quadratic form to the span of eigenvectors. So $\beta_k \leq \mu_k$. The upper bound follows in the same way from $\text{span}\{\mathbf{U}\mathbf{f}_k, \dots, \mathbf{U}\mathbf{f}_m\}$ and $\text{span}\{\mathbf{q}_1, \dots, \mathbf{q}_{k+N-m}\}$, whose dimensions add to $N + 1$.

■

21.5.3 The null distribution of d

Theorem 21.5.3 — Durbin–Watson

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$ with $\text{rank}(\mathbf{X}) = p < n$, let the columns of the $n \times (n-p)$ matrix $\mathbf{Q}_\perp$ be an orthonormal basis of $\mathcal{C}(\mathbf{X})^\perp$, and let $\nu_1 \leq \dots \leq \nu_{n-p}$ be the eigenvalues of $\mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp$. Put $m = n - p$.

- (a) d has the distribution of $\sum_k \nu_k \xi_k^2 / \sum_k \xi_k^2$, where $\xi_1, \dots, \xi_m$ are independent $N(0, 1)$. It depends on $\mathbf{X}$ but not on $\boldsymbol{\beta}$ or σ^2 , and d is independent of $\text{SSE} = \hat{\boldsymbol{\varepsilon}}^\top \hat{\boldsymbol{\varepsilon}}$.
- (b) $E d = \bar{\nu} = m^{-1} \sum_k \nu_k = \text{tr}\{(\mathbf{I} - \mathbf{M})\mathbf{A}\}/m$ and

$$\text{Var } d = \frac{2 \sum_k (\nu_k - \bar{\nu})^2}{m(m+2)}.$$

- (c) $\Pr(d \leq c) = \Pr\{\sum_k (\nu_k - c) \xi_k^2 \leq 0\}$ for every c .
- (d) (*Bounds.*) If $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, then $\lambda_{k+1} \leq \nu_k \leq \lambda_{k+p}$ for $k = 1, \dots, m$, with λ_j as in Lemma 21.5.1. Consequently $d_L \leq d \leq d_U$ with probability one, where, for the same ξ_k ,

$$d_L = \frac{\sum_k \lambda_{k+1} \xi_k^2}{\sum_k \xi_k^2}, \quad d_U = \frac{\sum_k \lambda_{k+p} \xi_k^2}{\sum_k \xi_k^2},$$

whose distributions depend only on n and p .

Proof.

- (a) $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon} = \mathbf{Q}_\perp \mathbf{Q}_\perp^\top \boldsymbol{\varepsilon}$, because $\mathbf{Q}_\perp \mathbf{Q}_\perp^\top$ is the projection onto $\mathcal{C}(\mathbf{X})^\perp$. Let $\boldsymbol{\zeta} = \mathbf{Q}_\perp^\top \boldsymbol{\varepsilon} / \sigma \sim N_m(\mathbf{0}, \mathbf{I}_m)$ (Theorem 3.3.1), and take a spectral decomposition $\mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp = \mathbf{P} \text{diag}(\nu_k) \mathbf{P}^\top$ with $\mathbf{P}$ orthogonal. Then $\boldsymbol{\xi} = \mathbf{P}^\top \boldsymbol{\zeta} \sim N_m(\mathbf{0}, \mathbf{I}_m)$, $\hat{\boldsymbol{\varepsilon}}^\top \mathbf{A} \hat{\boldsymbol{\varepsilon}} = \sigma^2 \boldsymbol{\zeta}^\top \mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp \boldsymbol{\zeta} = \sigma^2 \sum_k \nu_k \xi_k^2$ and $\hat{\boldsymbol{\varepsilon}}^\top \hat{\boldsymbol{\varepsilon}} = \sigma^2 \|\boldsymbol{\zeta}\|^2 = \sigma^2 \sum_k \xi_k^2$. For independence, put $G_k = \xi_k^2/2$, which are independent gamma variables with shape $\frac{1}{2}$ and density proportional to $g^{-1/2} e^{-g}$. Change variables from $(G_1, \dots, G_m)$ to $S = \sum_k G_k$ and $W_k = G_k/S$, $k < m$; the Jacobian is S^{m-1} , and the joint density becomes proportional to $S^{m/2-1} e^{-S} \prod_k w_k^{-1/2}$ (with $w_m = 1 - \sum_{k < m} w_k$), a product of a function of S and a function of the W_k . So $(W_1, \dots, W_m)$ is independent of S . Now $d = \sum_k \nu_k W_k$ and $\text{SSE} = 2\sigma^2 S$.
- (b) Let $N = \sum_k \nu_k \xi_k^2$ and $S_2 = \sum_k \xi_k^2$, so $N = d S_2$ with d independent of S_2 . Then $E N = E d E S_2$ and $E N^2 = E d^2 E S_2^2$. Here $E N = \sum_k \nu_k$, $E S_2 = m$, $E N^2 = \text{Var } N + (E N)^2 = 2 \sum_k \nu_k^2 + (\sum_k \nu_k)^2$ and $E S_2^2 = 2m + m^2$. Dividing gives $E d = \bar{\nu}$ and $E d^2 = \{2 \sum_k \nu_k^2 + (\sum_k \nu_k)^2\} / \{m(m+2)\}$, and $\text{Var } d = E d^2 - \bar{\nu}^2$ simplifies to the stated form. Finally $\sum_k \nu_k = \text{tr}(\mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp) = \text{tr}(\mathbf{A} \mathbf{Q}_\perp \mathbf{Q}_\perp^\top) = \text{tr}\{\mathbf{A}(\mathbf{I} - \mathbf{M})\}$.
- (c) $d \leq c$ iff $\sum_k \nu_k \xi_k^2 \leq c \sum_k \xi_k^2$.
- (d) Let $\mathbf{P}_1$ be the $n \times (n-1)$ matrix whose columns are the normalized eigenvectors

Figure 21.5.1: The Okun regression. (a) Residuals in time order. (b) Lag plot. (c) For the 40-quarter window 1999–2009: the exact null density of d given the regressors, between the densities of the bounds d_L and d_U ; the vertical line marks the observed d .

$\mathbf{v}_2, \dots, \mathbf{v}_n$ of $\mathbf{A}$; they span $\mathbf{1}^\perp$. Since $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, $\mathcal{C}(\mathbf{Q}_\perp) \subseteq \mathbf{1}^\perp$, so $\mathbf{Q}_\perp = \mathbf{P}_1 \mathbf{U}$ for an $(n-1) \times m$ matrix $\mathbf{U} = \mathbf{P}_1^\top \mathbf{Q}_\perp$ with orthonormal columns. Then $\mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp = \mathbf{U}^\top \text{diag}(\lambda_2, \dots, \lambda_n) \mathbf{U}$, and Lemma 21.5.2 with $N = n-1$ gives $\lambda_{k+1} \leq \nu_k \leq \lambda_{k+1+(n-1-m)} = \lambda_{k+p}$. Multiplying by ξ_k^2 , summing, and dividing by $\sum_k \xi_k^2$ gives $d_L \leq d \leq d_U$. The λ_j depend only on n .

■

Part (a) reduces the exact null distribution to that of a ratio of quadratic forms in normal variables, of the kind studied in Chapter 4. Part (c) turns its distribution function into that of a single indefinite quadratic form, whose distribution function Imhof (1961) showed how to compute by numerical inversion of its characteristic function. So the exact p-value, given $\mathbf{X}$, is a routine computation, and the listing below does it. When Durbin and Watson (1950, 1951) proposed the test, that computation was impractical, and part (d) was their way around it. The bounds d_L and d_U do not depend on $\mathbf{X}$, so their percentage points can be tabulated once for each n and p . The **bounds test** of the hypothesis of no autocorrelation against positive autocorrelation, at level α , rejects if $d < d_{L,\alpha}$, accepts if $d > d_{U,\alpha}$, and is inconclusive in between. To test against negative autocorrelation, use $4 - d$.

Example. (The exact test for the Okun regression)

Under the hypothesis of independent normal errors, and given the growth series, d has mean 2.0031 and standard deviation 0.1399, and its 5% point is 1.773. The bounds for $n = 202$, $p = 2$ are $d_{L,0.05} = 1.760$ and $d_{U,0.05} = 1.780$, close together for a sample this large. The observed $d = 1.386$ is far below both, and the exact one-sided p-value is 3.3×10^{-6} .

The bounds matter in small samples. For the 40 quarters from the second quarter of 1999 to the first quarter of 2009, the same regression gives $d = 1.478$, between the bounds 1.442 and 1.544: the bounds test is inconclusive. The exact p-value, 0.037, settles it. Figure 21.5.1(c) shows the three null densities for this window.

```
def dw_matrix(n):
    """A = D'D, where D takes first differences, so that d = e'Ae / e'e."""
    D = np.diff(np.eye(n), axis=0)
```

```

return D.T @ D

              0.5, 2.0)
dU_w = brentq(lambda t: prob_negative(lam_w[pw_:] - t) - 0.05, 0.5, 2.0)
p_w = prob_negative(null_eigenvalues(Xw) - d_w)
print(f"1999Q2-2009Q1: d = {d_w:.3f}, bounds ({dL_w:.3f}, {dU_w:.3f}), "
      f"exact p = {p_w:.3f}")

```

Three limitations should be kept in mind. The exact theory needs normal errors and regressors fixed in the sense of [Chapter 14](#): conditional on the regressors the argument goes through as long as they are not functions of past responses. It fails when a lagged response is among the regressors, and then d is biased towards 2, hiding autocorrelation; Durbin (1970) gave an alternative for that case. The bounds need an intercept. And the statistic is aimed at lag-one dependence. It is sensitive to other forms only insofar as they produce lag-one correlation, and it can miss, for example, quarterly seasonal correlation at lag four.

21.5.4 The Breusch–Godfrey test

A more flexible test comes from the score principle of [Section 21.2](#). Regress the residual $\hat{\varepsilon}_t$ on the original regressors $\mathbf{x}_{(t)}$ and on the lagged residuals $\hat{\varepsilon}_{t-1}, \dots, \hat{\varepsilon}_{t-q}$, with lagged values before the first observation set to zero, and let R^2 be the coefficient of determination. The statistic nR^2 is the score statistic for the hypothesis of no autocorrelation against autoregressive, or moving-average, errors of order q , and under the hypothesis it is approximately $\chi^2(q)$ in large samples (Breusch 1978; Godfrey 1978). Unlike d , it remains valid when lagged responses are among the regressors, and it looks at several lags at once. We state its null limit without proof; the argument parallels that of [Theorem 21.2.2\(c\)](#).

For the Okun regression with $q = 4$, $nR^2 = 22.43$ on four degrees of freedom, with p-value 1.6×10^{-4} . Portmanteau statistics such as that of Ljung and Box (1978), based on $\sum_{k \leq q} r_k^2$, serve the same purpose in time-series modelling.

```
lags = np.column_stack([np.concatenate([np.zeros(k), e[:-k]])
                        for k in range(1, 5)])
Z = np.column_stack([X, lags])
coef, *_ = np.linalg.lstsq(Z, e, rcond=None)
# n R^2
bg = n * (1 - np.sum((e - Z @ coef) ** 2) / np.sum((e - e.mean()) ** 2))
print(f"Breusch-Godfrey (4 lags) = {bg:.2f}, p = {stats.chi2.sf(bg, 4):.1e}")
```

21.5.5 Exercises

21.5.5.1 A. Check your understanding

Exercise A1.

Show that $0 \leq d < 4$ and that $d = 2(1 - r_1) - (\hat{\varepsilon}_1^2 + \hat{\varepsilon}_n^2) / \sum_t \hat{\varepsilon}_t^2$. Which residual patterns give values near 0 and near 4?

Exercise A2.

For the intercept-only model $\mathbf{X} = \mathbf{1}$, show that $Ed = 2$ exactly under the hypothesis.

Solution. By [Theorem 21.5.3\(b\)](#), $Ed = \text{tr}\{(\mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^\top)\mathbf{A}\} / (n-1) = \{\text{tr}\mathbf{A} - n^{-1}\mathbf{1}^\top\mathbf{A}\mathbf{1}\} / (n-1)$. The diagonal of $\mathbf{A}$ sums to $2(n-1)$, and $\mathbf{A}\mathbf{1} = \mathbf{0}$. So $Ed = 2$.

21.5.5.2 B. Practice

Exercise B1.

If $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2\mathbf{V}$, show that $E(\hat{\boldsymbol{\varepsilon}}^\top \mathbf{A} \hat{\boldsymbol{\varepsilon}}) = \sigma^2 \text{tr}\{\mathbf{A}(\mathbf{I} - \mathbf{M})\mathbf{V}(\mathbf{I} - \mathbf{M})\}$. For $n = 3$, $\mathbf{X} = \mathbf{1}$ and $v_{st} = \rho^{|s-t|}$, compute it and show that it decreases in ρ .

Exercise B2.

Suppose $\mathcal{C}(\mathbf{X})$ is spanned by the eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_p$ of $\mathbf{A}$. Show that $\nu_k = \lambda_{k+p}$ for all k , so that $d = d_U$. Which columns of $\mathbf{X}$ have this property, and what do they look like?

Solution. Then $\mathcal{C}(\mathbf{X})^\perp$ is spanned by $\mathbf{v}_{p+1}, \dots, \mathbf{v}_n$, and $\mathbf{Q}_\perp^\top \mathbf{A} \mathbf{Q}_\perp$ has eigenvalues $\lambda_{p+1}, \dots, \lambda_n$. The $\mathbf{v}_j$ are cosines of increasing frequency, starting with the constant $\mathbf{v}_1$; $\mathbf{v}_2$ is a single slow half-wave, close to a centred linear trend. Regressors that are smooth functions of time are close to this case, so d is close to d_U for trend regressions, and the upper bound is the relevant one.

Exercise B3.

Show that d is unchanged if $\mathbf{y}$ is replaced by $c\mathbf{y} + \mathbf{X}\mathbf{a}$ for any $c \neq 0$ and $\mathbf{a}$. Use this to explain why its null distribution cannot depend on $\boldsymbol{\beta}$ or σ , without appeal to normality.

21.5.5.3 C. Going deeper**Exercise C1.**

For the intercept-only model, show that under the hypothesis $\text{Var } d = 4(n-2)/\{(n-1)(n+1)\}$ exactly, so that the standard deviation of d is close to $2/\sqrt{n}$. (Use [Theorem 21.5.3\(b\)](#), $\sum_j \lambda_j^2 = \text{tr}(\mathbf{A}^2)$, and the entries of $\mathbf{A}$.) Compare with the Okun regression of [Example \(The exact test for the Okun regression\)](#).

Solution. Here $m = n - 1$ and the ν_k are $\lambda_2, \dots, \lambda_n$, so $\sum_k \nu_k = \text{tr } \mathbf{A} = 2(n-1)$ and $\sum_k \nu_k^2 = \text{tr}(\mathbf{A}^2)$, the sum of the squared entries of $\mathbf{A}$: $1 + 4(n-2) + 1$ from the diagonal and $2(n-1)$ from the off-diagonal, in total $6n-8$. Then $m \sum_k \nu_k^2 - (\sum_k \nu_k)^2 = (n-1)(6n-8) - 4(n-1)^2 = 2(n-1)(n-2)$, and $\text{Var } d = 4(n-1)(n-2)/\{(n-1)^2(n+1)\} = 4(n-2)/\{(n-1)(n+1)\}$. For $n = 202$, $2/\sqrt{202} = 0.141$, close to the standard deviation 0.1399 computed for the Okun design, which has one more column.

Exercise C2.

In the model $y_t = \beta y_{t-1} + \varepsilon_t$ with independent errors, fitted by least squares on $t = 2, \dots, n$, argue that the residuals are less autocorrelated than the errors would be under an autocorrelated alternative, so that d is biased towards 2. Relate this to the requirement in [Theorem 21.5.3](#) that $\mathbf{X}$ be fixed.

21.6 Autoregressive errors

Serial correlation raises the same choice as heteroscedasticity: model it and use generalized least squares, or keep least squares and estimate its covariance without a model. Either way dependence must be described by few parameters, and the simplest description, the one behind the Durbin–Watson test, is the first-order autoregression.

21.6.1 The AR(1) model

Definition 21.6.1 — First-order autoregressive errors

The errors follow a **first-order autoregressive process**, AR(1), if

$$\varepsilon_t = \rho \varepsilon_{t-1} + u_t, \quad t = 2, \dots, n,$$

with $|\rho| < 1$, where $u_2, \dots, u_n$ are uncorrelated with mean zero and variance σ_u^2 , and the starting value ε_1 has mean zero, variance $\sigma_u^2/(1 - \rho^2)$ and is uncorrelated with the u_t .

The variance of ε_1 is the one that makes the process **stationary**: it is the variance an AR(1) process reaches after running for a long time, and with it every ε_t has the same variance.

Theorem 21.6.1 — Regression with AR(1) errors

Let $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $\text{rank}(\mathbf{X}) = p$ and AR(1) errors.

- (a) $\text{Cov}(\varepsilon_s, \varepsilon_t) = \sigma_u^2 \rho^{|s-t|}/(1 - \rho^2)$. Write $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma_u^2 \mathbf{V}_\rho$.
- (b) (*Prais–Winsten transformation.*) Let $\mathbf{L}_\rho$ be the $n \times n$ lower bidiagonal matrix with $(\mathbf{L}_\rho)_{11} = \sqrt{1 - \rho^2}$, $(\mathbf{L}_\rho)_{tt} = 1$ and $(\mathbf{L}_\rho)_{t,t-1} = -\rho$ for $t \geq 2$. Then $\text{Cov}(\mathbf{L}_\rho \boldsymbol{\varepsilon}) = \sigma_u^2 \mathbf{I}$, so $\mathbf{V}_\rho^{-1} = \mathbf{L}_\rho^\top \mathbf{L}_\rho$ and $\det \mathbf{V}_\rho = 1/(1 - \rho^2)$. For known ρ , the generalized least squares estimate is ordinary least squares on $(\mathbf{L}_\rho \mathbf{y}, \mathbf{L}_\rho \mathbf{X})$, and it is the best linear unbiased estimator.
- (c) (*Likelihood.*) If the errors are normal, the log-likelihood is

$$\begin{aligned} \ell(\boldsymbol{\beta}, \rho, \sigma_u^2) = & -\frac{n}{2} \log(2\pi\sigma_u^2) + \frac{1}{2} \log(1 - \rho^2) \\ & - \frac{\|\mathbf{L}_\rho(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})\|^2}{2\sigma_u^2}. \end{aligned}$$

- (d) (*Cochrane–Orcutt.*) Let $S(\boldsymbol{\beta}, \rho) = \sum_{t=2}^n \{(y_t - \rho y_{t-1}) - (\mathbf{x}_{(t)} - \rho \mathbf{x}_{(t-1)})^\top \boldsymbol{\beta}\}^2$, the sum of squares of the last $n - 1$ rows of $\mathbf{L}_\rho(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})$. Alternate the steps

$$\begin{aligned} \rho_{k+1} &= \frac{\sum_{t \geq 2} e_t e_{t-1}}{\sum_{t \geq 2} e_{t-1}^2} \quad \text{with } \mathbf{e} = \mathbf{y} - \mathbf{X}\boldsymbol{\beta}_k, \\ \boldsymbol{\beta}_{k+1} &= \arg \min_{\mathbf{b}} S(\mathbf{b}, \rho_{k+1}). \end{aligned}$$

Then $S(\boldsymbol{\beta}_{k+1}, \rho_{k+1}) \leq S(\boldsymbol{\beta}_k, \rho_{k+1}) \leq S(\boldsymbol{\beta}_k, \rho_k)$, so S decreases along the iterations, and any limit point $(\boldsymbol{\beta}^*, \rho^*)$ with $|\rho^*| < 1$ at which the steps are continuous is a stationary point of S .

Proof.

- (a) By induction $\text{Var } \varepsilon_t = \sigma_u^2/(1 - \rho^2)$ for all t , because $\text{Var } \varepsilon_t = \rho^2 \text{Var } \varepsilon_{t-1} + \sigma_u^2$, ε_{t-1} being a linear combination of $\varepsilon_1, u_2, \dots, u_{t-1}$ and so uncorrelated with u_t . For $k \geq 1$, iterating the recursion gives $\varepsilon_t = \rho^k \varepsilon_{t-k} + \sum_{j=0}^{k-1} \rho^j u_{t-j}$, and the sum is uncorrelated with ε_{t-k} , so $\text{Cov}(\varepsilon_t, \varepsilon_{t-k}) = \rho^k \text{Var } \varepsilon_{t-k}$.

- (b) $\mathbf{L}_\rho \boldsymbol{\varepsilon} = (\sqrt{1-\rho^2} \varepsilon_1, u_2, \dots, u_n)^\top$, whose entries are uncorrelated with variance σ_u^2 . So $\sigma_u^2 \mathbf{L}_\rho \mathbf{V}_\rho \mathbf{L}_\rho^\top = \sigma_u^2 \mathbf{I}$, and since $\mathbf{L}_\rho$ is nonsingular, $\mathbf{V}_\rho^{-1} = \mathbf{L}_\rho^\top \mathbf{L}_\rho$. $\mathbf{L}_\rho$ is triangular with determinant $\sqrt{1-\rho^2}$, so $\det \mathbf{V}_\rho = 1/(1-\rho^2)$. The last statement is [Theorem 6.9.1](#) and [Corollary 7.2.3](#) with the whitening matrix $\mathbf{L}_\rho$, as in [Section 6.9](#).
- (c) The normal density of $\boldsymbol{\varepsilon}$ with covariance $\sigma_u^2 \mathbf{V}_\rho$ has $-\frac{1}{2} \log \det(\sigma_u^2 \mathbf{V}_\rho) = -\frac{n}{2} \log \sigma_u^2 + \frac{1}{2} \log(1-\rho^2)$ and quadratic form $(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})^\top \mathbf{V}_\rho^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) / \sigma_u^2 = \|\mathbf{L}_\rho(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})\|^2 / \sigma_u^2$.
- (d) For fixed $\boldsymbol{\beta}$, $S(\boldsymbol{\beta}, \rho) = \sum_{t \geq 2} (e_t - \rho e_{t-1})^2$ is a quadratic in ρ minimized by ρ_{k+1} , which gives the second inequality. For fixed ρ , S is a least squares criterion in $\mathbf{b}$, minimized by $\boldsymbol{\beta}_{k+1}$, which gives the first. At a limit point both steps leave $(\boldsymbol{\beta}^*, \rho^*)$ unchanged, so $\partial S / \partial \rho = 0$ and $\partial S / \partial \boldsymbol{\beta} = \mathbf{0}$ there.

■

The whitening in (b) is the transformation of Prais and Winsten (1954). Row $t \geq 2$ of the transformed model is the **quasi-difference** $y_t - \rho y_{t-1} = (\mathbf{x}_{(t)} - \rho \mathbf{x}_{(t-1)})^\top \boldsymbol{\beta} + u_t$, and row one is the first observation rescaled by $\sqrt{1-\rho^2}$. The inverse covariance $\mathbf{V}_\rho^{-1}$ is tridiagonal, with diagonal $(1, 1+\rho^2, \dots, 1+\rho^2, 1)$ and off-diagonal entries $-\rho$ ([Exercise \(A1\)](#)), which is why AR(1) models are cheap to fit however long the series. Cochrane and Orcutt (1949) dropped the first row, which leaves the conditional sum of squares S of (d). Dropping it loses little when the regressors are stationary, but it can lose a great deal when they trend, because the first observation is then the only one whose transformed regressor is not nearly constant. Maximizing the likelihood of (c) keeps the first row and the term $\frac{1}{2} \log(1-\rho^2)$, which keeps $\hat{\rho}$ inside $(-1, 1)$.

21.6.2 Feasible generalized least squares

In practice ρ is unknown. The two-step **feasible** estimator estimates it from the ordinary least squares residuals, $\hat{\rho} = \sum_{t \geq 2} \hat{e}_t \hat{e}_{t-1} / \sum_{t \geq 2} \hat{e}_{t-1}^2$, and then applies the Prais–Winsten transformation with $\hat{\rho}$. Iterating the two steps gives either the Cochrane–Orcutt estimate or, keeping the first row, a close relative of the maximum likelihood estimate.

Remark (What is known about feasible GLS with AR(1) errors). Suppose the errors are a stationary AR(1) process with independent innovations of finite variance, and the regressors are stationary, or have polynomial trends, with suitable limits for their sample moments. Then $\hat{\rho} \rightarrow \rho$ in probability, and $\sqrt{n}(\hat{\boldsymbol{\beta}}_{\text{FGLS}} - \hat{\boldsymbol{\beta}}_{\text{GLS}}) \rightarrow \mathbf{0}$ after the appropriate normalization for trending regressors, so the feasible estimator has the limiting distribution of the optimal one and the usual standard errors from the transformed regression are valid in large samples. We do not prove this. A sketch: $\hat{\rho}$ differs from the sample autocorrelation of the true errors by terms bounded by multiples of $\|\mathbf{M}\boldsymbol{\varepsilon}\| \|\boldsymbol{\varepsilon}\|/n$ and $\|\mathbf{M}\boldsymbol{\varepsilon}\|^2/n$, which tend to zero because $\|\mathbf{M}\boldsymbol{\varepsilon}\|$ is bounded in probability (compare the proof of [Theorem 21.2.2\(c\)](#)), and that autocorrelation is consistent by a law of large numbers for stationary sequences; the comparison of $\hat{\boldsymbol{\beta}}_{\text{FGLS}}$ with $\hat{\boldsymbol{\beta}}_{\text{GLS}}$ then follows the pattern of [Theorem 21.3.1\(d\)](#), because $\mathbf{L}_\rho$ depends smoothly on ρ . Fuller (1996) gives complete statements and proofs. The finite-sample behaviour must be checked by simulation.

Example. (Okun's law with AR(1) errors)

For the regression of [Example \(A quarterly Okun's-law regression\)](#), $\hat{\rho} = 0.303$. The two-step Prais–Winsten estimate of the slope is -0.0506 with standard error 0.0049 , against

the least squares -0.0671 with nominal standard error 0.0050 . Iterating Cochrane–Orcutt to convergence takes 17 iterations and ends at $\hat{\rho} = 0.548$ and slope -0.0380 . The estimate of the effect of growth on unemployment thus changes by almost half depending on the treatment of the errors, and the residuals of the transformed regression still have lag-one autocorrelation 0.148 . Both facts suggest that the AR(1) error model does not describe these data. We return to this below.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

macro = sm.datasets.macrodta.load_pandas().data
du = np.diff(macro["unemp"].to_numpy())
growth = 400 * np.diff(np.log(macro["realgdp"].to_numpy()))
n = len(du)
X = np.column_stack([np.ones(n), growth])

      f"slope {b_co[1]:.4f}")

```

21.6.3 Efficiency and validity of least squares

How much is lost by ignoring AR(1) errors? There are two separate questions: how much less efficient least squares is than generalized least squares, and how wrong its nominal standard error $s\{(\mathbf{X}^\top \mathbf{X})^{-1}\}_{jj}^{1/2}$ is. The answers depend on the regressor, and they run in opposite directions.

Example. (Three regressors)

Take $n = 100$, an intercept, and one of three regressors: a linear trend, a fixed draw of white noise, and a fixed draw of an AR(1) series with coefficient 0.8 (its sample lag-one autocorrelation is 0.87). For AR(1) errors, Figure 21.6.1 shows (a) the ratio of the generalized to the ordinary least squares variance of the slope, and (b) the ratio of the true least squares variance to the expected nominal one, $E(s^2)\{(\mathbf{X}^\top \mathbf{X})^{-1}\}_{22}$, with $E s^2$ from Theorem 2.3.1. All are exact computations.

At $\rho = 0.6$: for the trend, least squares is 0.970 efficient but its nominal variance is too small by a factor of 4.01. For white noise it is only 0.462 efficient, yet its nominal variance is nearly right (factor 1.11). The autocorrelated regressor suffers both ways: efficiency 0.650, variance understated by a factor of 3.19. At $\rho = 0.9$ the factors for the trend become 0.842 and 19.59.

The trend repeats the lesson of the autocorrelated-errors example of Section 19.2; the other two regressors are new.

The pattern has a simple explanation. The variance of $\hat{\beta}_1$ in a simple regression is $\sum_{s,t} (x_s - \bar{x})(x_t - \bar{x}) \text{Cov}(\varepsilon_s, \varepsilon_t) / S_{xx}^2$. When the regressor is itself autocorrelated, neighbouring terms add

up, and for a stationary regressor with lag-one autocorrelation ϕ the ratio of true to nominal variance is approximately $(1 + \rho\phi)/(1 - \rho\phi)$ (Exercise (B2)). For the AR(0.8) regressor this gives 3.18 at $\rho = 0.6$, against the exact 3.19. A white-noise regressor has $\phi \approx 0$, so the nominal variance is nearly right; but generalized least squares, which quasi-differences x_t , turns a rough regressor into an even rougher one with more information, and least squares' efficiency tends to $(1 - \rho^2)/(1 + \rho^2)$, which is 0.471 at $\rho = 0.6$ (Exercise (B1)). For polynomial trends, Grenander (1954) showed that least squares is asymptotically fully efficient, which the trend curve in panel (a) approaches; but its standard error is then at its most misleading.

21.6.4 Newey–West standard errors

The analogue of the sandwich of Section 21.4 for serially correlated errors keeps least squares and estimates the middle matrix $\mathbf{X}^\top \text{Cov}(\boldsymbol{\varepsilon})\mathbf{X} = \sum_{s,t} \text{Cov}(\varepsilon_s, \varepsilon_t) \mathbf{x}_{(s)} \mathbf{x}_{(t)}^\top$ without a parametric model. The products $\hat{\varepsilon}_s \hat{\varepsilon}_t$ can stand in for the covariances only when s and t are close, since distant covariances are small but their estimates are not. With $\mathbf{v}_t = \mathbf{x}_{(t)} \hat{\varepsilon}_t$ and a truncation lag L , Newey and West (1987) proposed

$$\begin{aligned}\hat{\boldsymbol{\Omega}}_L &= \sum_{k=-L}^L \left(1 - \frac{|k|}{L+1}\right) \hat{\mathbf{r}}_k, \\ \hat{\mathbf{r}}_k &= \sum_{t=k+1}^n \mathbf{v}_t \mathbf{v}_{t-k}^\top, \quad \hat{\mathbf{r}}_{-k} = \hat{\mathbf{r}}_k^\top,\end{aligned}\tag{21.6.1}$$

and the covariance estimate $(\mathbf{X}^\top \mathbf{X})^{-1} \hat{\boldsymbol{\Omega}}_L (\mathbf{X}^\top \mathbf{X})^{-1}$. The declining **Bartlett weights** $1 - |k|/(L+1)$ are not a matter of taste.

Proposition 21.6.2 — Newey–West estimates are nonnegative definite

For any vectors $\mathbf{v}_1, \dots, \mathbf{v}_n$ and any $L \geq 0$, $\hat{\boldsymbol{\Omega}}_L$ in Eq. 21.6.1 is nonnegative definite. Without the weights, $\sum_{|k| \leq L} \hat{\mathbf{r}}_k$ need not be.

Proof. Set $\mathbf{v}_t = \mathbf{0}$ for $t \leq 0$ and $t > n$, and let $\mathbf{s}_j = \sum_{i=0}^L \mathbf{v}_{j-i}$ for every integer j . Then

$$\sum_j \mathbf{s}_j \mathbf{s}_j^\top = \sum_j \sum_{i,l=0}^L \mathbf{v}_{j-i} \mathbf{v}_{j-l}^\top = \sum_{k=-L}^L (L+1-|k|) \sum_t \mathbf{v}_t \mathbf{v}_{t-k}^\top,$$

because for fixed $t = j - i$ and lag $k = l - i$ there are exactly $L+1-|k|$ pairs (i, l) in $\{0, \dots, L\}^2$ with $l - i = k$. Dividing by $L+1$ shows that $\hat{\boldsymbol{\Omega}}_L = (L+1)^{-1} \sum_j \mathbf{s}_j \mathbf{s}_j^\top$, a sum of nonnegative definite matrices. Exercise (C1) gives an example for the unweighted sum. ■

Newey and West (1987) proved that the estimator is consistent when L grows with n slowly enough, for errors and regressors that are stationary with dependence dying out fast enough. We do not prove this. Its practical weakness is the choice of L , which trades bias from truncation

against variance from estimating many autocovariances; Andrews (1991) studied data-based choices. A common rule of thumb is $L = \lfloor 4(n/100)^{2/9} \rfloor$. For the Okun regression, with $L = 4$, the Newey–West standard error of the slope is 0.0086, against the nominal 0.0050. With $L = 0$ the estimator is HC0 ([Exercise \(A2\)](#)).

```
def newey_west(X, e, L):
    """Bartlett-weighted HAC covariance of the OLS estimate, truncation lag L."""
    v = X * e[:, None]
    S = v.T @ v
    for k in range(1, L + 1):
        G = v[k:].T @ v[:-k]
        S += (1 - k / (L + 1)) * (G + G.T)
    B = np.linalg.inv(X.T @ X)
    return B @ S @ B

V_nw = newey_west(X, e, 4)
print(f"Newey-West (L = 4) se of slope {np.sqrt(V_nw[1, 1]):.4f}")
```

Example. (Coverage with AR(1) errors)

Let the regressor be a fixed draw of an AR(1) series with coefficient 0.8, and the errors AR(1) with $\rho = 0.6$ and normal innovations. Over 10,000 simulated data sets the nominal 95% intervals for the slope covered as follows. For $n = 50$: least squares with the usual standard error 0.747, least squares with Newey–West 0.784, two-step Prais–Winsten 0.913, and generalized least squares with the true ρ 0.946. For $n = 200$: 0.746, 0.871, 0.944 and 0.950. The Newey–West interval is valid only asymptotically, and converges slowly; when the AR(1) model is right, using it pays.

```
def ar1_draws(n, rho, reps, rng):
    u = rng.normal(size=(reps, n))
    x = np.empty((reps, n))
    x[:, 0] = u[:, 0] / np.sqrt(1 - rho**2)
    for t in range(1, n):
        x[:, t] = rho * x[:, t - 1] + u[:, t]
    return x

def coverage(n, reps, rng):
    """Coverage of 95% slope intervals: OLS, Newey-West, Prais-Winsten, GLS."""

        r = np.sum(res[1:] * res[:-1]) / np.sum(res[:-1] ** 2)
        b_f, _, V_f = ols(*prais_winsten(Xc, y, r))
        b_g, _, V_g = ols(*prais_winsten(Xc, y, 0.6))
        ses = [V[1, 1], newey_west(Xc, res, L)[1, 1], V_f[1, 1], V_g[1, 1]]
        hits += [abs(bb[1]) <= q * np.sqrt(v)
                  for bb, v in zip((b, b_f, b_g), ses)]
    return hits / reps
```

```

rng = np.random.default_rng(2109)
for n_sim in (50, 200):
    print(n_sim, "OLS, Newey-West, Prais-Winsten, GLS:",
          np.round(coverage(n_sim, 500, rng), 3))

```

21.6.5 Serial correlation as a symptom

An AR(1) error model is a restriction on a dynamic regression. Multiply the model at time $t-1$ by ρ and subtract:

$$y_t = \rho y_{t-1} + \mathbf{x}_{(t)}^\top \boldsymbol{\beta} - \rho \mathbf{x}_{(t-1)}^\top \boldsymbol{\beta} + u_t.$$

This is a regression of y_t on its own lag and on current and lagged regressors, with the coefficients of the lagged regressors constrained to equal $-\rho$ times those of the current ones, the **common factor restriction**. Residual autocorrelation is often the trace of a missing lag of y or of a regressor, and then the dynamic regression without the restriction is the better model. Hendry and Mizon (1978) argued that the restriction should be tested before the error model is adopted.

Example. (Okun's law, dynamically)

Regressing Δu_t on an intercept, Δu_{t-1} , g_t and g_{t-1} gives coefficients 0.2160, 0.3571 (standard error 0.0574), -0.0487 (0.0043) and -0.0162 (0.0055). The AR(1) model would require the last coefficient to be $-0.3571 \times (-0.0487) = 0.0174$. The estimate has the opposite sign, and the delta-method test of the restriction gives $z = -8.1$. The unrestricted dynamic regression has no remaining residual autocorrelation: its Breusch–Godfrey statistic with four lags is 4.42, with p-value 0.35. Unemployment responds to growth with a lag and with persistence; the AR(1) error model mistook this for correlated noise, and the slope estimates of [Example \(Okun's law with AR\(1\) errors\)](#), which move with $\hat{\rho}$, were artefacts of that mistake.

```

# the AR(1) error model is the dynamic regression
#   du_t = a + rho du_(t-1) + b g_t + c g_(t-1) + u_t
#   with the restriction c = -rho b
Xd = np.column_stack([np.ones(n - 1), du[:-1], growth[1:], growth[:-1]])
bd, ed, Vd = ols(Xd, du[1:])
# zero under the restriction
restr = bd[3] + bd[1] * bd[2]
grad = np.array([0.0, bd[2], bd[1], 1.0]) # delta method
z_cf = restr / np.sqrt(grad @ Vd @ grad)
print("dynamic regression: const, du(t-1), g(t), g(t-1) =", np.round(bd, 4))
print(f"common-factor restriction c + rho b = {restr:.4f}, z = {z_cf:.1f}")

```

An extreme case is the regression of one random walk on another, independent one, which gives large t statistics and a small d far more often than the nominal level suggests (Granger and Newbold 1974). There the residual autocorrelation signals a meaningless regression, and no correction of the standard errors repairs it.

21.6.6 Exercises

21.6.6.1 A. Check your understanding

Exercise A1.

Compute $\mathbf{L}_\rho^\top \mathbf{L}_\rho$ and show that it is tridiagonal with diagonal $(1, 1 + \rho^2, \dots, 1 + \rho^2, 1)$ and off-diagonal entries $-\rho$. Check $\mathbf{V}_\rho \mathbf{L}_\rho^\top \mathbf{L}_\rho = \mathbf{I}$ for $n = 2$.

Solution. Column t of $\mathbf{L}_\rho$ has entry 1 (or $\sqrt{1 - \rho^2}$ for $t = 1$) in row t and $-\rho$ in row $t + 1$ (for $t < n$). The inner product of columns t and t is $1 + \rho^2$ for $1 < t < n$, $(1 - \rho^2) + \rho^2 = 1$ for $t = 1$ and 1 for $t = n$; columns t and $t + 1$ share only row $t + 1$, giving $-\rho$; other pairs share nothing. For $n = 2$, $\mathbf{V}_\rho = (1 - \rho^2)^{-1} \begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$ and $\mathbf{L}_\rho^\top \mathbf{L}_\rho = \begin{pmatrix} 1 & -\rho \\ -\rho & 1 \end{pmatrix}$, whose product is $(1 - \rho^2)^{-1}(1 - \rho^2)\mathbf{I} = \mathbf{I}$.

Exercise A2.

Show that the Newey–West estimator with $L = 0$ is HC0, and that with $\mathbf{X} = \mathbf{1}$ and $L \geq 1$ it estimates the long-run variance $\sum_k \gamma_k$ of a stationary series, scaled by n .

21.6.6.2 B. Practice

Exercise B1.

Let the regressor x_t be white noise with variance τ^2 , independent of AR(1) errors, and consider the slope in a regression through the origin. Show heuristically that $n \text{Var}(\hat{\beta}_{\text{OLS}}) \rightarrow \sigma_u^2 / \{(1 - \rho^2)\tau^2\}$ and $n \text{Var}(\hat{\beta}_{\text{GLS}}) \rightarrow \sigma_u^2 / \{(1 + \rho^2)\tau^2\}$, so that the efficiency of least squares, the ratio bounded in [Theorem 19.2.3](#), tends to $(1 - \rho^2)/(1 + \rho^2)$.

Exercise B2.

Let the regressor be a stationary AR(1) series with coefficient ϕ , independent of AR(1) errors with coefficient ρ . Show heuristically that the ratio of the true variance of the least squares slope to its nominal variance tends to $(1 + \rho\phi)/(1 - \rho\phi)$.

Solution. Conditionally on the regressor, $\text{Var}(\hat{\beta}) = \sum_{s,t} \tilde{x}_s \tilde{x}_t \gamma_0 \rho^{|s-t|} / S_{xx}^2$, where $\tilde{x}_t = x_t - \bar{x}$. For large n , $\sum_t \tilde{x}_t \tilde{x}_{t-k} \approx S_{xx} \phi^{|k|}$, so the variance is about $(\gamma_0 / S_{xx}) \sum_k (\rho\phi)^{|k|} = (\gamma_0 / S_{xx})(1 + \rho\phi)/(1 - \rho\phi)$. The nominal variance $E(s^2)/S_{xx}$ is about γ_0 / S_{xx} , since s^2 estimates the marginal error variance γ_0 when p/n is small.

Exercise B3.

In the model $y_t = \alpha + \beta t + \varepsilon_t$, $t = 1, \dots, n$, with AR(1) errors, show that the Cochrane–Orcutt regression has columns $(1 - \rho)\mathbf{1}$ and $(1 - \rho)t + \rho$ on $t = 2, \dots, n$, and that the information it carries about β is $(1 - \rho)^2 \sum_{t \geq 2} (t - \bar{t})^2 / \sigma_u^2$, where $\bar{t}$ is the mean of $2, \dots, n$. What happens as $\rho \rightarrow 1$ with n fixed, and why does the Prais–Winsten first row change

the picture?

21.6.6.3 C. Going deeper

Exercise C1.

Give vectors v_1, v_2, v_3 (with $p = 1$) for which the unweighted sum $\sum_{|k| \leq 1} \hat{\Gamma}_k$ is negative.

Solution. Take $(v_1, v_2, v_3) = (1, -1, 1)$. Then $\hat{\Gamma}_0 = 3$ and $\hat{\Gamma}_1 = \hat{\Gamma}_{-1} = v_2 v_1 + v_3 v_2 = -2$, so the unweighted sum is $3 - 4 = -1$. With Bartlett weights it is $3 - 2 = 1$.

21.7 Summary and Notes

21.7.1 Summary

Idea.

1. Residuals mix all the errors. Each differs from its error with variance $\sigma^2 h_{ii}$, and residuals keep only part of the errors' skewness and kurtosis, so they look more normal than the errors when p/n is not small ([Proposition 21.1.1](#)).
2. Normal plots of studentized residuals with simulated envelopes are the main check of normality. Coefficient inference is protected by the central limit theorem; prediction intervals are not, and their coverage tends to $\Pr(|\varepsilon_0| \leq z\sigma)$ ([Proposition 12.3.3](#)), which [Table 21.1.1](#) evaluates for five error laws.
3. The Breusch–Pagan statistic is half the explained sum of squares of $\hat{\varepsilon}_i^2/\tilde{\sigma}^2$ on the variance variables, whatever the variance function. Non-normal errors inflate its null law by $(\kappa - 1)/2$, with κ the raw kurtosis, and Koenker's nR^2 corrects this ([Theorem 21.2.2](#), using [Lemma 21.2.1](#)). The Goldfeld–Quandt test is exact under normality ([Proposition 21.2.3](#)).
4. Weighted least squares is optimal with known weights, unbiased with wrong ones, unbiased under symmetric errors with weights from residuals, and asymptotically optimal with weights from well-replicated groups ([Theorem 21.3.1](#)). Weights from a few replicates can be worse than none.
5. HC0–HC3 estimate the covariance of least squares without a variance model ([Definition 21.4.1](#)). HC2 is unbiased under homoscedasticity and HC3 is the jackknife ([Proposition 21.4.1](#)). All are consistent ([Theorem 21.4.2](#)), but high leverage makes them unreliable in small samples.
6. Given $\mathbf{X}$ and normal errors, the Durbin–Watson $d \approx 2(1 - r_1)$ is a ratio of quadratic forms with a computable law, bracketed by design-free bounds when there is an intercept ([Theorem 21.5.3](#), [Lemma 21.5.1](#), [Lemma 21.5.2](#)).
7. AR(1) errors are whitened by the Prais–Winsten transformation, and Cochrane–Orcutt iteration decreases the conditional sum of squares ([Definition 21.6.1](#), [Theorem 21.6.1](#)). Smooth regressors make least squares efficient but its standard errors wrong. Newey–West estimates are nonnegative definite ([Proposition 21.6.2](#)). Residual autocorrelation often signals missing dynamics.

21.7.2 Notes and sources

Sources. The chapter covers Sen and Srivastava (1990, chapters 5–6 and sections 7.1–7.3 and 7.6), Seber and Lee (2003, sections 10.4–10.5) and Christensen (2020, sections 12.2–12.4). It adds proofs of the facts about residuals behind the diagnostics, the null limits of both forms of the Breusch–Pagan test, the properties of feasible weighting in the grouped case, the consistency of the sandwich estimators, and the Durbin–Watson bounds through interlacing. The limit theorems are from van der Vaart (1998).

Normality. Blom (1958) gave the plotting positions, Shapiro and Wilk (1965) and Shapiro and Francia (1972) the two correlation-type tests, and Jarque and Bera (1980) the skewness–kurtosis score test. Lilliefors (1967) tabulated the Kolmogorov–Smirnov test with estimated parameters, and Anderson and Darling (1952) introduced their tail-weighted distance. Simulated envelopes are due to Atkinson (1981). That residuals look more normal than errors is an old observation; [Proposition 21.1.1\(c\)](#) quantifies it.

Heteroscedasticity. The score test is due to Breusch and Pagan (1979) and to Cook and Weisberg (1983); the score principle is Rao’s (1948). Koenker (1981) exposed the sensitivity to kurtosis and gave the studentized form. White (1980) proposed the direct test and the covariance estimator, and Goldfeld and Quandt (1965) the exact F test. Levene (1960) and Brown and Forsythe (1974) gave robust tests for groups, and Box (1953) showed the non-robustness of normal-theory variance tests. Carroll and Ruppert (1988) is the standard monograph on weighting; Carroll (1982) showed that weights estimated by smoothing can be fully efficient asymptotically. The symmetry argument of [Theorem 21.3.1\(c\)](#) goes back to Kakwani (1967).

Sandwich estimators. Eicker (1963) gave conditions for asymptotic normality of least squares with unequal variances and Eicker (1967) the consistency of the covariance estimator; Huber (1967) introduced the sandwich form for general estimators, and White (1980) made it standard in econometrics. MacKinnon and White (1985) proposed HC2 and HC3. Long and Ervin (2000) recommended HC3, and Imbens and Kolesár (2016) recommend HC2 with the degrees-of-freedom adjustment of Bell and McCaffrey (2002).

Serial correlation. Durbin and Watson (1950, 1951, 1971) introduced the statistic and the bounds and studied its exact distribution; Imhof (1961) gave the inversion formula. Durbin (1970) treated lagged responses, Breusch (1978) and Godfrey (1978) the score test for higher-order errors, and Ljung and Box (1978) the portmanteau statistic. The transformations are those of Cochran and Orcutt (1949) and Prais and Winsten (1954). Grenander (1954) proved the asymptotic efficiency of least squares for polynomial trends. Newey and West (1987) proposed the Bartlett-weighted estimator and Andrews (1991) studied its bandwidth. Hendry and Mizon (1978) argued for testing the common factor restriction, and Granger and Newbold (1974) exposed spurious regressions. Fuller (1996) gives the asymptotic theory of regression with autocorrelated errors in full.

Chapter 22

Transformations

A regression is fitted on a scale, and nothing in least squares says which one. Food expenditure can be modelled in currency units or in logarithms, a count as it stands or through its square root. The choice affects all three claims of the normal linear model: a linear mean, a constant variance and normal errors. When the three failures share a cause, one transformation repairs them together; when they do not, the chapter says which to fix first and at what price. It treats the choice of scale as estimation: the Box–Cox profile likelihood for the response, the Box–Tidwell procedure and component-plus-residual plots for regressors, and the delta method for transformations that stabilize a variance tied to the mean. It ends with what a transformed model says on the scale the reader cares about: medians, means, prediction intervals and elasticities.

What you need. Least squares as projection and the Frisch–Waugh–Lovell theorem ([Chapter 6](#), [Theorem 6.6.2](#)), maximum likelihood and profile likelihood in the normal linear model ([Chapter 7](#), [Theorem 7.3.1](#) and [Definition 7.3.1](#)), the interpretation of log-scale coefficients ([Section 5.7](#)), prediction intervals ([Theorem 12.3.1](#)), the delta method as used in [Section 14.4](#), and the diagnostics of [Chapter 20](#) and [Chapter 21](#).

22.0.1 Roadmap

- [Transforming the response](#)
- [The Box–Cox family](#)
- [Transforming regressors](#)
- [Variance-stabilizing transformations](#)
- [Interpreting a transformed model](#)
- [Summary and notes](#)

22.1 Transforming the response

The normal linear model claims that the mean of the response is linear in the regressors, that its variance is constant, and that its distribution is normal. [Chapter 19](#) worked out what each failure costs, and [Chapter 20](#) and [Chapter 21](#) showed how to see them. Replacing y by $g(y)$, for a strictly increasing g , acts on all three claims at once. If the failures have a common cause, one

g removes them together; if not, the g that straightens the mean may worsen the variance.

22.1.1 Engel's data on two scales

Example. (Food expenditure on the raw and the log scale)

Engel's survey of 235 Belgian households ([Example \(Engel's food expenditure data\)](#)) records annual income, from 377 to 4958 in the survey's currency, and expenditure on food. The least squares line on the raw scale has slope 0.4852, and panel (b) of [Figure 22.1.1](#) shows a fan: the residual standard deviation among the richest third of households is 3.55 times that among the poorest third. The residuals have excess kurtosis 9.64 (zero for a normal distribution), largely a by-product of the fan, since a mixture of normals with different spreads has heavy tails.

On the log-log scale both defects nearly disappear. The spread ratio falls to 1.32, the excess kurtosis to -0.02 , and the residual plot, panel (d), shows a horizontal band. The slope is 0.8559 with standard error 0.0203 and 95% interval [0.816, 0.896]. It is an elasticity ([Section 5.7](#)): households with 1 percent more income spend about 0.86 percent more on food. That the interval lies below one is Engel's law, that the share of the budget spent on food falls as income rises.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

df = sm.datasets.engel.load_pandas().data
income, food = df["income"].to_numpy(), df["foodexp"].to_numpy()
n = len(food)

raw = sm.OLS(food, sm.add_constant(income)).fit() # food on income
loglog = sm.OLS(np.log(food), sm.add_constant(np.log(income))).fit() # log food on
    log income

def spread_ratio(fit):
    """Residual SD among the richest third over that among the poorest third."""
    order = np.argsort(income)
    low, high = order[: n // 3], order[-(n // 3):]
    return fit.resid[high].std(ddof=1) / fit.resid[low].std(ddof=1)

for name, fit in [("raw", raw), ("log-log", loglog)]:
    print(f"{name:8s} slope {fit.params[1]:.4f} spread ratio {spread_ratio(fit):.2f}
    {name:8s} excess kurtosis of residuals {stats.kurtosis(fit.resid):.2f}")
```

22.1.2 Multiplicative models

The logarithm worked because the variation in food expenditure behaves like a *percentage* of its level. A model in which the regressors and the error act multiplicatively makes this precise.

Figure 22.1.1: Engel's data. (a) Food expenditure against income with the least squares line. (b) Its residuals against fitted values: the spread grows with the level. (c) The same data on the log-log scale. (d) The log-log residuals form a band of nearly constant width.

Proposition 22.1.1 — Multiplicative errors

Let the model matrix $\mathbf{X}$ have first column $\mathbf{1}$, with β_0 the corresponding coefficient, and let

$$Y_i = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}) U_i, \quad i = 1, \dots, n, \quad (22.1.1)$$

where $U_1, \dots, U_n$ are independent and identically distributed positive random variables with $\nu = E(\log U_i)$ and $\tau^2 = \text{Var}(\log U_i)$ finite.

- (a) The logarithms follow the linear model with constant variance: $\log Y_i = (\beta_0 + \nu) + \sum_{j \geq 1} x_{ij} \beta_j + \varepsilon_i$, where $\varepsilon_i = \log U_i - \nu$ are independent with mean 0 and variance τ^2 . The slopes are $\beta_1, \dots, \beta_{p-1}$, unchanged; only the intercept absorbs ν .
- (b) If $E(U_i^2) < \infty$, then $E(Y_i) = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}) E(U_1)$ and the standard deviation of Y_i is $\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ times that of U_1 . The standard deviation is proportional to the mean, so the coefficient of variation is the same for every case.
- (c) For two regressor profiles $\mathbf{x}$ and $\mathbf{x}'$, every quantile of Y at $\mathbf{x}'$ is $\exp\{(\mathbf{x}' - \mathbf{x})^\top \boldsymbol{\beta}\}$ times the same quantile at $\mathbf{x}$. The same ratio holds for the geometric means $\exp E(\log Y)$, and for the means when they are finite.

Proof.

- (a) Take logarithms in [Eq. 22.1.1](#) and add and subtract ν . The ε_i are functions of the independent U_i , hence independent, and have the stated moments.
- (b) $\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$ is a constant, so it factors out of the mean and the standard deviation.
- (c) If u_q is a q -quantile of U_1 , then $\exp(\mathbf{x}^\top \boldsymbol{\beta}) u_q$ is a q -quantile of Y at $\mathbf{x}$, because multiplication by a positive constant preserves order. The geometric mean at $\mathbf{x}$ is $\exp(\mathbf{x}^\top \boldsymbol{\beta} + \nu)$. In each case the ratio of the value at $\mathbf{x}'$ to the value at $\mathbf{x}$ is $\exp\{(\mathbf{x}' - \mathbf{x})^\top \boldsymbol{\beta}\}$.

■

Part (c) makes log-scale coefficients easy to report: $(\mathbf{x}' - \mathbf{x})^\top \boldsymbol{\beta}$ is the log of the *same* ratio for medians, upper quartiles, geometric means and means. Part (b) is the diagnostic signature, a raw-scale spread proportional to the fitted value, as in panel (b) of [Figure 22.1.1](#).

Warning. The proposition needs the error to *multiply* the mean. If instead $Y_i = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}) + \varepsilon_i$ with errors of constant variance, then $\log Y_i$ is not a linear function of the regressors plus an error of mean zero. For large means $\log Y_i \approx \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \varepsilon_i \exp(-\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$, so the logarithm *creates* a variance that falls with the level ([Exercise \(B1\)](#)). A mean that is exponential in the regressors combined with errors of constant variance calls for fitting the mean directly, by nonlinear least squares or by a generalized linear model with a logarithmic link ([Chapter 34](#)), not for transforming the data.

22.1.3 The ladder of powers

The logarithm belongs to Tukey's (1977) *ladder* of powers y^p , $p = \dots, -1, -\frac{1}{2}, 0, \frac{1}{2}, 1, 2, \dots$, with $\log y$ in the place of y^0 and $-y^p$ for $p < 0$ so that every rung is increasing. Rungs below $p = 1$ are concave: they pull in a long right tail, reduce a spread that grows with the level, and straighten a relationship that curves upwards. Rungs above $p = 1$ do the opposite. [Section 22.2](#) makes the ordering precise ([Proposition 22.2.1](#)) and estimates the rung, and [Section 22.4](#) proves the rule linking rung and variance: a standard deviation proportional to μ^a calls for the power $1 - a$, the logarithm when $a = 1$ as in [Proposition 22.1.1\(b\)](#).

22.1.4 Three goals and one function

The three claims are not equally important. With non-normal errors, least squares and the usual tests remain asymptotically valid under mild conditions ([Theorem 19.3.2](#)). A non-constant variance leaves the coefficients unbiased but the standard errors wrong ([Theorem 19.2.2](#)). A wrong mean function biases everything. So the mean comes first, then the variance, then the shape of the errors.

Counts show the goals pulling apart. Suppose Y_i is Poisson with mean $\mu_i = \exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta})$. The logarithm linearizes the mean exactly, but the variance of $\log Y_i$ is, to first order in the delta method, about $1/\mu_i$ ([Exercise \(B2\)](#)), which changes with the regressors. The square root stabilizes the variance at about $\frac{1}{4}$ ([Section 22.4](#)), but its mean is about $\exp(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}/2)$, which is not linear in the regressors. (Strictly, zeros have probability $e^{-\mu_i} > 0$, so the statement concerns $\log Y_i$ given $Y_i > 0$, or $\log(Y_i + c)$.) No power does both. The remedy is a model that states the mean and the variance separately, the Poisson generalized linear model of [Chapter 34](#). A transformation can also remove an interaction, under the order condition of [Proposition 16.2.2](#), as the logarithm did for the running times of [Section 16.1](#).

22.1.5 Zeros and negative values

The logarithm and the negative powers need $y > 0$. The common fix $\log(y + c)$ for a “start” $c > 0$ makes the coefficients depend on c when zeros are frequent. The start can be estimated with the power ([Exercise \(B3\)](#)), but a spike at zero usually means two processes, whether a case is positive and how large it is, which no transformation separates; two-part models and generalized linear models ([Chapter 34](#)) are more natural. For responses of both signs, Yeo and Johnson (2000) give a family defined on the whole line.

22.1.6 Exercises

22.1.6.1 A. Check your understanding

Exercise A1.

In the log–log fit of [Example \(Food expenditure on the raw and the log scale\)](#) the slope is 0.8559. By what factor does the median food expenditure differ between two households whose incomes differ by 10 percent? By what factor between households whose incomes differ by a factor of two? Why is the answer the same for the median, the geometric

mean and, under Eq. 22.1.1, the mean?

Solution. The log of the ratio of incomes is $\log 1.1$, so the ratio of medians is $1.1^{0.8559} = \exp(0.8559 \log 1.1)$, about 1.085: a difference of about 8.5 percent. For a factor of two the ratio is $2^{0.8559}$, about 1.81. By Proposition 22.1.1(c) every quantile, the geometric mean and the mean scale by the same factor $\exp\{(\mathbf{x}' - \mathbf{x})^\top \boldsymbol{\beta}\}$, because the error multiplies the whole distribution.

22.1.6.2 B. Practice

Exercise B1.

Let $Y = \mu + \varepsilon$ with $\mu > 0$, $E\varepsilon = 0$, $\text{Var}\varepsilon = \sigma^2$ and σ/μ small. Use $\log(1+u) = u - u^2/2 + O(u^3)$ to show that, to the leading order, $E\log Y \approx \log \mu - \sigma^2/(2\mu^2)$ and $\text{Var}\log Y \approx \sigma^2/\mu^2$. Conclude that when errors are additive with constant variance, the log scale is heteroscedastic, with the variance falling as the mean rises, and its mean is not exactly $\log \mu$.

Solution. Write $\log Y = \log \mu + \log(1+u)$ with $u = \varepsilon/\mu$. Then $\log Y = \log \mu + u - u^2/2 + O(u^3)$. Taking expectations, $E u = 0$ and $E u^2 = \sigma^2/\mu^2$, which gives the mean. For the variance, the leading term of $\log Y - E\log Y$ is u , with variance σ^2/μ^2 . Both depend on μ , hence on the regressors, unless σ is proportional to μ , which is the multiplicative case.

Exercise B2.

Let Y be Poisson with a large mean μ . Use the first-order expansion of the delta method to show that $\text{Var}(\log Y) \approx 1/\mu$ and $\text{Var}(\sqrt{Y}) \approx \frac{1}{4}$, and that $E\sqrt{Y} \approx \sqrt{\mu}$. (Read $\log Y$ given $Y > 0$, since $\Pr(Y = 0) = e^{-\mu}$.) If $\mu = \exp(\mathbf{x}^\top \boldsymbol{\beta})$, which scale has a linear mean and which a constant variance?

Exercise B3.

A colleague fits the same regressors to y and to $\log y$ and prefers the log model because its R^2 is larger. Explain why the two values of R^2 are not comparable. Then take $x = (0, 1, 2)$ and $y = (1, 8, 7)$, fit a straight line to y and to $\log y$, and compare the two values of R^2 with the residual sums of squares on the original scale, using $\exp$ of the fitted values for the log model.

Solution. R^2 is the fraction of the total sum of squares of the response on its own scale that the model explains (Theorem 6.7.2). The two fits explain different totals, so their fractions answer different questions. A likelihood on a common scale, such as the Box–Cox profile of Section 22.2, which includes the Jacobian, does compare them. In the example the raw line has $R^2 = 0.628$ and the log line $R^2 = 0.699$. On the original scale the raw line leaves a residual sum of squares of $32/3$, about 10.67, while the exponentiated log fit leaves 27.37, more than twice as much. The larger R^2 belongs to the fit that predicts y worse, because it is measured on a scale where the large values count for less.

22.1.6.3 C. Going deeper

Exercise C1.

In a 2×2 layout let $\mu_{ij} = (a_i + b_j)^2$ with positive a_i, b_j . Show that the interaction contrast $\mu_{11} - \mu_{12} - \mu_{21} + \mu_{22}$ is $2(a_1 - a_2)(b_1 - b_2)$, and that it is zero on the square-root scale. Now let $Y_{ij} = \mu_{ij} + \varepsilon_{ij}$ with independent errors of variance σ^2 . Is the table of $E \sqrt{Y_{ij}}$ exactly additive? Relate your answer to the caution in [Section 16.2](#).

22.2 The Box–Cox family

Choosing a rung of the ladder by eye works when the evidence is strong, but it gives no measure of uncertainty and no way to compare rungs that fit almost equally well. Box and Cox (1964) turned the choice into a parameter: embed the powers in a family indexed by a real number λ , assume that for some λ the normal linear model holds on the transformed scale, and estimate λ by maximum likelihood along with everything else.

22.2.1 The family

Definition 22.2.1 — The Box–Cox family

For $y > 0$ and $\lambda \in \mathbb{R}$, the **Box–Cox transformation** of y is

$$y^{(\lambda)} = \begin{cases} \frac{y^\lambda - 1}{\lambda}, & \lambda \neq 0, \\ \log y, & \lambda = 0. \end{cases} \quad (22.2.1)$$

For a sample $y_1, \dots, y_n > 0$ with geometric mean $\dot{y} = \exp(n^{-1} \sum_i \log y_i)$, the **normalized** transformation is $z_i^{(\lambda)} = y_i^{(\lambda)} / \dot{y}^{\lambda-1}$, and $\mathbf{z}^{(\lambda)} = (z_1^{(\lambda)}, \dots, z_n^{(\lambda)})^\top$.

In a model with an intercept $y^{(\lambda)}$ and y^λ give the same fit. Subtracting 1 and dividing by λ make the family *continuous* in λ , with the logarithm in its place, and increasing for every λ .

Proposition 22.2.1 — Properties of the family

Let $y > 0$.

- (a) $y^{(\lambda)} \rightarrow \log y$ as $\lambda \rightarrow 0$, so $\lambda \mapsto y^{(\lambda)}$ is continuous.
- (b) For each λ , $y \mapsto y^{(\lambda)}$ is strictly increasing on $(0, \infty)$, with derivative $y^{\lambda-1}$. The normalized transformation has derivative $(y/\dot{y})^{\lambda-1}$, which equals 1 at $y = \dot{y}$ for every λ .
- (c) If $p < q$, then $y^{(q)} = \varphi(y^{(p)})$ for a strictly increasing and strictly convex function φ . Equivalently, moving down the ladder from q to p applies a strictly concave increasing function.

- (d) As y ranges over $(0, \infty)$, $y^{(\lambda)}$ ranges over $(-1/\lambda, \infty)$ if $\lambda > 0$, over $(-\infty, -1/\lambda)$ if $\lambda < 0$, and over $\mathbb{R}$ if $\lambda = 0$.

Proof.

- (a) $y^\lambda = \exp(\lambda \log y) = 1 + \lambda \log y + O(\lambda^2)$, so $(y^\lambda - 1)/\lambda = \log y + O(\lambda)$.
- (b) For $\lambda \neq 0$ the derivative of $(y^\lambda - 1)/\lambda$ is $y^{\lambda-1} > 0$, and for $\lambda = 0$ the derivative of $\log y$ is y^{-1} . Dividing by the constant $y^{\lambda-1}$ gives the second statement.
- (c) Let $u = y^{(p)}$. By (b) the map $y \mapsto u$ has an increasing inverse $y = \psi(u)$ with $\psi'(u) = y^{1-p}$. Then $\varphi = (\cdot)^{(q)} \circ \psi$ has derivative $\varphi'(u) = y^{q-1} y^{1-p} = \psi(u)^{q-p}$. Since $q - p > 0$ and ψ is strictly increasing, φ' is positive and strictly increasing, so φ is strictly increasing and strictly convex. The inverse of a strictly increasing convex function is strictly increasing and concave.
- (d) y^λ takes every value in $(0, \infty)$. For $\lambda > 0$ subtracting 1 and dividing by λ gives $(-1/\lambda, \infty)$, and for $\lambda < 0$ the division reverses the interval to $(-\infty, -1/\lambda)$.

■

Part (c) is the ladder's advice made precise: a plot of $y^{(q)}$ that bends upwards is a convex function of $y^{(p)}$, and a lower power removes some of the bend. Part (d) is a warning. For $\lambda \neq 0$ the transformed response is bounded on one side, so it *cannot* be exactly normal. The Box-Cox model is always an approximation, harmless when the bound is many standard deviations from the data.

22.2.2 The likelihood

The working model is that for some λ the $Y_i^{(\lambda)}$ are independent with $Y_i^{(\lambda)} \sim N(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \sigma^2)$, ignoring the small normal probability beyond the bound of Proposition 22.2.1(d). The likelihood must be written for the *observed* y_i , since otherwise changing λ changes the data being explained. That is where the Jacobian enters, and the geometric mean with it.

Theorem 22.2.2 — Profile likelihood of the Box-Cox parameter

Let $\mathbf{X}$ have rank $r < n$, let $y_1, \dots, y_n > 0$, and for each λ let $\text{SSE}_z(\lambda) = \|(\mathbf{I} - \mathbf{M})\mathbf{z}^{(\lambda)}\|^2$, assumed positive. Under the model above:

- (a) the log-likelihood of $(\boldsymbol{\beta}, \sigma^2, \lambda)$ is

$$\begin{aligned} \ell(\boldsymbol{\beta}, \sigma^2, \lambda) = & -\frac{n}{2} \log(2\pi\sigma^2) - \frac{\|\mathbf{y}^{(\lambda)} - \mathbf{X}\boldsymbol{\beta}\|^2}{2\sigma^2} \\ & + (\lambda - 1) \sum_{i=1}^n \log y_i; \end{aligned} \quad (22.2.2)$$

- (b) for fixed λ it is maximized by the least squares fit of $\mathbf{y}^{(\lambda)}$ on $\mathbf{X}$, and the profile log-likelihood of λ is

$$\ell_p(\lambda) = -\frac{n}{2} \left\{ \log \left(\frac{2\pi \text{SSE}_z(\lambda)}{n} \right) + 1 \right\}, \quad (22.2.3)$$

- so the maximum likelihood estimate $\hat{\lambda}$ is the value that minimizes $\text{SSE}_z(\lambda)$;
- (c) the likelihood ratio statistic for $H : \lambda = \lambda_0$ is $2\{\ell_p(\hat{\lambda}) - \ell_p(\lambda_0)\} = n \log\{\text{SSE}_z(\lambda_0)/\text{SSE}_z(\hat{\lambda})\}$, and the likelihood ratio confidence set of level $1 - \alpha$ is

$$\left\{ \lambda_0 : n \log \frac{\text{SSE}_z(\lambda_0)}{\text{SSE}_z(\hat{\lambda})} \leq \chi_{1,\alpha}^2 \right\}, \quad (22.2.4)$$

where $\chi_{1,\alpha}^2$ is the upper α point of $\chi^2(1)$.

Proof.

- (a) The map $y \mapsto y^{(\lambda)}$ is strictly increasing and differentiable with derivative $y^{\lambda-1}$ (Proposition 22.2.1(b)). By the change-of-variables formula the density of Y_i at y_i is the $N(\mathbf{x}_{(i)}^\top \boldsymbol{\beta}, \sigma^2)$ density at $y_i^{(\lambda)}$ times $y_i^{\lambda-1}$. The Y_i are independent, so the log-likelihood is the sum of the logs, which is Eq. 22.2.2.
- (b) The Jacobian term does not involve $(\boldsymbol{\beta}, \sigma^2)$, and the other two terms are the log-likelihood of the normal linear model with response $\mathbf{y}^{(\lambda)}$. By Theorem 7.3.1 its maximum over $(\boldsymbol{\beta}, \sigma^2)$ is attained at any least squares fit and equals $-\frac{n}{2}\{\log(2\pi \text{SSE}(\mathbf{y}^{(\lambda)})/n) + 1\}$. Now $\mathbf{y}^{(\lambda)} = \dot{y}^{\lambda-1} \mathbf{z}^{(\lambda)}$, so $\text{SSE}(\mathbf{y}^{(\lambda)}) = \dot{y}^{2(\lambda-1)} \text{SSE}_z(\lambda)$, and

$$-\frac{n}{2} \log \dot{y}^{2(\lambda-1)} = -n(\lambda-1) \log \dot{y} = -(\lambda-1) \sum_{i=1}^n \log y_i.$$

This cancels the Jacobian term exactly and leaves Eq. 22.2.3, which is a decreasing function of $\text{SSE}_z(\lambda)$.

- (c) Subtract two values of Eq. 22.2.3. ■

The theorem is algebraic. The *coverage* of Eq. 22.2.4 is a separate, asymptotic matter: if the model holds at λ_0 and the regularity conditions of Wilks's theorem are satisfied, the probability that the set contains λ_0 tends to $1 - \alpha$ (van der Vaart 1998, chapter 16). That result is not proved here, and by Proposition 22.2.1(d) its hypothesis can hold exactly only at $\lambda_0 = 0$. Otherwise, as Hernandez and Johnson (1980) showed, $\hat{\lambda}$ converges to the value whose normal model is closest in Kullback–Leibler divergence to the true distribution, and the interval describes the precision of that best approximation.

Remark (Why normalize). Residual sums of squares of $\mathbf{y}^{(\lambda)}$ are in the units of y^λ and cannot be compared across λ . The geometric mean builds the Jacobian into the response: every $\mathbf{z}^{(\lambda)}$ is in the units of y , with unit slope at $\dot{y}$ (Proposition 22.2.1(b)), so $s_z(\lambda) = \{\text{SSE}_z(\lambda)/(n-r)\}^{1/2}$ can be compared across λ , and minimizing it is maximizing the likelihood.

The normalization also makes the analysis independent of the units in which y is recorded.

Proposition 22.2.3 — Units of the response

Suppose $\mathbf{1} \in \mathcal{C}(\mathbf{X})$. If every y_i is multiplied by the same $c > 0$, then $\text{SSE}_z(\lambda)$ is multiplied

Figure 22.2.1: Box–Cox profile log-likelihoods for Engel’s data, relative to their maxima. (a) Food expenditure linear in income. (b) Linear in log income. The dashed line is at $-\chi^2_{1,0.05}/2$, and the vertical lines mark the 95% likelihood ratio intervals.

by c^2 for every λ . Consequently ℓ_p changes by a constant, and $\hat{\lambda}$, the likelihood ratio statistics and the set [Eq. 22.2.4](#) are unchanged.

Proof. The geometric mean of $cy_1, \dots, cy_n$ is $c\bar{y}$. For $\lambda \neq 0$,

$$\frac{(cy_i)^\lambda - 1}{\lambda(c\bar{y})^{\lambda-1}} = c \frac{y_i^\lambda - 1}{\lambda\bar{y}^{\lambda-1}} + c \frac{1 - c^{-\lambda}}{\lambda\bar{y}^{\lambda-1}},$$

and for $\lambda = 0$, $c\bar{y} \log(cy_i) = c\bar{y} \log y_i + c\bar{y} \log c$. In both cases the new normalized vector is $c\mathbf{z}^{(\lambda)} + k\mathbf{1}$ for a constant k . Since $(\mathbf{I} - \mathbf{M})\mathbf{1} = \mathbf{0}$, its residual vector is $c(\mathbf{I} - \mathbf{M})\mathbf{z}^{(\lambda)}$, and SSE_z is multiplied by c^2 . By [Eq. 22.2.3](#), ℓ_p changes by $-n \log c$, a constant. ■

Example. (Box–Cox for Engel’s data)

First let transformed food expenditure be linear in income. The profile log-likelihood, panel (a) of [Figure 22.2.1](#), peaks at $\hat{\lambda} = 0.63$, and the 95% interval given by [Eq. 22.2.4](#) is $[0.45, 0.80]$. Both the raw scale and the logarithm are rejected: the likelihood ratio statistics are 18.8 for $\lambda = 1$ and 37.2 for $\lambda = 0$, against the critical value 3.84.

Now let food expenditure be linear in *log* income. The profile, panel (b), peaks at $\hat{\lambda} = 0.025$, with interval $[-0.117, 0.162]$. The logarithm is well inside, with statistic 0.12, while the square root (46.6) and the raw scale (181.4) are firmly rejected. With log income as the regressor, the normalized residual standard deviation is 78.6 on the log scale and 115.6 on the raw scale, both in the currency of the survey (the geometric mean of food expenditure is 574.4).

The answers differ because a response transformation is chosen to make a *particular* mean function linear. [Section 22.3](#) estimates the two powers together.

```

22.2.3 Choosing a convenient value

Nobody thinks in units of food expenditure raised to the power 0.025. The usual practice is to pick a simple value inside the interval, here $\lambda = 0$, and to analyse on that scale as if it had

been chosen in advance. Simple values have interpretations: the logarithm gives percentages and elasticities, the reciprocal turns a time into a rate.

Treating the chosen scale as known ignores that the data chose it. Bickel and Doksum (1981) showed that when λ is estimated, the unconditional variance of $\hat{\beta}$ can be many times its fixed- λ value. Box and Cox (1982) replied that the unconditional variance of a coefficient whose *units* change with λ has no scientific meaning, and Hinkley and Runger (1984) argued for inference conditional on the selected scale. Quantities whose meaning does not depend on λ , such as a prediction of y or the hypothesis that a regressor has no effect at all ([Exercise \(C1\)](#)), avoid the difficulty, and resampling ([Chapter 23](#)) can include the choice of scale in their uncertainty.

22.2.4 The constructed variable

A single extra regression gives a quick check of a proposed λ_0 and shows which observations drive the evidence. Let

$$\mathbf{w}^{(\lambda_0)} = \left. \frac{\partial \mathbf{z}^{(\lambda)}}{\partial \lambda} \right|_{\lambda=\lambda_0}, \quad (22.2.5)$$

computed entry by entry. Differentiating $(y^\lambda - 1)y^{1-\lambda}/\lambda$ at $\lambda_0 = 1$ gives $w_i = y_i\{\log(y_i/\bar{y}) - 1\} + 1 + \log \bar{y}$, and at $\lambda_0 = 0$ it gives $w_i = \frac{1}{2}\dot{y}\{\log(y_i/\bar{y})\}^2 - \frac{1}{2}\dot{y}(\log \bar{y})^2$ ([Exercise \(B1\)](#)). In a model with an intercept the additive constants do not matter, so the **constructed variables** are $y_i\{\log(y_i/\bar{y}) - 1\}$ for checking the raw scale and $\frac{1}{2}\dot{y}\{\log(y_i/\bar{y})\}^2$ for checking the logarithm.

Proposition 22.2.4 — A constructed variable for the response power

Let $\hat{\mathbf{e}}_0 = (\mathbf{I} - \mathbf{M})\mathbf{z}^{(\lambda_0)}$ and $\mathbf{w} = \mathbf{w}^{(\lambda_0)}$, with $\mathbf{w} \notin \mathcal{C}(\mathbf{X})$.

- (a) $\left. \frac{d}{d\lambda} \text{SSE}_z(\lambda) \right|_{\lambda_0} = 2\hat{\mathbf{e}}_0^\top \mathbf{w}$, and so $\ell'_p(\lambda_0) = -n \hat{\mathbf{e}}_0^\top \mathbf{w} / \text{SSE}_z(\lambda_0)$.
- (b) In the least squares fit of $\mathbf{z}^{(\lambda_0)}$ on $[\mathbf{X}, \mathbf{w}]$, the coefficient of $\mathbf{w}$ is $\hat{\gamma} = \hat{\mathbf{e}}_0^\top \mathbf{w} / \|(\mathbf{I} - \mathbf{M})\mathbf{w}\|^2$. Hence $\hat{\gamma}$ and $\ell'_p(\lambda_0)$ have opposite signs, and $\hat{\gamma} = 0$ iff λ_0 is a stationary point of the profile log-likelihood. In particular $\hat{\gamma} = 0$ at an interior maximum $\lambda_0 = \hat{\lambda}$.

Proof.

- (a) $\text{SSE}_z(\lambda) = \mathbf{z}^{(\lambda)\top}(\mathbf{I} - \mathbf{M})\mathbf{z}^{(\lambda)}$. Its derivative is $2\mathbf{z}^{(\lambda)\top}(\mathbf{I} - \mathbf{M})\partial\mathbf{z}^{(\lambda)}/\partial\lambda$, because $\mathbf{I} - \mathbf{M}$ is symmetric. At λ_0 this is $2\hat{\mathbf{e}}_0^\top \mathbf{w}$. The chain rule applied to [Eq. 22.2.3](#) gives the derivative of ℓ_p .
- (b) By [Theorem 6.6.2](#) the coefficient of $\mathbf{w}$ is $\tilde{\mathbf{w}}^\top \mathbf{z}^{(\lambda_0)} / \|\tilde{\mathbf{w}}\|^2$ with $\tilde{\mathbf{w}} = (\mathbf{I} - \mathbf{M})\mathbf{w} \neq \mathbf{0}$, and $\tilde{\mathbf{w}}^\top \mathbf{z}^{(\lambda_0)} = \mathbf{w}^\top (\mathbf{I} - \mathbf{M})\mathbf{z}^{(\lambda_0)} = \mathbf{w}^\top \hat{\mathbf{e}}_0$. Comparing with (a) gives the rest. ■

To first order $\mathbf{z}^{(\lambda)} \approx \mathbf{z}^{(\lambda_0)} + (\lambda - \lambda_0)\mathbf{w}$, so if the model holds at λ , then $\mathbf{z}^{(\lambda_0)} \approx \mathbf{X}\beta - (\lambda - \lambda_0)\mathbf{w} + \boldsymbol{\varepsilon}$ and $\lambda_0 - \hat{\gamma}$ is a rough one-step estimate of λ . The added-variable plot of $\mathbf{w}$ ([Theorem 6.6.2](#)) shows which observations carry the evidence, the use Atkinson (1985) made of it. The t statistic

of $\hat{\gamma}$ tests $\lambda = \lambda_0$, but not exactly: $\mathbf{w}$ is a function of $\mathbf{y}$ itself, not only of the fitted values, so [Theorem 14.7.2](#) does not apply.

Example. (The constructed variable for Engel's data)

In the model with log income, the constructed variable for $\lambda_0 = 1$ has coefficient $\hat{\gamma} = 0.831$ and $t = 17.96$: overwhelming evidence against the raw scale. The one-step estimate $1 - 0.831 = 0.169$ is far from $\hat{\lambda} = 0.025$, as expected from so far away. For $\lambda_0 = 0$ the coefficient is -0.031 with $t = -0.38$.

In 4000 data sets simulated from the fitted log-log model, with normal errors and Engel's incomes (so $\lambda = 0$ is true), the 95% likelihood ratio interval covers 0 in a fraction 0.945, close to nominal, while the nominal 5% constructed-variable test rejects in a fraction 0.075. The constructed variable is a diagnostic; the likelihood interval is for inference.

Deleting one household at a time, the largest change moves $\hat{\lambda}$ from 0.025 to 0.081, when the household with income 2823 and food expenditure 2033, the largest in the survey, is removed. It lies well above the line in panels (a) and (c) of [Figure 22.1.1](#), at a point of high leverage (the leverage of Engel's households is examined in [Section 20.2](#)). The logarithm stays inside the interval whichever household is removed. For a fixed scale [Chapter 20](#) gives deletion formulas ([Theorem 20.3.1](#), and [Proposition 10.6.2](#) for their computation); for $\hat{\lambda}$ the refits are cheap enough to do directly.

```
def constructed(y, lam0, h=1e-5):
    """w = d z(lambda)/d lambda at lam0 (numerical derivative of the normalized
    transform)."""
    return (box_cox_z(y, lam0 + h) - box_cox_z(y, lam0 - h)) / (2 * h)

def constructed_test(y, X, lam0):
    """Regress z(lam0) on [X, w]: the coefficient of w and its t statistic."""
    w = constructed(y, lam0)
    fit = sm.OLS(box_cox_z(y, lam0), np.column_stack([X, w])).fit()
    return fit.params[-1], fit.tvalues[-1]

for lam0 in (1, 0):
    g, t = constructed_test(food, X_log, lam0)
    print(f"lambda0 = {lam0}: coefficient of w {g:.3f}, t = {t:.2f}, one-step
    estimate {lam0 - g:.3f}")
```

In the browser the simulation uses 200 replications, so its fractions are rough.

```
def simulate(reps, seed):
    rng = np.random.default_rng(seed)
    fit = sm.OLS(np.log(food), X_log).fit()           # the log-log fit: data
    generated with lambda = 0

      variable test {size:.3f}")

```

Warning. $\hat{\lambda}$ responds to anything that spoils the normal linear model: curvature, a variance that changes with the level, skewness, single outlying cases. A value that makes the residuals look better has not necessarily corrected the defect that mattered. After transforming, look at the residual plots of [Chapter 20](#) and [Chapter 21](#) again, on the new scale.

22.2.5 Exercises

22.2.5.1 A. Check your understanding

Exercise A1.

Compute $4^{(\lambda)}$ for $\lambda = -1, 0, \frac{1}{2}, 1, 2$. Check that the values increase with λ , and explain, using the definition, why $y^{(\lambda)}$ is increasing in λ for every fixed $y > 0$.

Exercise A2.

Show that if every y_i is multiplied by $c > 0$, the residual sum of squares of the *unnormalized* $\mathbf{y}^{(\lambda)}$ in a model with an intercept is multiplied by $c^{2\lambda}$. Conclude that choosing λ by minimizing the unnormalized residual sum of squares would give an answer that depends on the units of y .

Solution. For $\lambda \neq 0$, $((cy)^\lambda - 1)/\lambda = c^\lambda(y^\lambda - 1)/\lambda + (c^\lambda - 1)/\lambda$, a multiple c^λ of $y^{(\lambda)}$ plus a constant, which the intercept absorbs. So the residual sum of squares is multiplied by $c^{2\lambda}$, a factor that depends on λ . Changing the units reweights the comparison between different values of λ : as c grows the comparison is pushed towards ever more negative λ , and as c shrinks towards ever larger λ . By [Proposition 22.2.3](#) the normalized version has the common factor c^2 and no such problem.

22.2.5.2 B. Practice

Exercise B1.

Derive the constructed variable at $\lambda_0 = 0$. Write $z^{(\lambda)} = f(\lambda) \dot{y}^{1-\lambda}$ with $f(\lambda) = (y^\lambda - 1)/\lambda$, expand $f(\lambda) = \log y + \frac{1}{2}\lambda(\log y)^2 + O(\lambda^2)$, and show that $\partial z^{(\lambda)}/\partial \lambda$ at 0 is $\frac{1}{2}\dot{y}\{\log(y/\dot{y})\}^2 - \frac{1}{2}\dot{y}(\log \dot{y})^2$.

Solution. The expansion follows from $y^\lambda = 1 + \lambda \log y + \frac{1}{2}\lambda^2(\log y)^2 + O(\lambda^3)$, so $f(0) = \log y$ and $f'(0) = \frac{1}{2}(\log y)^2$. Also $\dot{y}^{1-\lambda} = \dot{y} \exp(-\lambda \log \dot{y})$ has value $\dot{y}$ and derivative

$-\dot{y} \log \dot{y}$ at 0. By the product rule the derivative of $z^{(\lambda)}$ at 0 is

$$\dot{y} \left\{ \frac{1}{2} (\log y)^2 - \log y \log \dot{y} \right\} = \frac{1}{2} \dot{y} \{ (\log y - \log \dot{y})^2 - (\log \dot{y})^2 \}.$$

Exercise B2.

In [Example \(Box-Cox for Engel's data\)](#), with log income as regressor, the normalized residual standard deviations are 78.6 at $\lambda = 0$ and 115.6 at $\lambda = 1$. Show from [Eq. 22.2.3](#) that the difference between the likelihood ratio statistics at $\lambda = 1$ and $\lambda = 0$ is $2n \log\{s_z(1)/s_z(0)\}$, and check it against the values 181.4 and 0.12 of the example.

Exercise B3.

For data that may include zeros, consider the shifted family $(y+c)^{(\lambda)}$ with an unknown c such that every $y_i + c > 0$. Write the log-likelihood of $(\boldsymbol{\beta}, \sigma^2, \lambda, c)$, show that the profile log-likelihood of (λ, c) is [Eq. 22.2.3](#) with $\mathbf{z}^{(\lambda)}$ computed from $y_i + c$ and its geometric mean, and state the likelihood ratio confidence region for (λ, c) .

Solution. The Jacobian of $y \mapsto (y+c)^{(\lambda)}$ is $(y+c)^{\lambda-1}$, so the log-likelihood is [Eq. 22.2.2](#) with y_i replaced by $y_i + c$ throughout. The proof of [Theorem 22.2.2](#) goes through word for word for each fixed c , with $\dot{y}$ the geometric mean of the $y_i + c$. The region is $\{(\lambda, c) : n \log\{\text{SSE}_z(\lambda, c)/\text{SSE}_z(\hat{\lambda}, \hat{c})\} \leq \chi_{2,\alpha}^2\}$, two degrees of freedom because two parameters are profiled. The maximization needs care near the boundary $c \rightarrow -\min_i y_i$: there $\log(\min_i y_i + c) \rightarrow -\infty$, so for $\lambda < 1$ the Jacobian term $(\lambda-1) \sum_i \log(y_i + c)$ grows without bound, and the likelihood can be unbounded, as it is for the three-parameter lognormal distribution.

22.2.5.3 C. Going deeper

Exercise C1.

Suppose that the conditional distribution of Y given $(x_1, \dots, x_k)$ does not depend on x_1 . Show that the same holds for $g(Y)$ for every strictly increasing g , so the hypothesis that x_1 has no effect is the same hypothesis on every scale. Why does the converse direction, from a zero coefficient on one scale to a zero coefficient on another, fail when the conditional distribution does depend on x_1 ? Give an example with two groups whose medians are equal but whose means are not.

Exercise C2.

Let $\hat{\lambda}$ be an interior maximizer of ℓ_p , and write $s(\lambda) = \hat{\mathbf{e}}(\lambda)^\top \mathbf{w}^{(\lambda)}$, which is zero at $\hat{\lambda}$ by [Proposition 22.2.4](#). Suppose case i is deleted. Show, by one Newton step for the equation $s = 0$, that the change in $\hat{\lambda}$ is approximately proportional to the contribution $\hat{\varepsilon}_{(i)} \tilde{w}_{(i)}$ of that case, where both factors are computed with the case deleted. Which cases does this predict to be influential for $\hat{\lambda}$, and how does leverage in the regression of $\mathbf{w}$ on $\mathbf{X}$ enter?

22.3 Transforming regressors

Transforming a regressor changes only the mean function. The errors are untouched, and there is no Jacobian, because the data being explained stay the same. What is at stake is bias. If $E(Y) = \mathbf{X}_2\boldsymbol{\beta}_2 + \beta_1 g(\mathbf{x}_1)$ and the analyst fits $\mathbf{x}_1$ itself, the missing part $\beta_1\{g(\mathbf{x}_1) - \mathbf{x}_1\}$ acts as an omitted regressor (Proposition 5.5.7(a) and Theorem 19.1.2). It shows up as curvature in the residuals, and tests against a larger model detect it (Proposition 14.7.1 and Theorem 14.7.2). This section finds the right g , first by looking, then by estimating a power.

22.3.1 Component-plus-residual plots

The component-plus-residual plot of Section 20.1 plots the partial residuals $\hat{\epsilon} + \hat{\beta}_1\mathbf{x}_1$ against $\mathbf{x}_1$. Its least squares line has slope $\hat{\beta}_1$ and residuals $\hat{\epsilon}$, as in the added-variable plot, and that section warns that it can mislead when $\mathbf{x}_1$ is related nonlinearly to the other regressors. The next result measures how far.

Proposition 22.3.1 — What the plot shows

Let $\mathbf{X} = [\mathbf{x}_1, \mathbf{X}_2]$ have full column rank, with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_2)$, and let $\hat{\boldsymbol{\beta}}$ and $\hat{\epsilon}$ be the coefficients and residuals of the least squares fit of $\mathbf{y}$ on $\mathbf{X}$. Let $\mathbf{M}$ and $\mathbf{M}_2$ project onto $\mathcal{C}(\mathbf{X})$ and $\mathcal{C}(\mathbf{X}_2)$, and $\tilde{\mathbf{x}}_1 = (\mathbf{I} - \mathbf{M}_2)\mathbf{x}_1$.

- (a) If $E(\mathbf{Y}) = \mathbf{g} + \mathbf{X}_2\boldsymbol{\beta}_2$, where $\mathbf{g}$ has entries $g(x_{i1})$ for some function g , then

$$E(\hat{\epsilon} + \hat{\beta}_1\mathbf{x}_1) = \mathbf{g} - \mathbf{M}_2(\mathbf{g} - b\mathbf{x}_1), \quad b = E(\hat{\beta}_1) = \frac{\tilde{\mathbf{x}}_1^\top \mathbf{g}}{\|\tilde{\mathbf{x}}_1\|^2}. \quad (22.3.1)$$

- (b) In particular, if $\mathcal{C}(\mathbf{X}_2)$ is spanned by $\mathbf{1}$ alone, the expected partial residuals are $\mathbf{g}$ shifted by a constant, so the plot shows g exactly apart from its level.

Proof.

- (a) Since $\mathbf{X}_2\boldsymbol{\beta}_2 \in \mathcal{C}(\mathbf{X})$, $E(\hat{\epsilon}) = (\mathbf{I} - \mathbf{M})(\mathbf{g} + \mathbf{X}_2\boldsymbol{\beta}_2) = (\mathbf{I} - \mathbf{M})\mathbf{g}$. By Theorem 6.6.2(a), $\hat{\beta}_1 = \tilde{\mathbf{x}}_1^\top \mathbf{Y} / \|\tilde{\mathbf{x}}_1\|^2$, whose mean is $\tilde{\mathbf{x}}_1^\top \mathbf{g} / \|\tilde{\mathbf{x}}_1\|^2 = b$ because $\tilde{\mathbf{x}}_1 \perp \mathcal{C}(\mathbf{X}_2)$. By Lemma 6.6.1(c), $\mathbf{M} = \mathbf{M}_2 + \tilde{\mathbf{x}}_1\tilde{\mathbf{x}}_1^\top / \|\tilde{\mathbf{x}}_1\|^2$, so $(\mathbf{I} - \mathbf{M})\mathbf{g} = \mathbf{g} - \mathbf{M}_2\mathbf{g} - b\tilde{\mathbf{x}}_1$. Adding $b\mathbf{x}_1 = b\tilde{\mathbf{x}}_1 + b\mathbf{M}_2\mathbf{x}_1$ gives $\mathbf{g} - \mathbf{M}_2\mathbf{g} + b\mathbf{M}_2\mathbf{x}_1$, which is Eq. 22.3.1.
- (b) If $\mathcal{C}(\mathbf{X}_2) = \text{span}\{\mathbf{1}\}$, then $\mathbf{M}_2\mathbf{v} = \bar{v}\mathbf{1}$ for every $\mathbf{v}$. ■

The distortion $\mathbf{M}_2(\mathbf{g} - b\mathbf{x}_1)$ is the part of the *nonlinearity* $\mathbf{g} - b\mathbf{x}_1$ that the other regressors reproduce linearly. Correlation with $\mathbf{x}_1$ is not in itself harmful; a regressor that resembles the curvature is. Cook (1993) showed for random regressors that the plot recovers g , up to a linear term, when the conditional mean of the other regressors given x_1 is linear in x_1 , and proposed CERES plots for other cases. The **augmented partial residual plot** of Mallows (1986) adds $\mathbf{x}_1^2$ to the fit and plots $\hat{\epsilon} + \hat{\beta}_1\mathbf{x}_1 + \hat{\beta}_{11}\mathbf{x}_1^2$. Its expectation is $\mathbf{g}$ minus the part of $\mathbf{g} - b_1\mathbf{x}_1 - b_{11}\mathbf{x}_1^2$ that the other regressors reproduce, small when g is nearly quadratic (Exercise (B3)).

Figure 22.3.1: Component-plus-residual plots for simulated data with $E(Y) = 3 \log x_1 + x_2$. Points: partial residuals. Dashed: the true g , centred. Small squares: the expected partial residuals Eq. 22.3.1, which scatter because they depend on the simulated x_2 . (a) x_2 linearly related to x_1 . (b) x_2 close to $\sqrt{x_1}$: the plot hides the curvature. (c) The augmented plot for the data of (b).

Example. (When the plot misleads)

The script simulates 120 cases with $E(Y) = 3 \log x_1 + x_2$, x_1 uniform on $[1, 10]$, and measures how much of the curvature of g the expected plot keeps (the coefficient of the nonlinear part of g in that of Eq. 22.3.1; 1 is faithful). In panel (a) of Figure 22.3.1, x_2 is linear in x_1 plus noise, with correlation 0.95, and the plot keeps 0.99. In panel (b), x_2 is a noisy square root of x_1 , with correlation 0.99; it resembles the logarithm and takes over much of the curvature, and the plot keeps only 0.45, its slope even changing sign. The augmented plot, panel (c), restores 0.88.

```

22.3.2 Power transformations: Box and Tidwell

When the plot suggests a power, it can be estimated. Box and Tidwell (1962) considered the mean function

$$E(\mathbf{Y}) = \mathbf{X}_2 \boldsymbol{\beta}_2 + \beta_1 \mathbf{x}^{(\alpha)}, \quad \mathbf{x}^{(\alpha)} = (x_1^{(\alpha)}, \dots, x_n^{(\alpha)})^\top, \quad (22.3.2)$$

for a positive regressor $\mathbf{x}$, with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_2)$ and Eq. 22.2.1 applied to the regressor. For fixed α this is a linear model, and $\hat{\alpha}$ minimizes the residual sum of squares $\text{SSE}(\alpha)$ of the fit of $\mathbf{y}$ on $[\mathbf{X}_2, \mathbf{x}^{(\alpha)}]$. Under normal errors it is the maximum likelihood estimate, and $\{\alpha : n \log\{\text{SSE}(\alpha)/\text{SSE}(\hat{\alpha})\} \leq \chi_{1,0.05}^2\}$ is an asymptotic 95% interval under the conditions of Wilks's theorem, which include $\beta_1 \neq 0$ (Exercise (C1)). The derivative of $x^{(\alpha)}$ with respect to α at $\alpha_0 \neq 0$ is $x^{\alpha_0} \log x / \alpha_0 - x^{(\alpha_0)} / \alpha_0$, and at $\alpha_0 = 0$ it is $\frac{1}{2}(\log x)^2$ (Exercise (B1)). Since $x^{(\alpha_0)}$ and $\mathbf{1}$ are already in the model, the part that matters is the **constructed variable**

$$\mathbf{w} = \begin{cases} (x_i^{\alpha_0} \log x_i / \alpha_0)_{i=1}^n, & \alpha_0 \neq 0, \\ (\frac{1}{2}(\log x_i)^2)_{i=1}^n, & \alpha_0 = 0. \end{cases} \quad (22.3.3)$$

For $\alpha_0 = 1$ it is $x \log x$.

Theorem 22.3.2 — Box–Tidwell

Let $\mathbf{X}_0 = [\mathbf{X}_2, \mathbf{x}^{(\alpha_0)}]$ have full column rank p , with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_2)$, let $\mathbf{w}$ be the constructed variable Eq. 22.3.3, and suppose $[\mathbf{X}_0, \mathbf{w}]$ has full column rank $p+1 < n$. Let $\hat{\beta}_1$ be the coefficient of $\mathbf{x}^{(\alpha_0)}$ and $\hat{\boldsymbol{\varepsilon}}_0$ the residual vector in the least squares fit of $\mathbf{y}$ on $\mathbf{X}_0$, and let $\hat{\gamma}$ be the coefficient of $\mathbf{w}$ in the fit of $\mathbf{y}$ on $[\mathbf{X}_0, \mathbf{w}]$.

- (a) **Exact test.** If $\mathbf{Y} \sim N_n(\mathbf{X}_0\boldsymbol{\beta}, \sigma^2\mathbf{I})$, which is Eq. 22.3.2 with $\alpha = \alpha_0$, then the t statistic of $\hat{\gamma}$ has the $t(n-p-1)$ distribution.
- (b) **The step.** If $\hat{\beta}_1 \neq 0$, one Gauss–Newton step for minimizing $\|\mathbf{y} - \mathbf{X}_2\boldsymbol{\beta}_2 - \beta_1\mathbf{x}^{(\alpha)}\|^2$, started from the least squares coefficients at α_0 , moves α to

$$\alpha_1 = \alpha_0 + \hat{\gamma}/\hat{\beta}_1. \quad (22.3.4)$$

- (c) **Stationarity.** $\text{SSE}(\alpha)$ is differentiable at α_0 with $\text{SSE}'(\alpha_0) = -2\hat{\beta}_1\hat{\boldsymbol{\epsilon}}_0^\top \mathbf{w} = -2\hat{\beta}_1\hat{\gamma}\|(\mathbf{I} - \mathbf{M}_0)\mathbf{w}\|^2$, where $\mathbf{M}_0$ projects onto $\mathcal{C}(\mathbf{X}_0)$. So if $\hat{\beta}_1 \neq 0$, then $\hat{\gamma} = 0$ iff α_0 is a stationary point of SSE, and every fixed point of the iteration Eq. 22.3.4 is a stationary point.

Proof. Write $\mathbf{d} = \partial\mathbf{x}^{(\alpha)}/\partial\alpha$ at α_0 . By the derivative computed above, $\mathbf{d} - \mathbf{w}$ is a multiple of $\mathbf{x}^{(\alpha_0)}$, so $\mathbf{d} - \mathbf{w} \in \mathcal{C}(\mathbf{X}_0)$ and $(\mathbf{I} - \mathbf{M}_0)\mathbf{d} = (\mathbf{I} - \mathbf{M}_0)\mathbf{w} =: \tilde{\mathbf{w}}$, which is nonzero because $[\mathbf{X}_0, \mathbf{w}]$ has full rank. By Theorem 6.6.2(a), $\hat{\gamma} = \tilde{\mathbf{w}}^\top \mathbf{y}/\|\tilde{\mathbf{w}}\|^2$, and $\tilde{\mathbf{w}}^\top \mathbf{y} = \mathbf{w}^\top (\mathbf{I} - \mathbf{M}_0)\mathbf{y} = \mathbf{w}^\top \hat{\boldsymbol{\epsilon}}_0$.

- (a) The column $\mathbf{w}$ depends on $\mathbf{x}$ alone, not on $\mathbf{Y}$. The t test for $\hat{\gamma}$ is therefore the F test of $\mathcal{C}(\mathbf{X}_0)$ against the fixed larger space $\mathcal{C}([\mathbf{X}_0, \mathbf{w}])$, with $t^2 = F$ and a symmetric null distribution. By Proposition 14.7.1(a), $F \sim F(1, n-p-1)$ when $\mathbf{E}(\mathbf{Y}) \in \mathcal{C}(\mathbf{X}_0)$, so $t \sim t(n-p-1)$.
- (b) The mean function $\boldsymbol{\mu}(\boldsymbol{\beta}_2, \beta_1, \alpha) = \mathbf{X}_2\boldsymbol{\beta}_2 + \beta_1\mathbf{x}^{(\alpha)}$ has derivative matrix $\mathbf{J} = [\mathbf{X}_2, \mathbf{x}^{(\alpha_0)}, \hat{\beta}_1\mathbf{d}]$ at the starting point, where the residual is $\hat{\boldsymbol{\epsilon}}_0$. The Gauss–Newton step is the least squares coefficient vector of $\hat{\boldsymbol{\epsilon}}_0$ on $\mathbf{J}$, and its last entry is the change in α . By Theorem 6.6.2(a) that entry is

$$\frac{\{(\mathbf{I} - \mathbf{M}_0)\hat{\beta}_1\mathbf{d}\}^\top \hat{\boldsymbol{\epsilon}}_0}{\|(\mathbf{I} - \mathbf{M}_0)\hat{\beta}_1\mathbf{d}\|^2} = \frac{1}{\hat{\beta}_1} \frac{\tilde{\mathbf{w}}^\top \hat{\boldsymbol{\epsilon}}_0}{\|\tilde{\mathbf{w}}\|^2} = \frac{\hat{\gamma}}{\hat{\beta}_1},$$

using $\tilde{\mathbf{w}}^\top \hat{\boldsymbol{\epsilon}}_0 = \tilde{\mathbf{w}}^\top \mathbf{y}$, which holds because $\tilde{\mathbf{w}} \perp \mathcal{C}(\mathbf{X}_0)$.

- (c) Let $\mathbf{X}(\alpha) = [\mathbf{X}_2, \mathbf{x}^{(\alpha)}]$, which has full column rank near α_0 , and let $\hat{\boldsymbol{\beta}}(\alpha)$ be its least squares coefficients, a differentiable function of α . Then $\text{SSE}(\alpha) = \|\mathbf{y} - \mathbf{X}(\alpha)\hat{\boldsymbol{\beta}}(\alpha)\|^2$, and

$$\text{SSE}'(\alpha_0) = -2\hat{\boldsymbol{\epsilon}}_0^\top \{\hat{\beta}_1\mathbf{d} + \mathbf{X}_0\hat{\boldsymbol{\beta}}'(\alpha_0)\} = -2\hat{\beta}_1\hat{\boldsymbol{\epsilon}}_0^\top \mathbf{d} = -2\hat{\beta}_1\hat{\boldsymbol{\epsilon}}_0^\top \mathbf{w},$$

because $\hat{\boldsymbol{\epsilon}}_0 \perp \mathcal{C}(\mathbf{X}_0)$ and $\mathbf{d} - \mathbf{w} \in \mathcal{C}(\mathbf{X}_0)$. Finally $\hat{\boldsymbol{\epsilon}}_0^\top \mathbf{w} = \hat{\gamma}\|\tilde{\mathbf{w}}\|^2$ from the first paragraph. ■

Part (a) is exact because this constructed variable is built from the fixed regressor, not from the response as in Proposition 22.2.4. Part (b) identifies the Box–Tidwell iteration with Gauss–Newton, fast near a well-determined minimum and liable to oscillate otherwise, so in one dimension it is safer to minimize $\text{SSE}(\alpha)$ directly; by part (c) the two agree at convergence. Several powers can be stepped at once (Exercise (C2)).

Example. (Transforming income)

With $\log(\text{food})$ as the response and $\text{income}^{(\alpha)}$ as the regressor, starting from $\alpha_0 = 1$,

the Box–Tidwell iteration gives -0.053 after one step and -0.182 after two, where it stays. The direct minimization agrees: $\hat{\alpha} = -0.182$, with 95% likelihood ratio interval $[-0.334, -0.036]$. The constructed-variable t statistic is -16.58 at $\alpha_0 = 1$, so untransformed income is decisively rejected, and -2.47 at $\alpha_0 = 0$, beyond the critical value 1.97 , so the logarithm is rejected at the 5% level as well. As a check on part (a), 4000 data sets simulated from the log–log fit give a rejection rate of 0.047 for this test.

The rejection rests largely on one household. The richest, with income 4958 and food expenditure 1827, sits far to the right in panel (c) of [Figure 22.1.1](#), below the line. Without it, $\hat{\alpha} = -0.119$, and the likelihood ratio statistic for $\alpha = 0$ falls from 5.98 to 1.77 . A negative power says food expenditure flattens among the richest households, where the data are few; Cook’s distance ([Definition 20.4.1](#)) pursues this.

```
import numpy as np
import statsmodels.api as sm

df = sm.datasets.engel.load_pandas().data
income, food = df["income"].to_numpy(), df["foodexp"].to_numpy()
n = len(food)
y = np.log(food)

def bc(x, a):
    """Box-Cox transform (x^a - 1)/a, with log x at a = 0."""
    return np.log(x) if abs(a) < 1e-12 else np.expml(a * np.log(x)) / a

def fit(y, x, a):
    return sm.OLS(y, np.column_stack([np.ones(len(y)), bc(x, a)]).fit()

def box_tidwell_step(y, x, a0):
    """One Box-Tidwell (Gauss-Newton) step: a1 = a0 + gamma/beta1."""
    beta1 = fit(y, x, a0).params[1] # slope of x^(a0) in the null
    fit
    w = x**a0 * np.log(x) / a0 if a0 != 0 else np.log(x) ** 2 / 2 # d bc(x, a)/da,
    up to C(X0)
    aug = sm.OLS(y, np.column_stack([np.ones(len(y)), bc(x, a0), w])).fit()
    return a0 + aug.params[2] / beta1, aug.tvalues[2]

a, path = 1.0, [1.0]
for _ in range(8):
    a, t = box_tidwell_step(y, income, a)
    path.append(a)
print("Box-Tidwell iterates from alpha = 1:", " ".join(f"{v:.4f}" for v in path))
```

22.3.3 Choosing both scales together

The best power for the response depends on the scale of the regressor, and conversely, so the two can be estimated together. With response $\mathbf{z}^{(\lambda)}$ and model matrix $[\mathbf{1}, \mathbf{x}^{(\alpha)}]$ the proof of [Theorem 22.2.2](#) goes through unchanged, since the Jacobian involves only $\mathbf{y}$: the joint profile log-likelihood is $-\frac{n}{2} \log \text{SSE}_z(\lambda, \alpha)$ plus a constant.

Figure 22.3.2: Joint profile log-likelihood of the response power λ and the income power α for Engel's data. The thick contour bounds the 95% likelihood ratio region, the thin contours are 10, 20 and 40 units of log-likelihood below the maximum (the dot). Squares mark the log-log and raw models.

Example. (Two powers for Engel's data)

Figure 22.3.2 shows the joint profile. The maximum is at $(\hat{\lambda}, \hat{\alpha}) = (-0.25, -0.39)$. The raw scale $(1, 1)$ has likelihood ratio statistic 186.5, and the best pair with untransformed income, $(0.63, 1)$ from [Example \(Box-Cox for Engel's data\)](#), has 167.8: whatever is done to the response, income needs transforming. The log-log pair $(0, 0)$ has statistic 11.2, outside the 95% region, whose cut-off is 5.99 for two parameters. Without the richest household the statistic falls to 6.55, still outside.

The region is a long tilted ellipse, since a lower response power can be partly compensated by a lower income power ([Exercise \(B2\)](#)). The log-log model lies outside the region (11.2 against 5.99), largely because of the richest household. It is still the natural working choice for interpretation, since its slope is an elasticity, with the caveat that the data reject a constant elasticity and that it may fall among the richest households ([Proposition 22.5.3](#)).

22.3.4 Polynomials and other alternatives

Powers suit positive regressors with monotone, smoothly bending effects. Otherwise the alternative is to add columns rather than change one: a polynomial or a spline. These buy flexibility with interpretability, since no single coefficient measures the effect of x ([Definition 5.7.1](#), third qualification), and high-degree polynomials behave badly at the edges of the data. Royston and Altman's (1994) *fractional polynomials* use one or two terms from a small set of powers including the logarithm. [Chapter 42](#) treats polynomial and spline regression, and [Chapter 43](#) the smoothers that replace the choice of knots by a penalty.

22.3.5 Exercises

22.3.5.1 A. Check your understanding

Exercise A1.

At $\alpha_0 = 1$ a fit gives $\hat{\beta}_1 = 2.5$, and adding $x \log x$ gives it the coefficient $\hat{\gamma} = -1.5$. What is the next Box–Tidwell value of α ? What does the sign of $\hat{\gamma}$ say about the curvature of the relation?

22.3.5.2 B. Practice

Exercise B1.

Show that $\partial x^{(\alpha)} / \partial \alpha = x^\alpha \log x / \alpha - x^{(\alpha)} / \alpha$ for $\alpha \neq 0$, and that its limit as $\alpha \rightarrow 0$ is $\frac{1}{2}(\log x)^2$. Conclude that in a model containing **1** and $\mathbf{x}^{(\alpha_0)}$ the constructed variable may be taken to be [Eq. 22.3.3](#).

Solution. Differentiate $(x^\alpha - 1)/\alpha$: the quotient rule gives $\{\alpha x^\alpha \log x - (x^\alpha - 1)\}/\alpha^2 = x^\alpha \log x / \alpha - x^{(\alpha)} / \alpha$. As $\alpha \rightarrow 0$, expand $x^\alpha = 1 + \alpha \log x + \frac{1}{2}\alpha^2(\log x)^2 + O(\alpha^3)$: the numerator is $\alpha \log x + \alpha^2(\log x)^2 - \alpha \log x - \frac{1}{2}\alpha^2(\log x)^2 + O(\alpha^3) = \frac{1}{2}\alpha^2(\log x)^2 + O(\alpha^3)$, and dividing by α^2 gives the limit. The term $-\mathbf{x}^{(\alpha_0)}/\alpha_0$ lies in the model space, and removing it changes neither the residualized column $\tilde{\mathbf{w}}$ nor $\hat{\gamma}$.

Exercise B2.

Suppose $y = c x^\beta$ exactly, with $c, \beta > 0$. Show that for $\lambda \neq 0$, $y^{(\lambda)}$ is an affine function of $x^{(\alpha)}$ iff $\alpha = \beta\lambda$, and that for $\lambda = 0$ it is affine in $x^{(\alpha)}$ iff $\alpha = 0$. Explain why data close to a power law give a joint likelihood for (λ, α) with a ridge, and why the slope of the ridge need not be exactly β when the variance also depends on λ .

Solution. For $\lambda \neq 0$, $y^\lambda = c^\lambda x^{\beta\lambda}$, so $y^{(\lambda)} = (c^\lambda x^{\beta\lambda} - 1)/\lambda$, an affine function of $x^{\beta\lambda}$. An affine function of $x^{\beta\lambda}$ is affine in x^α (equivalently in $x^{(\alpha)}$) for all $x > 0$ iff $\alpha = \beta\lambda$, since distinct powers, and a power and the logarithm, are affinely independent functions on $(0, \infty)$. For $\lambda = 0$, $\log y = \log c + \beta \log x$ is affine in $x^{(\alpha)}$ iff $\alpha = 0$, which is again $\alpha = \beta\lambda$. So every pair on the line $\alpha = \beta\lambda$ makes the mean exactly linear, and nearby data make the residual sum of squares small along it. The likelihood also rewards a constant variance and normal errors, which depend on λ alone, so the maximum lies somewhere along the tilted valley, and its exact direction mixes the two requirements.

Exercise B3.

Let $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_1^2, \mathbf{X}_2]$, with $\mathbf{1} \in \mathcal{C}(\mathbf{X}_2)$ and full column rank, and let $E(\mathbf{Y}) = \mathbf{g} + \mathbf{X}_2\boldsymbol{\beta}_2$. Show that the augmented partial residuals $\hat{\mathbf{e}} + \hat{\beta}_1\mathbf{x}_1 + \hat{\beta}_{11}\mathbf{x}_1^2$ have expectation $\mathbf{g} - \mathbf{M}_2(\mathbf{g} - b_1\mathbf{x}_1 - b_{11}\mathbf{x}_1^2)$, where (b_1, b_{11}) are the expectations of $(\hat{\beta}_1, \hat{\beta}_{11})$. Conclude that the plot is exact, up to a vertical shift, when g is a quadratic.

Solution. Let $\mathbf{Q} = [\mathbf{x}_1, \mathbf{x}_1^2]$ and $\tilde{\mathbf{Q}} = (\mathbf{I} - \mathbf{M}_2)\mathbf{Q}$. As in the proof of [Proposition 22.3.1](#), $\mathbf{M} = \mathbf{M}_2 + \tilde{\mathbf{Q}}(\tilde{\mathbf{Q}}^\top \tilde{\mathbf{Q}})^{-1} \tilde{\mathbf{Q}}^\top$ and the coefficient vector $\mathbf{b}$ of $\mathbf{Q}$ has expectation $(\tilde{\mathbf{Q}}^\top \tilde{\mathbf{Q}})^{-1} \tilde{\mathbf{Q}}^\top \mathbf{g}$. Then $E(\hat{\mathbf{e}}) = (\mathbf{I} - \mathbf{M})\mathbf{g} = \mathbf{g} - \mathbf{M}_2\mathbf{g} - \mathbf{Q}\mathbf{b}$, and adding $\mathbf{Q}\mathbf{b} = \tilde{\mathbf{Q}}\mathbf{b} + \mathbf{M}_2\mathbf{Q}\mathbf{b}$ gives $\mathbf{g} - \mathbf{M}_2(\mathbf{g} - \mathbf{Q}\mathbf{b})$. If $\mathbf{g} = c_0\mathbf{1} + c_1\mathbf{x}_1 + c_2\mathbf{x}_1^2$, then $\mathbf{g}$ lies in $\mathcal{C}(\mathbf{X})$, $\mathbf{b} = (c_1, c_2)^\top$, and $\mathbf{g} - \mathbf{Q}\mathbf{b} = c_0\mathbf{1}$, whose projection is $c_0\mathbf{1}$.

Exercise B4.

In the setting of [Proposition 22.3.1](#), let $\mathbf{X}_2 = [\mathbf{1}, \mathbf{q}]$ with $q_i = x_{i1}^2$, so the second regressor is an exact quadratic in the first, and write $\boldsymbol{\beta}_2 = (\beta_{20}, \delta)^\top$.

- If $g(x) = cx^2$, show that $b = 0$ and that the expected partial residuals are $\mathbf{0}$: the plot is flat, although $E(Y)$ curves in x_1 when $\delta \neq -c$.
- If $g(x) = cx$, show that the plot is exact.
- Explain why no plot against x_1 can tell which of the two regressors carries the curvature in (a).

Solution.

- Here $\mathbf{g} = c\mathbf{q} \in \mathcal{C}(\mathbf{X}_2)$, so $\tilde{\mathbf{x}}_1^\top \mathbf{g} = 0$ and $b = 0$; then $\mathbf{M}_2(\mathbf{g} - b\mathbf{x}_1) = \mathbf{M}_2\mathbf{g} = \mathbf{g}$ and [Eq. 22.3.1](#) is $\mathbf{0}$. The whole of g is the nonlinearity $\mathbf{g} - b\mathbf{x}_1$, and $\mathbf{q}$ reproduces all of it. The mean $E(Y) = \beta_{20} + (c + \delta)x_1^2$ curves unless $c + \delta = 0$.
- Now $b = c\tilde{\mathbf{x}}_1^\top \mathbf{x}_1 / \|\tilde{\mathbf{x}}_1\|^2 = c$, because $\tilde{\mathbf{x}}_1^\top \mathbf{x}_1 = \|\tilde{\mathbf{x}}_1\|^2$, so $\mathbf{g} - b\mathbf{x}_1 = \mathbf{0}$ and the expected partial residuals are $\mathbf{g}$.
- The models $E(Y) = \beta_{20} + cx_1^2 + \delta x_1^2$ with the same $c + \delta$ have the same mean for every case: the split between g and $\mathbf{X}_2\boldsymbol{\beta}_2$ is not identified from the data, so no display of them can recover it.

22.3.5.3 C. Going deeper

Exercise C1.

Suppose $\beta_1 = 0$ in [Eq. 22.3.2](#). Show that the model does not depend on α , so α is not identified. Show that the test of [Theorem 22.3.2\(a\)](#) still has exact size, and argue that its power against changes in α tends to zero as $\beta_1 \rightarrow 0$. What happens to the Box–Tidwell step, and to the likelihood ratio interval for α ?

Exercise C2.

Let $E(\mathbf{Y}) = \mathbf{X}_3\boldsymbol{\beta}_3 + \beta_1\mathbf{x}_1^{(\alpha_1)} + \beta_2\mathbf{x}_2^{(\alpha_2)}$. Show that one Gauss–Newton step from (α_1^0, α_2^0) and the least squares coefficients there changes α_j by $\hat{\gamma}_j/\hat{\beta}_j$, where $\hat{\gamma}_1, \hat{\gamma}_2$ are the coefficients of the two constructed variables in a single regression of $\mathbf{y}$ on the model matrix augmented by both.

22.4 Variance-stabilizing transformations

For many responses the variance is tied to the mean by the nature of the measurement: counts, proportions, amounts measured with a fixed *relative* precision. Then $\text{Var}(Y) = \phi v(\mu)$ for a known or plausible variance function v , where $\mu = E(Y)$ and ϕ is a constant. The transformation that makes the variance constant turns out to be determined by v up to an affine change.

22.4.1 The idea

If g is smooth and Y is concentrated near μ , then $g(Y) \approx g(\mu) + g'(\mu)(Y - \mu)$, so

$$\text{Var } g(Y) \approx g'(\mu)^2 \phi v(\mu).$$

This is constant in μ exactly when $g'(\mu)$ is proportional to $v(\mu)^{-1/2}$, that is, when

$$g(\mu) = \int^\mu \frac{dt}{\sqrt{v(t)}}. \quad (22.4.1)$$

Part (a) of the theorem below makes this precise, with m measuring the information; it is [Exercise \(B1\)](#), where Fisher's z arose this way. Part (b) adds uniqueness.

Theorem 22.4.1 — Variance-stabilizing transformations

Let I be an open interval and $v : I \rightarrow (0, \infty)$ continuous. Suppose that for every $\theta \in I$ the random variables T_m satisfy $\sqrt{m}(T_m - \theta) \rightarrow N(0, v(\theta))$ in distribution as $m \rightarrow \infty$. Fix $t_0 \in I$ and let $g(t) = \int_{t_0}^t v(s)^{-1/2} ds$ for $t \in I$, extended in any way outside I .

- (a) For every $\theta \in I$, $\sqrt{m}\{g(T_m) - g(\theta)\} \rightarrow N(0, 1)$ in distribution.
- (b) If $h : I \rightarrow \mathbb{R}$ is continuously differentiable and $\sqrt{m}\{h(T_m) - h(\theta)\} \rightarrow N(0, 1)$ for every $\theta \in I$, then $h = g + c$ or $h = -g + c$ on I for a constant c .

Proof.

- (a) By the fundamental theorem of calculus $g' = v^{-1/2}$ on I , so this is [Exercise \(B1\)](#) with $s = v^{1/2}$; the values of g outside I do not matter because $T_m \rightarrow \theta$ in probability.
- (b) By the delta method (stated in [Section 14.4](#)), $\sqrt{m}\{h(T_m) - h(\theta)\} \rightarrow N(0, h'(\theta)^2 v(\theta))$. Limits in distribution are unique, so $h'(\theta)^2 v(\theta) = 1$ and $|h'(\theta)| = v(\theta)^{-1/2}$ for every $\theta \in I$. The continuous function h' never vanishes on the interval I , so by the intermediate value theorem it has one sign throughout. Hence $h' = g'$ or $h' = -g'$ on I , and integrating gives the result. ■

Convergence in distribution does not by itself imply that the *variance* of $g(T_m)$ is close to $1/m$; that needs uniform integrability, which the theorem does not assert ([Exercise \(C2\)](#) supplies it for Poisson counts).

Corollary 22.4.2 — The classical transformations

- (a) **Counts.** If $Y \sim \text{Poisson}(\mu)$, then $2(\sqrt{Y} - \sqrt{\mu}) \rightarrow N(0, 1)$ as $\mu \rightarrow \infty$.
- (b) **Proportions.** If $S \sim \text{Binomial}(m, p)$ with $0 < p < 1$ fixed and $\hat{p} = S/m$, then $2\sqrt{m} \{\arcsin \sqrt{\hat{p}} - \arcsin \sqrt{p}\} \rightarrow N(0, 1)$ as $m \rightarrow \infty$.
- (c) **Constant coefficient of variation.** If $Y = \mu U$ for a positive random variable U whose distribution does not depend on μ , then $\text{Var}(\log Y) = \text{Var}(\log U)$ exactly, for every μ , whenever it is finite.
- (d) **Power variance functions.** If $v(\mu) = \mu^{2a}$ on $(0, \infty)$, then [Eq. 22.4.1](#) gives $\mu^{1-a}/(1-a)$ for $a \neq 1$ and $\log \mu$ for $a = 1$. Up to an affine change this is the Box–Cox transformation with $\lambda = 1 - a$.

Proof.

- (a) The characteristic function of $(Y - \mu)/\sqrt{\mu}$ is $\exp\{\mu(e^{it/\sqrt{\mu}} - 1 - it/\sqrt{\mu})\}$, which tends to $e^{-t^2/2}$ because $e^{iu} - 1 - iu = -u^2/2 + O(u^3)$. By the continuity theorem of Lévy (van der Vaart 1998, chapter 2), $(Y - \mu)/\sqrt{\mu} \rightarrow N(0, 1)$. Now write

$$2(\sqrt{Y} - \sqrt{\mu}) = \frac{Y - \mu}{\sqrt{\mu}} \cdot \frac{2\sqrt{\mu}}{\sqrt{Y} + \sqrt{\mu}}.$$

Since $\text{Var}(Y/\mu) = 1/\mu$, Chebyshev's inequality gives $Y/\mu \rightarrow 1$ in probability, so the second factor tends to 1 in probability, and Slutsky's lemma gives the limit.

- (b) By the central limit theorem $\sqrt{m}(\hat{p} - p) \rightarrow N(0, p(1-p))$. With $v(p) = p(1-p)$ on $(0, 1)$, the derivative of $\arcsin \sqrt{p}$ is $\frac{1}{2}\{p(1-p)\}^{-1/2}$, so [Eq. 22.4.1](#) gives $g(p) = 2 \arcsin \sqrt{p}$, and [Theorem 22.4.1\(a\)](#) applies.
- (c) $\log Y = \log \mu + \log U$, and adding a constant does not change a variance.
- (d) Integrate t^{-a} .

■

Part (c) is exact: for gamma data with shape k , $\text{Var}(\log Y)$ is the trigamma function at k whatever the mean, 0.2213 for $k = 5$ against the first-order value $1/k = 0.2$. Part (d) is the rule quoted in [Section 22.1](#). A known variance function determines the power; otherwise the Box–Cox likelihood estimates one, chosen partly to stabilize the variance.

22.4.2 How well they work

The limits say nothing about moderate means, but the variances can be computed exactly by summing probability mass functions. [Figure 22.4.1](#) and the table show them, scaled so that the target is 1.

Poisson mean					
μ	1	2	5	10	20
$4 \text{ Var } \sqrt{Y}$	1.609	1.560	1.144	1.045	1.020
$4 \text{ Var } \sqrt{Y + 3/8}$	0.717	0.924	1.002	1.001	1.000

Figure 22.4.1: Exact variances of transformed counts and proportions, scaled so that the target is 1 (dashed). (a) Poisson counts: $\sqrt{y}$ and Anscombe's $\sqrt{y + 3/8}$, against the mean on a log scale. (b) Binomial proportions with $m = 20$ trials: the arcsine square root, plain and with Anscombe's constants.

Without transformation the variance of a Poisson count grows in proportion to the mean, a factor of 20 between $\mu = 1$ and $\mu = 20$. After the square root the scaled variance stays between 1 and 1.7 over the same range, and from $\mu = 5$ on it is within 15 percent of the target. Anscombe's (1948) modification $\sqrt{Y + c} = \frac{1}{4} + (3 - 8c)/(32\mu) + O(\mu^{-2})$ (Exercise (C1)), and $c = 3/8$ removes the $1/\mu$ term. For binomial proportions from $m = 20$ trials, $4m \text{Var}(\arcsin \sqrt{\hat{p}})$ is 1.056 at $p = 0.5$, 1.118 at $p = 0.25$, 1.546 at $p = 0.1$ and 1.632 at $p = 0.05$. Anscombe's version $\arcsin \sqrt{(S + 3/8)/(m + 3/4)}$ gives 0.977, 0.979, 0.919 and 0.720. Both transformations fail near the boundary, where most of the probability sits on a few values and no smooth function can equalize anything.

```
import numpy as np
from scipy import stats

def poisson_var(h, mu):
    """Var h(Y) for Y ~ Poisson(mu), by summing the probability mass function."""
    k = np.arange(0, int(mu + 40 * np.sqrt(mu) + 60))
    p = stats.poisson.pmf(k, mu)
    m1 = p @ h(k)
    return p @ (h(k) - m1) ** 2

def binomial_var(h, m, prob):
    """Var h(S) for S ~ Binomial(m, prob)."""
    s = np.arange(m + 1)
    p = stats.binom.pmf(s, m, prob)
    m1 = p @ h(s)
    return p @ (h(s) - m1) ** 2

for mu in (1, 2, 5, 10, 20):
    print(f"Poisson mean {mu:2d}: 4 Var sqrt(Y) = {4 * poisson_var(np.sqrt, mu):.3f}")
    print(f"4 Var sqrt(Y + 3/8) = {4 * poisson_var(lambda k: np.sqrt(k + 3 / 8),
```

```

    mu):.3f}")
m = 20
for prob in (0.05, 0.1, 0.25, 0.5):
    plain = 4 * m * binomial_var(lambda s: np.arcsin(np.sqrt(s / m)), m, prob)
    anscombe = 4 * m * binomial_var(lambda s: np.arcsin(np.sqrt((s + 3 / 8) / (m + 3
        / 4))), m, prob)
    print(f"binomial m = {m}, p = {prob:.2f}: 4m Var = {plain:.3f}    with 3/8: {
        anscombe:.3f}")

```

A stabilized scale also gives a check: for Poisson counts the residual variance on the square-root scale should be near $\frac{1}{4}$. A much larger value says the counts are *overdispersed*, and then the square root no longer stabilizes ([Exercise \(B1\)](#)).

22.4.3 Estimating the variance function

With replicates at several settings, plot the log standard deviation of each group against the log of its mean. If $s \propto \mu^a$ the points lie near a line of slope a , and the power $1 - a$ stabilizes the variance ([Exercise \(B3\)](#)), an idea that goes back to Bartlett (1947). Without replicates, residuals can be grouped by fitted value, but misfit of the mean then inflates some spreads, so the plot should come *after* the mean function is roughly right. Whether the variance depends on the regressors at all is tested formally by [Theorem 21.2.2](#).

22.4.4 Transform, weight, or model the variance

Transformation is one of three remedies for a variance that depends on the mean.

1. **Transform.** Fit the linear model to $g(y)$. The variance becomes nearly constant, but the *mean* is now modelled on the new scale, and statements about y need the retransformation of [Section 22.5](#).
2. **Weight.** Keep the scale and fit by weighted least squares with weights $1/v(\hat{\mu}_i)$ ([Theorem 21.3.1](#) and [Definition 6.9.1](#)), or keep ordinary least squares with heteroscedasticity-consistent standard errors ([Theorem 21.4.2](#)).
3. **Model.** Specify the mean through a link function and the variance through v : a generalized linear model, such as Poisson or logistic regression, whose coefficients refer to the mean of y itself. [Chapter 34](#) develops this modern default.

The first two can be combined. The *logit* of a binomial proportion is not variance-stabilizing, but its variance is about $1/\{m p(1 - p)\}$, so weighted least squares on empirical logits with weights $m\hat{p}(1 - \hat{p})$ gives a linear model for the log odds ([Exercise \(B2\)](#)), the approach of Grizzle, Starmer and Koch (1969) for categorical data.

22.4.5 Exercises

22.4.5.1 A. Check your understanding

Exercise A1.

Find the variance-stabilizing transformation for $v(\mu) = \mu^3$, the variance function of the

inverse Gaussian distribution. Which Box–Cox power is it?

Exercise A2.

Let T_m be the mean of m independent exponential waiting times with mean $\theta > 0$. Find the variance-stabilizing transformation. Use [Theorem 22.4.1\(b\)](#) to show that the square root, although it stabilizes Poisson counts, does not stabilize T_m , and find the limiting variance of $\sqrt{m}(\sqrt{T_m} - \sqrt{\theta})$.

22.4.5.2 B. Practice

Exercise B1.

Negative binomial counts have $v(\mu) = \mu + \mu^2/\kappa$ for a shape parameter $\kappa > 0$. Show that [Eq. 22.4.1](#) gives $g(\mu) = 2\sqrt{\kappa} \sinh^{-1} \sqrt{\mu/\kappa}$. Show that g behaves like $2\sqrt{\mu}$ for $\mu \ll \kappa$ and like $\sqrt{\kappa} \log \mu$ plus a constant for $\mu \gg \kappa$, and interpret.

Solution. Substitute $t = \kappa u^2$: $dt = 2\kappa u du$ and $t + t^2/\kappa = \kappa u^2(1 + u^2)$, so the integrand becomes $2\kappa u du / \{\sqrt{\kappa} u \sqrt{1 + u^2}\} = 2\sqrt{\kappa} du / \sqrt{1 + u^2}$, whose integral is $2\sqrt{\kappa} \sinh^{-1} u$ with $u = \sqrt{\mu/\kappa}$. For small u , $\sinh^{-1} u \approx u$, giving $2\sqrt{\mu}$. For large u , $\sinh^{-1} u = \log(2u) + o(1)$, giving $\sqrt{\kappa} \log \mu$ plus a constant. Small counts behave like Poisson counts and need a square root; large counts have a nearly constant coefficient of variation and need a logarithm.

Exercise B2.

Let $S \sim \text{Binomial}(m, p)$ with $0 < p < 1$. Show by the delta method that $\sqrt{m} \{\text{logit}(S/m) - \text{logit } p\} \rightarrow N(0, 1/\{p(1-p)\})$, where $\text{logit } p = \log\{p/(1-p)\}$. For independent groups $i = 1, \dots, k$ with $S_i \sim \text{Binomial}(m_i, p_i)$ and $\text{logit } p_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta}$, write down the weighted least squares estimate of $\boldsymbol{\beta}$ from the empirical logits, and its approximate covariance matrix.

Solution. The derivative of $\text{logit } p$ is $1/\{p(1-p)\}$, and $\sqrt{m}(S/m - p) \rightarrow N(0, p(1-p))$, so the limiting variance is $p(1-p)/\{p(1-p)\}^2$. With $\ell_i = \text{logit}(S_i/m_i)$ and $\mathbf{W} = \text{diag}\{m_i \hat{p}_i(1 - \hat{p}_i)\}$, the estimate is $\boldsymbol{\beta} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \boldsymbol{\ell}$ ([Definition 6.9.1](#)), with approximate covariance $(\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1}$, since the weights are the approximate inverse variances and no σ^2 needs estimating. The empirical logit is infinite when $S_i = 0$ or m_i , which is why $\frac{1}{2}$ is often added to S_i and to $m_i - S_i$.

Exercise B3.

Replicate observations at four settings have means 10, 40, 160, 640 and standard deviations 2, 5.7, 16, 45. Fit the spread–level line $\log s = c + a \log \mu$ described above by eye or by least squares, and use [Corollary 22.4.2\(d\)](#) to choose the power.

22.4.5.3 C. Going deeper

Exercise C1.

Let $Y \sim \text{Poisson}(\mu)$ and $c \geq 0$. Expand $\sqrt{Y+c} = \sqrt{\mu}(1+u)^{1/2}$ with $u = (Y-\mu+c)/\mu$ to third order in u , use the Poisson central moments $E(Y-\mu)^2 = \mu$, $E(Y-\mu)^3 = \mu$, $E(Y-\mu)^4 = 3\mu^2 + \mu$, and show formally that $\text{Var} \sqrt{Y+c} = \frac{1}{4} + (3-8c)/(32\mu) + O(\mu^{-2})$. (The expansion is formal: making the remainder rigorous needs a bound on the tail of Y .)

Exercise C2.

[Corollary 22.4.2\(a\)](#) is a statement about distributions. Show that the variance converges too: $4 \text{Var} \sqrt{Y} \rightarrow 1$ as $\mu \rightarrow \infty$ for $Y \sim \text{Poisson}(\mu)$. Use the bound $(\sqrt{Y} - \sqrt{\mu})^2 \leq (Y-\mu)^2/\mu$, and the fact that a family of nonnegative random variables that converges in distribution, and whose means converge to the mean of the limit, is uniformly integrable.

Solution. The bound holds because $\sqrt{Y} - \sqrt{\mu} = (Y-\mu)/(\sqrt{Y} + \sqrt{\mu})$ and $\sqrt{Y} + \sqrt{\mu} \geq \sqrt{\mu}$. The variables $V_\mu = (Y-\mu)^2/\mu$ converge in distribution to $\chi^2(1)$ (by the proof of [Corollary 22.4.2\(a\)](#)) and have mean exactly 1, the mean of the limit, so they are uniformly integrable, and so is the dominated family $W_\mu = 4(\sqrt{Y} - \sqrt{\mu})^2$. Since $W_\mu \rightarrow \chi^2(1)$ in distribution, uniform integrability gives $E W_\mu \rightarrow 1$. The same argument applied to $2(\sqrt{Y} - \sqrt{\mu})$, which is dominated by $1 + W_\mu$, gives $E\{2(\sqrt{Y} - \sqrt{\mu})\} \rightarrow 0$. Hence $4 \text{Var} \sqrt{Y} = E W_\mu - [E\{2(\sqrt{Y} - \sqrt{\mu})\}]^2 \rightarrow 1$.

22.5 Interpreting a transformed model

A model fitted on a transformed scale answers questions on that scale, but readers ask about the original one: how much will a household with income 2000 spend on food, within what range, and how much more if its income rises? The dividing line is simple. Quantiles pass through a monotone transformation unchanged; means do not.

Throughout this section g is strictly increasing with inverse h , and the model on the transformed scale is

$$g(Y_i) = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \varepsilon_i, \quad i = 1, \dots, n, \quad (22.5.1)$$

where $\varepsilon_1, \dots, \varepsilon_n$ are independent with distribution F , mean 0 and variance σ^2 .

22.5.1 Medians and means

Proposition 22.5.1 — Retransformation bias and the smearing estimate

Assume [Eq. 22.5.1](#).

- (a) **Quantiles.** If ξ_q is a q -quantile of F , then $h(\mathbf{x}^\top \boldsymbol{\beta} + \xi_q)$ is a q -quantile of Y at $\mathbf{x}$.

In particular, if F has median 0 (for instance, if it is symmetric), the median of Y at $\mathbf{x}$ is $h(\mathbf{x}^\top \boldsymbol{\beta})$.

- (b) **Means.** $E(Y | \mathbf{x}) = \int h(\mathbf{x}^\top \boldsymbol{\beta} + e) dF(e)$ whenever this is finite. If h is strictly convex and $\sigma^2 > 0$, then $E(Y | \mathbf{x}) > h(\mathbf{x}^\top \boldsymbol{\beta})$. For $h = \exp$, $E(Y | \mathbf{x}) = \exp(\mathbf{x}^\top \boldsymbol{\beta}) E e^\varepsilon$, and for normal errors $E e^\varepsilon = \exp(\sigma^2/2)$.
- (c) **Smearing.** Let $h = \exp$, let $\mathbf{X}$ have full column rank p for every n , with leverages h_{ii} , and let the ε_i be the first n terms of an independent and identically distributed sequence with $E e^\varepsilon < \infty$. If $\max_i h_{ii} \rightarrow 0$ as $n \rightarrow \infty$, then the **smearing factor** satisfies

$$\frac{1}{n} \sum_{i=1}^n \exp(\hat{\varepsilon}_i) \rightarrow E e^\varepsilon \quad \text{in probability.} \quad (22.5.2)$$

If moreover $\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} \rightarrow \mathbf{x}_0^\top \boldsymbol{\beta}$ in probability, the **smearing estimate** $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}) n^{-1} \sum_i \exp(\hat{\varepsilon}_i)$ converges in probability to $E(Y | \mathbf{x}_0)$.

Proof.

- (a) $Y \leq h(\mathbf{x}^\top \boldsymbol{\beta} + \xi_q)$ iff $g(Y) \leq \mathbf{x}^\top \boldsymbol{\beta} + \xi_q$ iff $\varepsilon \leq \xi_q$, because g is strictly increasing, and likewise with strict inequalities. So the two events have the probabilities that define a q -quantile.
- (b) $Y = h(\mathbf{x}^\top \boldsymbol{\beta} + \varepsilon)$. If h is strictly convex and ε is not degenerate, Jensen's inequality is strict: $E h(\mathbf{x}^\top \boldsymbol{\beta} + \varepsilon) > h(\mathbf{x}^\top \boldsymbol{\beta} + E \varepsilon) = h(\mathbf{x}^\top \boldsymbol{\beta})$. For $h = \exp$ the factor $\exp(\mathbf{x}^\top \boldsymbol{\beta})$ comes out of the expectation, and the normal moment generating function (Theorem 3.2.1) at 1 is $\exp(\sigma^2/2)$.
- (c) Put $\mathbf{d} = \mathbf{X}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) = \mathbf{M}\boldsymbol{\varepsilon}$, so that $\hat{\varepsilon}_i = \varepsilon_i - d_i$. With $\mathbf{e}_i$ the i th standard basis vector, $d_i = \mathbf{e}_i^\top \mathbf{M}\boldsymbol{\varepsilon} = (\mathbf{M}\mathbf{e}_i)^\top (\mathbf{M}\boldsymbol{\varepsilon})$, so by the Cauchy–Schwarz inequality and Proposition 6.8.1(a),

$$|d_i| \leq \|\mathbf{M}\mathbf{e}_i\| \|\mathbf{M}\boldsymbol{\varepsilon}\| = \sqrt{h_{ii}} \|\mathbf{M}\boldsymbol{\varepsilon}\|.$$

Since $E\|\mathbf{M}\boldsymbol{\varepsilon}\|^2 = \sigma^2 \text{tr}(\mathbf{M}) = p\sigma^2$, Markov's inequality gives $\Pr(\|\mathbf{M}\boldsymbol{\varepsilon}\| > K) \leq p\sigma^2/K^2$ for every K , and therefore $\delta_n = \max_i |d_i| \leq (\max_i h_{ii})^{1/2} \|\mathbf{M}\boldsymbol{\varepsilon}\| \rightarrow 0$ in probability. Let $A_n = n^{-1} \sum_i \exp(\varepsilon_i)$, which tends to $E e^\varepsilon$ in probability by the weak law of large numbers. Because $\hat{\varepsilon}_i = \varepsilon_i - d_i$, we have

$$e^{-\delta_n} A_n \leq \frac{1}{n} \sum_{i=1}^n \exp(\hat{\varepsilon}_i) \leq e^{\delta_n} A_n,$$

and both bounds tend to $E e^\varepsilon$ in probability. This proves Eq. 22.5.2. The last statement follows because $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}) \rightarrow \exp(\mathbf{x}_0^\top \boldsymbol{\beta})$ in probability, and products of convergent sequences converge. ■

By part (a), a transformed model is naturally read through medians: $h(\mathbf{x}^\top \hat{\boldsymbol{\beta}})$ estimates the conditional median when the errors are symmetric. Part (b) is the **retransformation bias**: for the exponential, $h(\mathbf{x}^\top \hat{\boldsymbol{\beta}})$ underestimates the mean by the factor $E e^\varepsilon$. Under normal errors this suggests $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} + \sigma^2/2)$, but the factor depends on the whole error distribution, and with non-normal errors that estimate is in general inconsistent: it converges to $\exp(\sigma^2/2)$, not to $E e^\varepsilon$.

Part (c) is Duan's (1983) remedy, the empirical distribution of the residuals standing in for F , under the familiar condition that no observation keep a fixed share of the fit (Section 6.8). For general h the smearing estimate is $n^{-1} \sum_i h(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} + \hat{\varepsilon}_i)$ (Exercise (C1)).

Example. (Skewed errors)

The script simulates the log-linear model $\log Y = 1 + 0.5x + \varepsilon$ with $n = 100$ equally spaced values of x in $[0, 2]$ and right-skewed errors $\varepsilon = 0.6(E - 1)$, E exponential with mean 1. The errors have mean 0 and variance 0.36. The true factor is $E e^\varepsilon = e^{-0.6}/0.4$, about 1.372, while the normal-theory factor $\exp(0.36/2)$ is about 1.197. At $x_0 = 1$, averaged over 4000 samples, the ratio of the estimate to the true mean is 0.730 for the naive $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}})$, 0.877 for the normal-theory correction and 0.986 for the smearing estimate. Its remaining bias of about one percent reflects that residuals vary slightly less than errors.

```
import numpy as np

def simulate(reps, n_sim, seed):
    """Log-linear model with right-skewed errors  $e = 0.6 (E - 1)$ ,  $E \sim \text{Exp}(1)$ :
    estimate / true mean."""
    rng = np.random.default_rng(seed)
    xs = np.linspace(0, 2, n_sim)
    Xs = np.column_stack([np.ones(n_sim), xs])
    beta, sig = np.array([1.0, 0.5]), 0.6
    x0 = np.array([1.0, 1.0])
    true_mean = np.exp(x0 @ beta) * np.exp(-sig) / (1 - sig)  #  $E \exp(e) = e^{(-sig)/(1-sig)}$ 
    out = np.empty((reps, 3))
    for r in range(reps):
        e = sig * (rng.exponential(size=n_sim) - 1)
        z = Xs @ beta + e
        coef, *_ = np.linalg.lstsq(Xs, z, rcond=None)
        res = z - Xs @ coef
        s2_sim = res @ res / (n_sim - 2)
        naive = np.exp(x0 @ coef)
        out[r] = [naive, naive * np.exp(s2_sim / 2), naive * np.mean(np.exp(res))]
    return out.mean(axis=0) / true_mean

ratios = simulate(reps=300, n_sim=100, seed=2205)
print("mean of estimate / true mean:  naive %.3f   lognormal %.3f   smearing %.3f" %
      tuple(ratios))
```

The browser cell uses 300 samples, so its ratios differ slightly from those quoted.

Warning. Smearing needs identically distributed errors on the transformed scale. If their variance depends on the regressors, so does $E e^\varepsilon$, and a single average corrects too much where the variance is small and too little where it is large (Exercise (C2)); Manning (1998) showed how large the errors can be. Check the residual spread on the transformed scale (Chapter 21) before retransforming a mean.

22.5.2 Intervals on the original scale

Proposition 22.5.2 — Intervals after a transformation

Assume [Eq. 22.5.1](#), and let Y_0 be a new response at $\mathbf{x}_0$, independent of $\mathbf{Y}$ and following the same model.

- (a) If $L \leq U$ are statistics with values in the range of g such that $\Pr\{L \leq g(Y_0) \leq U\} = 1 - \alpha$, then $\Pr\{h(L) \leq Y_0 \leq h(U)\} = 1 - \alpha$. Under normal errors the prediction interval of [Theorem 12.3.1](#) therefore transforms into an exact prediction interval for Y_0 .
- (b) If $[L, U]$ is a confidence interval for $\mathbf{x}_0^\top \boldsymbol{\beta}$ with coverage $1 - \alpha$ and F has median 0, then $[h(L), h(U)]$ is a confidence interval for the median of Y_0 with coverage $1 - \alpha$.
- (c) Let $g = \log$, let the errors be normal, and let $\mathbf{X}$ have rank $r < n$ with $\mathbf{x}_0 \in \mathcal{C}(\mathbf{X}^\top)$ and $h_0 = \mathbf{x}_0^\top (\mathbf{X}^\top \mathbf{X})^- \mathbf{x}_0$. The logarithm of the mean, $\theta = \mathbf{x}_0^\top \boldsymbol{\beta} + \sigma^2/2$, is estimated by $\hat{\theta} = \mathbf{x}_0^\top \hat{\boldsymbol{\beta}} + s^2/2$, which is unbiased with

$$\text{Var}(\hat{\theta}) = \sigma^2 h_0 + \frac{\sigma^4}{2(n-r)}. \quad (22.5.3)$$

Proof.

- (a) and (b): since g is strictly increasing with inverse h , the events $\{L \leq g(Y_0) \leq U\}$ and $\{h(L) \leq Y_0 \leq h(U)\}$ are equal, and so are $\{L \leq \mathbf{x}_0^\top \boldsymbol{\beta} \leq U\}$ and $\{h(L) \leq h(\mathbf{x}_0^\top \boldsymbol{\beta}) \leq h(U)\}$; by [Proposition 22.5.1\(a\)](#), $h(\mathbf{x}_0^\top \boldsymbol{\beta})$ is the median of Y_0 . (c) By [Theorem 7.5.1](#), $\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}$ is normal with mean $\mathbf{x}_0^\top \boldsymbol{\beta}$ and variance $\sigma^2 h_0$, $(n-r)s^2/\sigma^2 \sim \chi^2(n-r)$, and the two are independent. So $E\hat{\theta} = \theta$, $\text{Var}(s^2) = 2\sigma^4/(n-r)$, and the variances add.

■

Part (c) gives the approximate interval $\exp\{\hat{\theta} \pm z_{\alpha/2}(s^2 h_0 + s^4/\{2(n-r)\})^{1/2}\}$ for the mean, approximate because the variance is estimated and $\hat{\theta}$ is only approximately normal, and dependent on the lognormal assumption. The intervals of parts (a) and (b) are exact under the normal model on the log scale.

Example. (Engel's data on the original scale)

With the log-log fit of [Example \(Food expenditure on the raw and the log scale\)](#), [Figure 22.5.1](#) shows the data on the original scale with the fitted median curve, the smearing estimate of the mean and a 95% prediction band. For a household with income 500 the estimated median food expenditure is 352.2, with 95% confidence interval [342.2, 362.5], and a 95% prediction interval for a single household ([Theorem 12.3.1](#) and [Proposition 22.5.2\(a\)](#)) is [269, 462]. At income 2000 the median is 1153.7, with interval [1111.7, 1197.3], and the prediction interval is [879, 1514]. A fraction 0.455 of the households lie below the fitted median curve.

The log-scale residual variance $s^2 = 0.01871$ is small, and so is the retransformation bias: the smearing factor is 1.0091 and $\exp(s^2/2)$ is 1.0094. The estimated mean at income 2000 is 1164.2 by smearing and 1164.5 under normality, about one percent above the

Figure 22.5.1: Engel's data on the original scale with the log-log fit transformed back: the median curve $\exp(\hat{\beta}_0 + \hat{\beta}_1 \log x)$, the smearing estimate of the mean (dashed), nearly indistinguishable here because s^2 is small, and the 95% prediction band, which widens and becomes asymmetric as income grows.

median. The approximate 95% interval for the mean from Eq. 22.5.3 is [1122.4, 1208.3] at income 2000 and [345.4, 365.9] at income 500.

```
import numpy as np
import statsmodels.api as sm
from scipy import stats

df = sm.datasets.engel.load_pandas().data
income, food = df["income"].to_numpy(), df["foodexp"].to_numpy()
n = len(food)
X = np.column_stack([np.ones(n), np.log(income)])
fit = sm.OLS(np.log(food), X).fit()
b, s2, resid = fit.params, fit.scale, fit.resid
XtX_inv = np.linalg.inv(X.T @ X)
t = stats.t.ppf(0.975, n - 2)

smear = np.mean(np.exp(resid))          # Duan's smearing factor
lognormal = np.exp(s2 / 2)             # the normal-theory factor
print(f"smearing factor {smear:.4f}, lognormal factor {lognormal:.4f}")

for x0 in (500, 2000):
    v0 = np.array([1, np.log(x0)])
    eta, h0 = v0 @ b, v0 @ XtX_inv @ v0
    median = np.exp(eta)
    ci_med = np.exp(eta + np.array([-1, 1]) * t * np.sqrt(s2 * h0))    # for
    the median, exact
    pi = np.exp(eta + np.array([-1, 1]) * t * np.sqrt(s2 * (1 + h0)))  # for a
    new household, exact
    print(f"income {x0}: median {median:.1f}, CI [{ci_med[0]:.1f}, {ci_med[1]:.1f}];")
    print(f"      mean {median * smear:.1f} (smearing), {median * lognormal:.1f} (")
    print(f"      lognormal);")
    print(f"      95% prediction interval [{pi[0]:.0f}, {pi[1]:.0f}]")
```

22.5.3 Elasticities and marginal effects

In a transformed model a coefficient is not a rate of change of y per unit of x ; rates and elasticities follow by differentiating through both transformations.

Proposition 22.5.3 — Elasticities in a transformed model

Let $x_1 > 0$, and suppose that the median $m(\mathbf{x})$ of Y satisfies $m(\mathbf{x})^{(\lambda)} = \beta_0 + \beta_1 x_1^{(\alpha)} + c(\mathbf{x}_{-1})$, where c does not involve x_1 and the Box–Cox transformation Eq. 22.2.1 is applied to both m and x_1 . Then

$$\frac{\partial m}{\partial x_1} = \beta_1 x_1^{\alpha-1} m^{1-\lambda}, \quad \frac{x_1}{m} \frac{\partial m}{\partial x_1} = \beta_1 x_1^\alpha m^{-\lambda}. \quad (22.5.4)$$

In particular the elasticity is the constant β_1 in the log–log model ($\lambda = \alpha = 0$), $\beta_1 x_1$ in the log–level model ($\lambda = 0, \alpha = 1$), β_1/m in the level–log model ($\lambda = 1, \alpha = 0$) and $\beta_1 x_1/m$ in the untransformed model. Under Eq. 22.1.1 the mean is a constant multiple of the median, so for $\lambda = 0$ the elasticity of the mean is the same.

Proof. Differentiate the identity with respect to x_1 . By Proposition 22.2.1(b) the derivative of $m^{(\lambda)}$ with respect to m is $m^{\lambda-1}$ and that of $x_1^{(\alpha)}$ is $x_1^{\alpha-1}$, so $m^{\lambda-1} \partial m / \partial x_1 = \beta_1 x_1^{\alpha-1}$. Multiply by $m^{1-\lambda}$, and then by x_1/m . If the mean is $k m(\mathbf{x})$ for a constant k , the factor k cancels in the elasticity. ■

The model fixes the *shape* of the elasticity profile before the data have a say. For Engel’s data the log–log slope 0.8559 (interval [0.816, 0.896]) is one elasticity for all households. The untransformed linear fit implies an elasticity $\hat{\beta}_1 x / \hat{m}$ rising from 0.62 at income 500 to 0.87 at income 2000, only because a line with a positive intercept forces that shape. The Box–Tidwell estimate $\hat{\alpha} = -0.182$ of Example (Transforming income), with $\lambda = 0$, implies an elasticity proportional to $x^{-0.182}$, which *falls* between the same incomes by the factor $4^{-0.182} = \exp(-0.182 \log 4)$, about 0.78. Which shape the data support is a question about the mean function (Section 22.3).

22.5.4 Which scale to report

A transformation chosen for statistical reasons need not be the reporting scale. The logarithm is often worth keeping, since its coefficients are ratios and elasticities (Proposition 22.1.1). For other powers, report on the original scale: medians and prediction intervals, which transform exactly, and means, which need a correction factor and a constant variance. Compare models fitted on different scales on a common scale, through the Box–Cox likelihood (Section 22.2) or the accuracy of predictions of y (Chapter 29), not through R^2 (Exercise (B3)).

22.5.5 Exercises

22.5.5.1 A. Check your understanding

Exercise A1.

For Engel's log-log fit $s^2 = 0.01871$. Check that $\exp(s^2/2)$ is 1.0094. The smearing factor is 1.0091. Why are the two so close here, and in what kind of data would they differ substantially?

Exercise A2.

Explain why the prediction interval of [Example \(Engel's data on the original scale\)](#), obtained from [Theorem 12.3.1](#), is longer above the median than below it, and why its coverage is nevertheless exactly 95% under the normal model on the log scale.

22.5.5.2 B. Practice**Exercise B1.**

Under normal errors on the log scale, show that $E \exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}) = \exp(\mathbf{x}_0^\top \boldsymbol{\beta} + \sigma^2 h_0/2)$, so the naive median estimate is biased upwards by a factor that tends to one as $h_0 \rightarrow 0$. Suggest an approximately mean-unbiased alternative, and explain why $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}})$ is exactly median-unbiased.

Solution. $\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} \sim N(\mathbf{x}_0^\top \boldsymbol{\beta}, \sigma^2 h_0)$ ([Theorem 7.5.1](#)), and the normal moment generating function ([Theorem 3.2.1](#)) at 1 gives the mean. The median of $\mathbf{x}_0^\top \hat{\boldsymbol{\beta}}$ is $\mathbf{x}_0^\top \boldsymbol{\beta}$, and $\exp$ preserves medians, so $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}})$ is exactly median-unbiased for $\exp(\mathbf{x}_0^\top \boldsymbol{\beta})$. For mean-unbiasedness one can use $\exp(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} - s^2 h_0/2)$, which is approximately unbiased. The factor $\exp(\sigma^2 h_0/2)$ is tiny when h_0 is small, so the choice rarely matters.

Exercise B2.

Let $\sqrt{Y_i} = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + \varepsilon_i$ with $\mathbf{1} \in \mathcal{C}(\mathbf{X})$. Show that $E(Y | \mathbf{x}_0) = (\mathbf{x}_0^\top \boldsymbol{\beta})^2 + \sigma^2$ and that the smearing estimate $n^{-1} \sum_i (\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} + \hat{\varepsilon}_i)^2$ equals $(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}})^2 + \text{SSE}/n$. How does this compare with the plug-in estimate $(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}})^2 + s^2$?

Exercise B3.

For Engel's data at income 500, $s^2 = 0.01871$, $h_0 = 0.01147$ and $n - r = 233$. Evaluate the two terms of [Eq. 22.5.3](#) with σ^2 replaced by s^2 , and check the standard error 0.0147 used for the interval [345.4, 365.9]. Which term dominates, and why?

22.5.5.3 C. Going deeper**Exercise C1.**

Extend [Proposition 22.5.1\(c\)](#) to a general strictly increasing h that is continuously differentiable with $|h'(t)| \leq K(1 + e^{\kappa|t|})$ for some constants, assuming $E e^{\kappa'|\varepsilon|} < \infty$ for some

$\kappa' > \kappa$. Show that $n^{-1} \sum_i h(\mathbf{x}_0^\top \hat{\boldsymbol{\beta}} + \hat{\varepsilon}_i)$ converges in probability to $E(Y \mid \mathbf{x}_0)$. (Use the mean value theorem and the bound on $\max_i |\hat{\varepsilon}_i - \varepsilon_i|$ from the proof.)

Exercise C2.

Suppose that on the log scale $\varepsilon_i \sim N(0, \sigma^2(\mathbf{x}_{(i)}))$, independent, with the variance depending on the regressors. Show that $E(Y \mid \mathbf{x}_0) = \exp\{\mathbf{x}_0^\top \boldsymbol{\beta} + \sigma^2(\mathbf{x}_0)/2\}$, and that, when the leverages tend to zero and the average $n^{-1} \sum_i \exp\{\sigma^2(\mathbf{x}_{(i)})/2\}$ converges to a limit $\bar{c}$, the smearing factor tends to $\bar{c}$. For which $\mathbf{x}_0$ does the smearing estimate overestimate the mean, and for which does it underestimate it?

Solution. Given $\mathbf{x}_0$, $\log Y$ is normal with mean $\mathbf{x}_0^\top \boldsymbol{\beta}$ and variance $\sigma^2(\mathbf{x}_0)$, and the moment generating function (Theorem 3.2.1) gives the mean. The argument of Proposition 22.5.1(c) goes through with $A_n = n^{-1} \sum_i e^{\varepsilon_i}$, whose mean is $n^{-1} \sum_i \exp\{\sigma^2(\mathbf{x}_{(i)})/2\}$; if the variances are bounded, its variance tends to zero, so $A_n \rightarrow \bar{c}$. The smearing estimate therefore targets $\exp(\mathbf{x}_0^\top \boldsymbol{\beta}) \bar{c}$. It overestimates the mean where $\exp\{\sigma^2(\mathbf{x}_0)/2\} < \bar{c}$, that is, where the log-scale variance is below its average in this sense, and underestimates it where the variance is above.

22.6 Summary and Notes

22.6.1 Summary

Idea.

1. A strictly increasing transformation of the response acts on linearity, constant variance and normality at once. Multiplicative errors make the logarithm exact for the first two, and log-scale coefficients are then ratios of quantiles and means (Proposition 22.1.1). The mean comes first.
2. The Box–Cox family is continuous in λ , increasing, ordered by convexity, and bounded on one side except at the logarithm (Definition 22.2.1 and Proposition 22.2.1).
3. With the geometric-mean normalization the profile log-likelihood of λ is $-\frac{n}{2} \log \text{SSE}_z(\lambda)$ plus a constant, which gives the likelihood ratio interval (Theorem 22.2.2), free of the units of y (Proposition 22.2.3). The constructed variable locates its stationary points (Proposition 22.2.4).
4. Component-plus-residual plots show the shape of a regressor's effect, distorted by the part of the nonlinearity the other regressors reproduce (Proposition 22.3.1). The Box–Tidwell constructed variable gives an exact test of a regressor's power, and its iteration is Gauss–Newton (Theorem 22.3.2).
5. $\int v^{-1/2}$ stabilizes a variance function v , uniquely up to sign and a constant (Theorem 22.4.1): square roots for counts, arcsine square roots for proportions, logarithms for a constant coefficient of variation (Corollary 22.4.2).
6. Quantiles pass through a monotone transformation, means do not. The back-transformed fit estimates medians; the mean needs a factor, which smearing sup-

plies without normality ([Proposition 22.5.1](#)). Prediction intervals and intervals for medians transform exactly ([Proposition 22.5.2](#)), and elasticities follow by differentiating through both scales ([Proposition 22.5.3](#)).

22.6.2 Notes and sources

Source books. Coverage was checked against Sen and Srivastava (1990, chapter 9), Seber and Lee (2003, section 10.3 and parts of sections 10.4–10.5) and Christensen (2020, section 12.7). Proofs, examples and exercises here are this book’s own.

Power transformations. Tukey (1957) studied the powers systematically, and Tukey (1977) popularized the ladder. Box and Cox (1964) introduced the likelihood approach and the geometric-mean normalization, and Hernandez and Johnson (1980) gave its large-sample theory when no power is exactly right. On whether inference should allow for estimating λ , see Bickel and Doksum (1981), Box and Cox (1982) and Hinkley and Runger (1984). Carroll and Ruppert (1988) is the standard monograph on transformation and weighting, including the *transform-both-sides* model, which transforms the response and a known nonlinear mean function alike. Yeo and Johnson (2000) give a family defined on the whole line.

Diagnostics. Constructed variables and their added-variable plots are developed by Atkinson (1985) and Cook and Weisberg (1982); Atkinson and Cook and Wang (1983) study the influence of single cases on $\hat{\lambda}$. Larsen and McCleary (1972) analysed partial residual plots, Mallows (1986) augmented them, and Cook (1993) explained when they work. Box and Tidwell (1962) proposed the regressor transformation, and Royston and Altman (1994) fractional polynomials.

Variance stabilization and retransformation. Bartlett (1947) reviewed variance-stabilizing transformations and the spread-versus-level idea, Anscombe (1948) derived the constants 3/8, and Grizzle, Starmer and Koch (1969) developed weighted least squares on transformed proportions. The limit theorems are in van der Vaart (1998). The smearing estimate is due to Duan (1983). Manning (1998) showed how heteroscedasticity on the log scale biases retransformed means, one reason why generalized linear models with a log link ([Chapter 34](#)) are now the usual alternative for skewed positive responses.

Chapter 23

Bootstrap and Permutation Inference

Every test and interval in Part III took its reference distribution from the normal model. This chapter asks whether the reference distribution can be taken from the data instead. The bootstrap imitates the process that produced the data by resampling residuals, whole cases, or residuals with random signs, and each choice assumes a different model. A permutation test rearranges the data in ways that leave their distribution unchanged under the null hypothesis, and is exact whenever such rearrangements exist. In regression they exist only for simple hypotheses, and the Freedman–Lane scheme shows how to get close in other cases.

What you need. Chapter 6 (projections, leverage, Proposition 6.8.1, and the Frisch–Waugh–Lovell theorem, Theorem 6.6.2), Chapter 7 (sampling distributions in the normal model, Theorem 7.5.1 and Corollary 7.5.2), Chapter 10 (the deletion formulas, Proposition 10.6.2), Chapter 11 (the F test of a linear hypothesis, Theorem 11.1.1), Chapter 14 (random regressors and conditional inference) and Chapter 18 (randomized blocks). From this part: Chapter 19 (asymptotic normality without normal errors), Chapter 20 (studentized residuals) and Chapter 21 (sandwich covariance estimators and serial correlation).

23.0.1 Roadmap

- Resampling cases versus resampling residuals
- The wild bootstrap
- Bootstrap confidence intervals
- Permutation tests for linear hypotheses
- Freedman–Lane and related schemes
- When resampling fails
- Summary and notes

23.1 Resampling cases versus resampling residuals

Let $\theta = \mathbf{c}^\top \boldsymbol{\beta}$ be estimated by $\hat{\theta} = \mathbf{c}^\top \hat{\boldsymbol{\beta}}$. An interval or a test for θ needs the distribution of a **root** such as $\hat{\theta} - \theta$, or a studentized version of it. That distribution depends on the mechanism

P that produced the data. In Part III, P lay in the normal linear model, where the studentized root is $t(n-r)$ whatever the parameters. Without that assumption the distribution is unknown.

The **bootstrap** (Efron 1979) replaces P by an estimate $\hat{P}$. Draw a data set $\mathbf{Y}^*$ from $\hat{P}$, compute $\hat{\theta}^*$ from it, and use the distribution of $\hat{\theta}^* - \hat{\theta}$, given the data, as the approximation to that of $\hat{\theta} - \theta$. Here $\hat{\theta}$ plays the true value, because it is the value of θ under $\hat{P}$. Probabilities, expectations and covariances under $\hat{P}$ with the data held fixed are written $\Pr_*$, E_* and Cov_* . In practice B resamples approximate the bootstrap distribution. Their Monte Carlo error shrinks as B grows; the statistical error, from the gap between $\hat{P}$ and P , does not, and it is the subject of this chapter.

23.1.1 Two ways to estimate the data-generating mechanism

In the **fixed-design model** the rows $\mathbf{x}_{(i)}^\top$ of $\mathbf{X}$ are constants and $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with independent, identically distributed errors from an unknown law F . Estimate $\boldsymbol{\beta}$ by $\hat{\boldsymbol{\beta}}$ and F by the empirical distribution of the residuals. In the **random-design model** the cases $(\mathbf{x}_{(i)}, Y_i)$ are independent draws from an unknown joint distribution. Estimate it by the empirical distribution of the n cases.

Definition 23.1.1 — Residual and case bootstraps

Let $\mathbf{X}$ be $n \times p$ of rank p , with least squares estimate $\hat{\boldsymbol{\beta}}$ and residuals $\hat{\varepsilon}_1, \dots, \hat{\varepsilon}_n$ with mean $\bar{\hat{\varepsilon}}$.

- (a) The **residual bootstrap** draws $\varepsilon_1^*, \dots, \varepsilon_n^*$ independently and uniformly from the centred residuals $\tilde{\varepsilon}_i = \hat{\varepsilon}_i - \bar{\hat{\varepsilon}}$, sets $\mathbf{Y}^* = \mathbf{X}\hat{\boldsymbol{\beta}} + \boldsymbol{\varepsilon}^*$, and computes $\hat{\boldsymbol{\beta}}^* = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}^*$. The design is the same in every resample.
- (b) The **case bootstrap** (or pairs bootstrap) draws n indices $I_1, \dots, I_n$ independently and uniformly from $\{1, \dots, n\}$ and computes the least squares estimate $\hat{\boldsymbol{\beta}}^*$ from the cases $(\mathbf{x}_{(I_k)}, Y_{I_k})$, $k = 1, \dots, n$. The design changes from resample to resample.

Variants of (a) resample the **leverage-adjusted residuals** $r_i = \hat{\varepsilon}_i / \sqrt{1 - h_{ii}}$, centred, or the residuals rescaled by $\sqrt{n/(n-p)}$.

With an intercept the residuals already sum to zero (Proposition 6.4.3(b)). Without one, centring prevents a bias in the bootstrap world (Exercise (A1)).

23.1.2 The moments of the residual bootstrap

Proposition 23.1.1 — Moments of the residual bootstrap

In the residual bootstrap, put $\hat{\sigma}_*^2 = n^{-1} \sum_i \tilde{\varepsilon}_i^2$, the variance of the resampled law. Then:

- (a) $E_*(\hat{\boldsymbol{\beta}}^*) = \hat{\boldsymbol{\beta}}$ and $\text{Cov}_*(\hat{\boldsymbol{\beta}}^*) = \hat{\sigma}_*^2 (\mathbf{X}^\top \mathbf{X})^{-1}$;
- (b) if $\mathbf{1} \in \mathcal{C}(\mathbf{X})$, then $\hat{\sigma}_*^2 = \text{SSE}/n = (n-p)s^2/n$;

- (c) if the data follow the linear model with $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$, then $E(r_i^2) = \sigma^2$ for each i with $h_{ii} < 1$.

Proof.

- (a) Given the data, $\hat{\boldsymbol{\beta}}^* = \hat{\boldsymbol{\beta}} + (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \boldsymbol{\varepsilon}^*$, where the ε_i^* are independent with $E_*(\varepsilon_i^*) = n^{-1} \sum_j \tilde{\varepsilon}_j = 0$ and $\text{Var}_*(\varepsilon_i^*) = \hat{\sigma}_*^2$. Apply [Theorem 5.5.1](#) in the bootstrap world. (b) The residuals sum to zero, so $\tilde{\varepsilon}_i = \hat{\varepsilon}_i$. (c) $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$ by [Proposition 6.4.3\(e\)](#), so $E(\hat{\varepsilon}_i) = 0$ and $\text{Var}(\hat{\varepsilon}_i) = \sigma^2(1 - h_{ii})$. ■

By (b) the plain residual bootstrap shrinks the usual variance by the factor $(n - p)/n$: residuals are shorter than errors because least squares fits part of the noise ([Theorem 5.6.1](#)). The factor matters only when p/n is not small ([Section 23.6](#)). Rescaling by $\sqrt{n/(n - p)}$ removes it exactly when the model has an intercept. The leverage-adjusted residuals remove it observation by observation. They are s times the internally studentized residuals of [Chapter 20](#) ([Definition 20.1.1](#)).

23.1.3 Consistency for a linear contrast

Consider designs $\mathbf{X}_n$ of rank p , with p fixed, and errors $\varepsilon_{n1}, \dots, \varepsilon_{nn}$ drawn independently from a fixed law F with mean zero and variance $\sigma^2 \in (0, \infty)$. For $\mathbf{c}_n \neq \mathbf{0}$ put

$$\begin{aligned} \mathbf{a}_n &= \mathbf{X}_n (\mathbf{X}_n^\top \mathbf{X}_n)^{-1} \mathbf{c}_n, & \mathbf{c}_n^\top (\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) &= \mathbf{a}_n^\top \boldsymbol{\varepsilon}, \\ \|\mathbf{a}_n\|^2 &= \mathbf{c}_n^\top (\mathbf{X}_n^\top \mathbf{X}_n)^{-1} \mathbf{c}_n, \end{aligned}$$

so the contrast estimate is a weighted sum of the errors with standard deviation $\sigma \|\mathbf{a}_n\|$. The condition we need is that no single weight dominates:

$$m_n = \max_i \frac{|a_{ni}|}{\|\mathbf{a}_n\|} \rightarrow 0. \quad (23.1.1)$$

The Cauchy–Schwarz bound $a_{ni}^2 \leq h_{ii} \|\mathbf{a}_n\|^2$ in the proof of [Theorem 19.3.2](#) shows that [Eq. 23.1.1](#) holds for every contrast when the largest leverage tends to zero. The limit theorem used there is the Lindeberg–Feller theorem of [Chapter 19](#); for a triangular array U_{ni} its condition holds in particular when $\sum_i E U_{ni}^4 \rightarrow 0$ (Lyapunov), since the Lindeberg sum is at most $\eta^{-2} \sum_i E U_{ni}^4$. We add one more result from probability, used without proof (van der Vaart 1998, chapter 2).

Remark (Pólya’s theorem). If distribution functions G_n converge pointwise to a continuous distribution function G , then $\sup_x |G_n(x) - G(x)| \rightarrow 0$.

A bootstrap distribution is a conditional distribution that changes with the data, so we need a conditional form of the Lindeberg–Feller theorem.

Lemma 23.1.2 — A conditional central limit theorem

For each n , given the data $\mathcal{D}_n$, let $U_{n1}^*, \dots, U_{nn}^*$ be independent with $E_*(U_{ni}^*) = 0$ and

$\sum_i E_*(U_{ni}^{*2}) = 1$. If for every $\eta > 0$

$$L_n^*(\eta) = \sum_i E_*[U_{ni}^{*2} \mathbf{1}\{|U_{ni}^*| > \eta\}] \rightarrow 0 \quad \text{in probability,}$$

then $\Delta_n = \sup_x |\Pr_*(\sum_i U_{ni}^* \leq x) - \Phi(x)| \rightarrow 0$ in probability.

Proof. Random variables converge to zero in probability if and only if every subsequence has a further subsequence along which they converge almost surely. Given a subsequence, a diagonal argument gives a further subsequence along which $L_n^*(1/k) \rightarrow 0$ almost surely for every $k = 1, 2, \dots$ at once. Since $L_n^*(\eta)$ decreases in η , on this event $L_n^*(\eta) \rightarrow 0$ for every $\eta > 0$. For each outcome in the event the conditional laws satisfy the Lindeberg condition, so $\Delta_n \rightarrow 0$ by the Lindeberg–Feller and Pólya theorems. ■

Lemma 23.1.3 — Residuals have uniformly small tails

In the setting above, $\hat{\sigma}_*^2 \rightarrow \sigma^2$ in probability, and for every sequence of constants $K_n \rightarrow \infty$, $n^{-1} \sum_i \tilde{\varepsilon}_i^2 \mathbf{1}\{|\tilde{\varepsilon}_i| > K_n\} \rightarrow 0$ in probability.

Proof. Write $\tilde{\varepsilon}_i = \varepsilon_i - \delta_i$ with $\boldsymbol{\delta} = \mathbf{M}\boldsymbol{\varepsilon} + \bar{\varepsilon}\mathbf{1}$. Here $E\|\mathbf{M}\boldsymbol{\varepsilon}\|^2 = \sigma^2 p$, and $\bar{\varepsilon} = n^{-1}\mathbf{1}^\top(\mathbf{I} - \mathbf{M})\boldsymbol{\varepsilon}$ has $E(\bar{\varepsilon}^2) = \sigma^2 n^{-2}\mathbf{1}^\top(\mathbf{I} - \mathbf{M})\mathbf{1} \leq \sigma^2/n$. So $E\|\boldsymbol{\delta}\|^2 \leq 2\sigma^2(p+1)$, and $n^{-1}\|\boldsymbol{\delta}\|^2 \rightarrow 0$ in probability.

First claim: $\hat{\sigma}_*^2 = n^{-1}\|\boldsymbol{\varepsilon}\|^2 - n^{-1}\|\mathbf{M}\boldsymbol{\varepsilon}\|^2 - \bar{\varepsilon}^2$. The first term tends to σ^2 by the weak law of large numbers (the errors of the n th model are an independent sample from F), and the others tend to zero.

Second claim: for $K > 0$ and reals u, d , with $v = u - d$,

$$v^2 \mathbf{1}\{|v| > K\} \leq 2u^2 \mathbf{1}\{|u| > K/2\} + 4d^2.$$

If $|u| > K/2$, use $v^2 \leq 2u^2 + 2d^2$. If $|u| \leq K/2$ and $|v| > K$, then $|d| \geq |v| - |u| > K/2 \geq |u|$, so $|v| \leq 2|d|$. Otherwise the left side is zero. With $u = \varepsilon_i$, $d = \delta_i$ and $K = K_n$, averaging gives

$$\begin{aligned} \frac{1}{n} \sum_i \tilde{\varepsilon}_i^2 \mathbf{1}\{|\tilde{\varepsilon}_i| > K_n\} &\leq \frac{2}{n} \sum_i \varepsilon_i^2 \mathbf{1}\{|\varepsilon_i| > K_n/2\} \\ &\quad + \frac{4}{n} \|\boldsymbol{\delta}\|^2. \end{aligned}$$

The first term has expectation $2E[\varepsilon^2 \mathbf{1}\{|\varepsilon| > K_n/2\}] \rightarrow 0$ by dominated convergence, and the second tends to zero in probability. ■

Theorem 23.1.4 — Consistency of the residual bootstrap

In the fixed-design setting above, assume [Eq. 23.1.1](#). Let

$$G_n(x) = \Pr(\mathbf{c}_n^\top(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}) \leq x\|\mathbf{a}_n\|),$$

$$\hat{G}_n(x) = \Pr_*(\mathbf{c}_n^\top(\hat{\boldsymbol{\beta}}^* - \hat{\boldsymbol{\beta}}) \leq x\|\mathbf{a}_n\|),$$

where $\hat{\boldsymbol{\beta}}^*$ comes from the residual bootstrap. Then:

- (a) $\sup_x |G_n(x) - \Phi(x/\sigma)| \rightarrow 0$;
- (b) $\sup_x |\hat{G}_n(x) - \Phi(x/\sigma)| \rightarrow 0$ in probability;
- (c) $\sup_x |\hat{G}_n(x) - G_n(x)| \rightarrow 0$ in probability.

Proof. Put $w_i = a_{ni}/\|\mathbf{a}_n\|$, so $\sum_i w_i^2 = 1$ and $\max_i |w_i| = m_n \rightarrow 0$.

- (a) $\mathbf{c}_n^\top(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})/\|\mathbf{a}_n\| = \sum_i w_i \varepsilon_i$. When $\max_i h_{ii} \rightarrow 0$ the claim is [Theorem 19.3.2\(a\)](#) with Pólya's theorem. The same Lindeberg argument needs only [Eq. 23.1.1](#): with $U_{ni} = w_i \varepsilon_i/\sigma$, the Lindeberg sum is at most $E[\sigma^{-2} \varepsilon_i^2 \mathbf{1}\{|\varepsilon_i| > \eta\sigma/m_n\}] \rightarrow 0$, by dominated convergence.
- (b) Similarly $\mathbf{c}_n^\top(\hat{\boldsymbol{\beta}}^* - \hat{\boldsymbol{\beta}})/\|\mathbf{a}_n\| = \sum_i w_i \varepsilon_i^*$. Take $U_{ni}^* = w_i \varepsilon_i^*/\hat{\sigma}_*$. As in (a),

$$L_n^*(\eta) \leq \frac{1}{n\hat{\sigma}_*^2} \sum_i \varepsilon_i^{*2} \mathbf{1}\{|\varepsilon_i^*| > \eta\hat{\sigma}_*/m_n\}.$$

By [Lemma 23.1.3](#), $\hat{\sigma}_* \rightarrow \sigma$ in probability. On the event $\hat{\sigma}_* > \sigma/2$, whose probability tends to one, the right side is at most $4\sigma^{-2}n^{-1} \sum_i \varepsilon_i^{*2} \mathbf{1}\{|\varepsilon_i^*| > K_n\}$ with $K_n = \eta\sigma/(2m_n) \rightarrow \infty$, which tends to zero in probability by the lemma. So [Lemma 23.1.2](#) gives $\sup_x |\hat{G}_n(x) - \Phi(x/\hat{\sigma}_*)| \rightarrow 0$ in probability. Finally $\sup_x |\Phi(x/\hat{\sigma}_*) - \Phi(x/\sigma)|$ is a continuous function of $\hat{\sigma}_*/\sigma$ that vanishes at 1, so it tends to zero in probability.

- (c) follows from (a) and (b) by the triangle inequality. ■

The theorem holds for the rescaled residuals too, since they differ by the factor $\sqrt{n/(n-p)} \rightarrow 1$; for the leverage-adjusted ones the proof adapts when $\max_i h_{ii} \rightarrow 0$, with small changes we omit. It needs neither normal errors nor moments beyond the second. Freedman (1981) proved it in a stronger metric, together with a statement for the case bootstrap. It does not say that the bootstrap beats the normal approximation $\Phi(x/s)$, which is consistent under the same conditions. The bootstrap earns its keep through studentization ([Section 23.3](#)) and through its flexibility for statistics with no convenient standard error.

Warning. The residual bootstrap treats the residuals as exchangeable. It gives $\text{Cov}_*(\hat{\boldsymbol{\beta}}^*) = \hat{\sigma}_*^2(\mathbf{X}^\top \mathbf{X})^{-1}$ whatever the data look like, which is the classical formula, so it inherits that formula's failure under heteroscedasticity ([Theorem 19.2.2](#), [Exercise \(B1\)](#)). Wu (1986) made this point forcefully.

23.1.4 The case bootstrap

The case bootstrap assumes only that the cases are independent draws from a population. By [Proposition 6.11.3](#), least squares then estimates the population projection coefficient whether

or not the regression function is linear, and the case bootstrap estimates the variability of $\hat{\beta}$ around that target.

Let W_i be the number of times case i is drawn, so that $(W_1, \dots, W_n)$ is multinomial with n trials and equal probabilities, and put $\mathbf{W} = \text{diag}(W_i)$. When $\mathbf{X}^\top \mathbf{W} \mathbf{X}$ is invertible, $\hat{\beta}^* = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{y}$, and since $\mathbf{y} = \mathbf{X} \hat{\beta} + \hat{\epsilon}$,

$$\hat{\beta}^* - \hat{\beta} = (\mathbf{X}^\top \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \hat{\epsilon}. \quad (23.1.2)$$

The matrix $n^{-1} \mathbf{X}^\top \mathbf{W} \mathbf{X}$ has expectation $n^{-1} \mathbf{X}^\top \mathbf{X}$ and is close to it for large n . Replacing it by its expectation gives a linear approximation whose covariance is exact.

Proposition 23.1.5 — The case bootstrap, linearized, is the sandwich

Let $\mathbf{L}^* = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{W} \hat{\epsilon}$. Then $E_*(\mathbf{L}^*) = \mathbf{0}$ and

$$\text{Cov}_*(\mathbf{L}^*) = (\mathbf{X}^\top \mathbf{X})^{-1} \left(\sum_i \hat{\epsilon}_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \right) (\mathbf{X}^\top \mathbf{X})^{-1},$$

the sandwich covariance estimator HC0 of Chapter 21 (Theorem 21.4.2).

Proof. For multinomial counts with n trials and probabilities $1/n$, $E(W_i) = 1$, $\text{Var}(W_i) = 1 - 1/n$ and $\text{Cov}(W_i, W_j) = -1/n$ for $i \neq j$. So $E_*(\mathbf{W} \hat{\epsilon}) = \hat{\epsilon}$ and $\text{Cov}_*(\mathbf{W} \hat{\epsilon}) = \text{diag}(\hat{\epsilon})(\mathbf{I} - n^{-1} \mathbf{1} \mathbf{1}^\top) \text{diag}(\hat{\epsilon})$. Hence $E_*(\mathbf{L}^*) = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \hat{\epsilon} = \mathbf{0}$ by Proposition 6.4.3(a), and $\text{Cov}_*(\mathbf{X}^\top \mathbf{W} \hat{\epsilon}) = \sum_i \hat{\epsilon}_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top - n^{-1} (\mathbf{X}^\top \hat{\epsilon})(\mathbf{X}^\top \hat{\epsilon})^\top = \sum_i \hat{\epsilon}_i^2 \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$. ■

To first order, then, the case bootstrap estimates the variance of $\hat{\beta}$ by the sandwich, not the classical formula. The price is a varying design: a case of high leverage appears in some resamples several times and in others not at all, and with indicator columns some resamples are singular (Exercise (B2)).

Example. (Engel's food expenditure)

Return to Engel's data on the income and food expenditure of 235 households (Example (Engel's food expenditure data)). The least squares slope is 0.4852, and the scatter fans out (Figure 23.1.1(a)): the residual standard deviation is 2.36 times larger for the richer half of the households.

The classical standard error of the slope is 0.01437. The residual bootstrap with $B = 4000$ resamples gives 0.01433, near its exact value 0.01431, the classical value times $\sqrt{(n-2)/n} = 0.9957$ (Proposition 23.1.1); with leverage-adjusted residuals the exact value is 0.01484. The case bootstrap gives 0.05032, more than three times as large and close to the HC0 value 0.05177 of Proposition 23.1.5; Chapter 21 computed this and the other sandwich standard errors for the same slope. The residual bootstrap's answer rests on a constant variance that the data contradict.

```
import numpy as np
import statsmodels.api as sm
```

```
data = sm.datasets.engel.load_pandas().data

y = data["foodexp"].to_numpy()
x = data["income"].to_numpy()
X = np.column_stack([np.ones(len(y)), x])
n, p = X.shape
XtX_inv = np.linalg.inv(X.T @ X)
beta_hat = XtX_inv @ X.T @ y
e_hat = y - X @ beta_hat
h = np.sum((X @ XtX_inv) * X, axis=1)          # leverages
s2 = e_hat @ e_hat / (n - p)
se_classical = np.sqrt(s2 * XtX_inv[1, 1])
print(f"slope {beta_hat[1]:.4f}, classical se {se_classical:.5f}, max leverage {h.
      max():.3f}")

rng = np.random.default_rng(2301)
B = 4000
A = XtX_inv @ X.T                               # beta_hat = A y
fit = X @ beta_hat
e_c = e_hat - e_hat.mean()                       # centred residuals
r = e_hat / np.sqrt(1 - h)                       # leverage-adjusted residuals
r_c = r - r.mean()

def residual_bootstrap(resid, B):
    """Slopes from  $y^* = X \beta_{\text{hat}} + e^*$ , with  $e^*$  drawn with replacement from resid.
    """
    idx = rng.integers(0, n, size=(B, n))
    y_star = fit + resid[idx]
    return (y_star @ A.T)[: , 1]

slopes_res = residual_bootstrap(e_c, B)
slopes_mod = residual_bootstrap(r_c, B)
print(f"residual bootstrap se: raw {slopes_res.std():.5f}, leverage-adjusted {
      slopes_mod.std():.5f}")

def pairs_bootstrap(B):
    """Slopes refitted to  $n$  cases drawn with replacement from the  $(x_i, y_i)$ ."""
```

```

idx = rng.integers(0, n, size=(B, n))
xs, ys = x[idx], y[idx]
xc = xs - xs.mean(axis=1, keepdims=True)
return np.sum(xc * ys, axis=1) / np.sum(xc ** 2, axis=1)

slopes_pairs = pairs_bootstrap(B)
print(f"case bootstrap se {slopes_pairs.std():.5f}")

```

The choice between the two is a choice of model. The residual bootstrap suits a linear mean with exchangeable errors, even for sampled cases: when the error law does not depend on $\mathbf{X}$, conditioning on the design is justified as in [Section 14.1](#), where [Theorem 14.1.2](#) makes it exact under normality. It is then the more accurate, since it adds no noise from a varying design. Under heteroscedasticity or a nonlinear mean the case bootstrap is safer. The wild bootstrap of the next section keeps the design fixed and still respects heteroscedasticity.

23.1.5 Exercises

23.1.5.1 A. Check your understanding

Exercise A1.

In a regression through the origin, $E(Y_i) = \beta x_i$, the residuals need not sum to zero. Show that if the residual bootstrap resampled the uncentred residuals, then $E_*(\hat{\beta}^*) - \hat{\beta} = \bar{\tilde{\varepsilon}} \sum_i x_i / \sum_i x_i^2$.

Solution. Here $\hat{\beta}^* - \hat{\beta} = \sum_i x_i \varepsilon_i^* / \sum_i x_i^2$, and each uncentred draw has $E_*(\varepsilon_i^*) = n^{-1} \sum_j \hat{\varepsilon}_j = \bar{\tilde{\varepsilon}}$. Taking expectations gives the stated bias, which is not zero unless $\bar{\tilde{\varepsilon}} = 0$ or $\sum_i x_i = 0$.

Exercise A2.

A case-bootstrap resample of size n contains each original case with probability $1 - (1 - 1/n)^n$. Show that the expected number of distinct cases in a resample is $n(1 - (1 - 1/n)^n)$, about $0.632n$ for large n .

23.1.5.2 B. Practice

Exercise B1.

Suppose the errors are independent with variances σ_i^2 , and the model has an intercept. Show that the residual bootstrap variance of $\mathbf{c}^\top \hat{\boldsymbol{\beta}}^*$ has expectation $\|\mathbf{a}\|^2 n^{-1} \sum_i (1 - h_{ii}) \sigma_i^2$, whereas $\text{Var}(\mathbf{c}^\top \hat{\boldsymbol{\beta}}) = \sum_i a_i^2 \sigma_i^2$. Construct a two-group example in which the ratio of the two is as small as you like.

Solution. By [Proposition 23.1.1](#) the bootstrap variance is $\|\mathbf{a}\|^2 \text{SSE}/n$, and $E(\text{SSE}) = \text{tr}((\mathbf{I} - \mathbf{M})\boldsymbol{\Sigma}) = \sum_i (1 - h_{ii}) \sigma_i^2$ for diagonal $\boldsymbol{\Sigma}$. The true variance is $\mathbf{a}^\top \boldsymbol{\Sigma} \mathbf{a}$. Take two groups of sizes n_1 and n_2 and the contrast of the group means, so $a_i = 1/n_1$ in group 1 and $-1/n_2$ in group 2. With $\sigma_i^2 = \sigma_1^2$ in the small group and 0 in the large one, the true

variance is σ_1^2/n_1 and the expected bootstrap variance is $(1/n_1 + 1/n_2)(n_1 - 1)\sigma_1^2/n$. With n_1 fixed the ratio of the second to the first tends to 0 as $n_2 \rightarrow \infty$.

Exercise B2.

In a one-way layout with g groups of m observations each, find the probability that a case-bootstrap resample omits some group entirely, so that the cell-means model cannot be fitted. Evaluate it for $g = 5$, $m = 4$, and describe a resampling scheme that avoids the problem.

23.2 The wild bootstrap

The residual bootstrap keeps the design but moves every residual to a random position, destroying any link between the size of an error and where it occurred. The case bootstrap keeps that link but changes the design. The **wild bootstrap** keeps both: each residual stays with its own row of $\mathbf{X}$, and only a random multiplier changes (Wu 1986; Liu 1988; Mammen 1993).

Definition 23.2.1 — Wild bootstrap

Let $\mathbf{X}$ have rank p , with least squares estimate $\hat{\boldsymbol{\beta}}$, residuals $\hat{\varepsilon}_i$ and leverages $h_{ii} < 1$. Choose transformed residuals u_i , one of

$$u_i = \hat{\varepsilon}_i, \quad u_i = \frac{\hat{\varepsilon}_i}{\sqrt{1 - h_{ii}}}, \quad u_i = \frac{\hat{\varepsilon}_i}{1 - h_{ii}},$$

and a law for the **multipliers**, with mean 0 and variance 1. The wild bootstrap draws $v_1, \dots, v_n$ independently from that law, independently of the data, sets

$$Y_i^* = \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}} + u_i v_i, \quad i = 1, \dots, n,$$

and computes $\hat{\boldsymbol{\beta}}^* = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}^*$. Two standard multiplier laws are the **Rademacher** law, $v = \pm 1$ with probability 1/2 each, and **Mammen's** two-point law

$$\Pr\left(v = \frac{1 - \sqrt{5}}{2}\right) = \frac{\sqrt{5} + 1}{2\sqrt{5}}, \quad \Pr\left(v = \frac{1 + \sqrt{5}}{2}\right) = \frac{\sqrt{5} - 1}{2\sqrt{5}}.$$

In the bootstrap world the error of case i is $u_i v_i$, with mean zero and its own variance u_i^2 . One residual is a poor estimate of a variance, but $\mathbf{c}^\top \hat{\boldsymbol{\beta}}$ needs only a weighted average of the variances, as for the sandwich.

Proposition 23.2.1 — Moments of the wild bootstrap

In the wild bootstrap, with $\mathbf{U} = \text{diag}(u_1, \dots, u_n)$ and $\mathbf{a} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{c}$:

(a) $E_*(\hat{\boldsymbol{\beta}}^*) = \hat{\boldsymbol{\beta}}$ and

$$\text{Cov}_*(\hat{\boldsymbol{\beta}}^*) = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{U}^2 \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1}, \quad (23.2.1)$$

which is the sandwich estimator HC0, HC2 or HC3 (Theorem 21.4.2) for the three choices of u_i ;

$$(b) \ E_*[(\mathbf{c}^\top \hat{\boldsymbol{\beta}}^* - \mathbf{c}^\top \hat{\boldsymbol{\beta}})^3] = E(v^3) \sum_i a_i^3 u_i^3.$$

Proof. $\hat{\boldsymbol{\beta}}^* - \hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{U} \mathbf{v}$, where $\mathbf{v} = (v_1, \dots, v_n)^\top$ has mean $\mathbf{0}$ and covariance $\mathbf{I}$. So $E_*(\hat{\boldsymbol{\beta}}^*) = \hat{\boldsymbol{\beta}}$ and $\text{Cov}_*(\hat{\boldsymbol{\beta}}^*) = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{U} \mathbf{U} \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1}$. For (b), $\mathbf{c}^\top (\hat{\boldsymbol{\beta}}^* - \hat{\boldsymbol{\beta}}) = \sum_i a_i u_i v_i$ is a sum of independent terms with mean zero, and the third moment of such a sum is the sum of the third moments, because every cross term contains some v_i to the first power. ■

So the wild bootstrap reproduces the sandwich exactly, not only to first order as the case bootstrap does (Proposition 23.1.5). Part (b) explains the choice of multipliers. The true third moment is $\sum_i a_i^3 E(\varepsilon_i^3)$, not zero for skewed errors. Rademacher multipliers have $E(v^3) = 0$ and give a symmetric bootstrap distribution; Mammen's law is the two-point law with third moment 1 (Exercise (B1)) and carries the skewness of the residuals. Davidson and Flachaire (2008) nonetheless favour Rademacher weights for tests, because matching the third moment costs accuracy in the fourth.

23.2.1 Consistency under heteroscedasticity

Take the fixed designs of Section 23.1, with contrasts $\mathbf{c}_n$, weights $\mathbf{a}_n$, $w_i = a_{ni}/\|\mathbf{a}_n\|$ and Eq. 23.1.1. The errors $\varepsilon_{n1}, \dots, \varepsilon_{nn}$ are independent with mean zero and variances σ_{ni}^2 , and for some constants $0 < \underline{\sigma}^2$ and $K < \infty$,

$$\sigma_{ni}^2 \geq \underline{\sigma}^2, \quad E \varepsilon_{ni}^4 \leq K \quad \text{for all } n, i. \quad (23.2.2)$$

The variance of the standardized contrast is $\tau_n^2 = \sum_i w_i^2 \sigma_{ni}^2$, which lies between $\underline{\sigma}^2$ and $\sqrt{K}$, since $\sigma_{ni}^2 \leq (E \varepsilon_{ni}^4)^{1/2}$.

Theorem 23.2.2 — Consistency of the wild bootstrap

Under Eq. 23.1.1 and Eq. 23.2.2, let $\hat{\boldsymbol{\beta}}^*$ come from the wild bootstrap with $u_i = \hat{\varepsilon}_i$ and multipliers from any fixed law with mean 0 and variance 1, and let G_n and $\hat{G}_n$ be defined as in Theorem 23.1.4, with this $\hat{\boldsymbol{\beta}}^*$. Then $\sup_x |\hat{G}_n(x) - G_n(x)| \rightarrow 0$ in probability, and both are uniformly close to $\Phi(x/\tau_n)$.

Proof. Write $\mathbf{d} = \mathbf{M}\boldsymbol{\varepsilon}$, so that $\hat{\varepsilon}_i = \varepsilon_i - d_i$, and put $m_n = \max_i |w_i|$. Four steps.

Step 1: the bootstrap variance. Let $S_n^2 = \sum_i w_i^2 \hat{\varepsilon}_i^2$, the bootstrap variance of $\mathbf{c}_n^\top (\hat{\boldsymbol{\beta}}^* - \hat{\boldsymbol{\beta}})/\|\mathbf{a}_n\|$ by Proposition 23.2.1. We show $S_n^2 - \tau_n^2 \rightarrow 0$ in probability. Expand $S_n^2 = \sum_i w_i^2 \varepsilon_i^2 - 2 \sum_i w_i^2 \varepsilon_i d_i + \sum_i w_i^2 d_i^2$. The first sum has mean τ_n^2 and variance $\sum_i w_i^4 \text{Var}(\varepsilon_i^2) \leq K m_n^2 \sum_i w_i^2 = K m_n^2 \rightarrow 0$. The third is at most $m_n^2 \|\mathbf{d}\|^2$, and $E\|\mathbf{d}\|^2 = \text{tr}(\mathbf{M} \text{Cov}(\boldsymbol{\varepsilon})) \leq$

$p\sqrt{K}$, so it tends to zero in probability. The middle sum is at most $2(\sum_i w_i^2 \varepsilon_i^2)^{1/2}(\sum_i w_i^2 d_i^2)^{1/2}$ by Cauchy–Schwarz, a bounded factor times one that tends to zero.

Step 2: no dominant term. $\max_i |w_i \hat{\varepsilon}_i| \leq \max_i |w_i \varepsilon_i| + m_n \|\mathbf{d}\|$. The second term tends to zero in probability, and for $\eta > 0$

$$\Pr(\max_i |w_i \varepsilon_i| > \eta) \leq \sum_i \frac{w_i^4 \mathbb{E} \varepsilon_i^4}{\eta^4} \leq \frac{K m_n^2}{\eta^4},$$

which tends to zero. So $\max_i |w_i \hat{\varepsilon}_i| \rightarrow 0$ in probability.

Step 3: the bootstrap limit. Given the data, $U_{ni}^* = w_i \hat{\varepsilon}_i v_i / S_n$ are independent with mean zero and variances summing to one. With $g(t) = \mathbb{E}[v^2 \mathbf{1}\{|v| > t\}]$, which decreases to zero as $t \rightarrow \infty$,

$$\begin{aligned} L_n^*(\eta) &= \sum_i \frac{w_i^2 \hat{\varepsilon}_i^2}{S_n^2} g\left(\frac{\eta S_n}{|w_i \hat{\varepsilon}_i|}\right) \\ &\leq g\left(\frac{\eta S_n}{\max_i |w_i \hat{\varepsilon}_i|}\right). \end{aligned}$$

By Steps 1 and 2 the argument of g tends to infinity in probability, because $S_n^2 \geq \sigma^2/2$ with probability tending to one. So $L_n^*(\eta) \rightarrow 0$ in probability, and [Lemma 23.1.2](#) gives $\sup_x |\Pr_*(\sum_i w_i \hat{\varepsilon}_i v_i \leq x) - \Phi(x/S_n)| \rightarrow 0$ in probability. Since $S_n/\tau_n \rightarrow 1$ in probability, the same holds with $\Phi(x/\tau_n)$, as at the end of the proof of [Theorem 23.1.4](#).

Step 4: the true distribution. $\mathbf{c}_n^\top(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})/\|\mathbf{a}_n\| = \sum_i w_i \varepsilon_i$. With $U_{ni} = w_i \varepsilon_i / \tau_n$, Lyapunov's condition holds: $\sum_i \mathbb{E} U_{ni}^4 \leq K m_n^2 / \sigma^4 \rightarrow 0$. So $\sum_i w_i \varepsilon_i / \tau_n \rightarrow N(0, 1)$, and by Pólya's theorem $\sup_x |\Pr(\sum_i w_i \varepsilon_i \leq x) - \Phi(x/\tau_n)| \rightarrow 0$. The triangle inequality completes the proof. ■

An argument like Step 1 shows why the residual bootstrap fails here. Its variance for the standardized contrast is $\hat{\sigma}_*^2$, whose expectation $n^{-1} \sum_i (1 - h_{ii}) \sigma_{ni}^2$ is an unweighted average of the error variances ([Exercise \(B1\)](#)), not the weighted average τ_n^2 . So it settles on a normal law with the variance the classical formula gives. The wild bootstrap succeeds because each resampled error keeps the variance of its own case.

Example. (The wild bootstrap for Engel's data)

For the line of [Example \(Engel's food expenditure\)](#), 4000 wild resamples with $u_i = \hat{\varepsilon}_i$ give standard errors 0.05119 (Rademacher) and 0.05217 (Mammen), Monte Carlo estimates of the HC0 value 0.05177. With $u_i = \hat{\varepsilon}_i / (1 - h_{ii})$ they give 0.06653, estimating HC3, 0.06639.

The shape is more interesting. The wild distribution in [Figure 23.1.1\(b\)](#) has two modes, at 0.439 and 0.531. The cause is the richest household, whose leverage 0.255 was examined in [Chapter 20](#) and whose share of the HC3 variance was measured in [Chapter 21](#). Its term $a_i^2 \hat{\varepsilon}_i^2$ accounts for a fraction 0.78 of the HC0 variance $\sum_j a_j^2 \hat{\varepsilon}_j^2$, so the condition behind Step 2 of the proof is badly violated. The bootstrap slope is dominated by the contribution $a_i \hat{\varepsilon}_i v_i$ of this one household, which with Rademacher multipliers is ± 0.046 , and the modes sit at $\hat{\beta}_1 \mp 0.046$. The sampling distribution of the slope is dominated

by that household's error too, and one observation cannot reveal the law it came from; the remedy is the one given in those chapters.

```

23.2.2 Bootstrap or sandwich?

For a standard error the wild bootstrap adds nothing to the sandwich it reproduces. It earns its place through the *studentized* statistic $(\mathbf{c}^\top \hat{\boldsymbol{\beta}} - \mathbf{c}^\top \boldsymbol{\beta}) / \widehat{\text{se}}_{\text{HC}}$, whose noisy denominator makes its small-sample distribution far from t when some leverages are large; the simulations of [Section 23.3](#) show the wild bootstrap- t beating the HC2 t interval. For a test of $\mathbf{c}^\top \boldsymbol{\beta} = d$, the resamples should come from the restricted fit, so that the bootstrap approximates the null distribution even when the null hypothesis is false (Davidson and Flachaire 2008).

23.2.3 Exercises

23.2.3.1 A. Check your understanding

Exercise A1.

With Rademacher multipliers and $u_i = \hat{\varepsilon}_i$, how many distinct wild resamples are there? Show that the bootstrap variance of $\mathbf{c}^\top \hat{\boldsymbol{\beta}}^*$ computed by averaging over all of them equals the HC0 variance exactly.

Solution. There are 2^n sign vectors, equally likely. Averaging $(\sum_i a_i \hat{\varepsilon}_i v_i)^2$ over them, every cross term $a_i a_j \hat{\varepsilon}_i \hat{\varepsilon}_j v_i v_j$ with $i \neq j$ averages to zero, because half of the sign vectors give $v_i v_j = 1$ and half give -1 . What remains is $\sum_i a_i^2 \hat{\varepsilon}_i^2$, the $(\mathbf{c}, \mathbf{c})$ entry of HC0. The bootstrap mean is $\mathbf{c}^\top \hat{\boldsymbol{\beta}}$, so this is the variance.

Exercise A2.

Two groups of sizes n_1 and n_2 are compared through the difference of their means, fitted by least squares with one indicator column per group. Show that the wild bootstrap with $u_i = \hat{\varepsilon}_i$ gives the variance $\hat{\sigma}_1^2/n_1 + \hat{\sigma}_2^2/n_2$, where $\hat{\sigma}_k^2$ is the within-group variance with divisor n_k , and that $u_i = \hat{\varepsilon}_i/\sqrt{1 - h_{ii}}$ gives the Welch variance $s_1^2/n_1 + s_2^2/n_2$.

23.2.3.2 B. Practice

Exercise B1.

Let v take two values $a < 0 < b$. Show that $E(v) = 0$ and $E(v^2) = 1$ force $ab = -1$ and $\Pr(v = a) = b/(b - a)$, and that then $E(v^3) = a + b$. Deduce that Mammen's law of [Definition 23.2.1](#) is the only two-point law with mean 0, variance 1 and third moment 1, and compute its fourth moment.

Solution. With $q = \Pr(v = a)$, $qa + (1 - q)b = 0$ gives $q = b/(b - a)$. Then $E(v^2) = (ba^2 - ab^2)/(b - a) = -ab$, so $ab = -1$. Similarly $E(v^3) = (ba^3 - ab^3)/(b - a) = -ab(a + b) = a + b$. Third moment one means $a + b = 1$ and $ab = -1$, so a and b are the roots of $t^2 - t - 1 = 0$, namely $(1 \mp \sqrt{5})/2$, and $q = b/(b - a) = (1 + \sqrt{5})/(2\sqrt{5})$. The fourth moment is $(ba^4 - ab^4)/(b - a) = -ab(a^2 + ab + b^2) = (a + b)^2 - ab = 2$, compared with 1 for Rademacher weights and 3 for the normal.

23.2.3.3 C. Going deeper

Exercise C1.

Suppose the cases fall into clusters and errors are correlated within clusters but independent between them. Show that the wild bootstrap of [Definition 23.2.1](#) gives the HC0 covariance, which ignores the correlation. Propose a version in which all cases in a cluster share one multiplier, and show that its bootstrap covariance is the cluster-robust sandwich $(\mathbf{X}^\top \mathbf{X})^{-1} \sum_g \mathbf{X}_g^\top \hat{\boldsymbol{\varepsilon}}_g \hat{\boldsymbol{\varepsilon}}_g^\top \mathbf{X}_g (\mathbf{X}^\top \mathbf{X})^{-1}$.

23.3 Bootstrap confidence intervals

A bootstrap distribution gives a confidence interval through its quantiles, in several ways. They agree to first order, which is all the consistency theorems guarantee, and differ in how fast their coverage approaches the nominal level.

Let se be a standard error for $\hat{\theta} = \mathbf{c}^\top \hat{\boldsymbol{\beta}}$, classical or sandwich, and let $\hat{\theta}^*$ and se^* be computed from a resample in the same way. Write $\hat{q}(\gamma)$ and $\hat{t}(\gamma)$ for the γ quantiles of the bootstrap distributions of $\hat{\theta}^*$ and of the **bootstrap t statistic** $T^* = (\hat{\theta}^* - \hat{\theta})/se^*$.

Definition 23.3.1 — Percentile, basic and studentized intervals

The nominal $1 - \alpha$ bootstrap intervals for θ are:

- (a) the **percentile** interval $[\hat{q}(\alpha/2), \hat{q}(1 - \alpha/2)]$;
- (b) the **basic** interval $[2\hat{\theta} - \hat{q}(1 - \alpha/2), 2\hat{\theta} - \hat{q}(\alpha/2)]$;
- (c) the **studentized** (or **bootstrap- t**) interval $[\hat{\theta} - \hat{t}(1 - \alpha/2)se, \hat{\theta} - \hat{t}(\alpha/2)se]$.

The basic interval translates the bootstrap idea directly: if $\hat{\theta} - \theta$ had the distribution of $\hat{\theta}^* - \hat{\theta}$, then $\hat{q}(\alpha/2) - \hat{\theta} \leq \hat{\theta} - \theta \leq \hat{q}(1 - \alpha/2) - \hat{\theta}$ would have probability $1 - \alpha$, and solving for θ gives (b). The studentized interval does the same with the root $(\hat{\theta} - \theta)/se$, as the t interval of [Corollary 7.5.2](#) does. The percentile interval looks naive, but if some increasing ϕ makes $\phi(\hat{\theta}) - \phi(\theta)$ a pivot symmetric about zero, it is exact without knowing ϕ ([Exercise \(B1\)](#)). It is also **transformation respecting**, because quantiles commute with increasing functions; the basic and studentized intervals are not.

23.3.1 First-order correctness

The consistency theorems translate into coverage through a lemma about quantiles.

Lemma 23.3.1 — Consistent bootstrap quantiles

Let R_n be random variables with distribution functions H_n , and let $\hat{H}_n$ be random distribution functions with $\sup_x |\hat{H}_n(x) - H_n(x)| \rightarrow 0$ in probability. Suppose $H_n(x) \rightarrow H(x)$ for every x , where H is continuous and strictly increasing on $\mathbb{R}$. For $0 < \gamma < 1$, let $\hat{\xi}_n(\gamma) = \inf\{x : \hat{H}_n(x) \geq \gamma\}$ and $\xi(\gamma) = H^{-1}(\gamma)$. Then $\hat{\xi}_n(\gamma) \rightarrow \xi(\gamma)$ in probability, and $\Pr(R_n \leq \hat{\xi}_n(\gamma)) \rightarrow \gamma$.

Proof. By Pólya's theorem $\sup_x |H_n(x) - H(x)| \rightarrow 0$, so $\delta_n = \sup_x |\hat{H}_n(x) - H(x)| \rightarrow 0$ in probability. Fix $\epsilon > 0$, write $\xi = \xi(\gamma)$, and let $\kappa = \min\{\gamma - H(\xi - \epsilon), H(\xi + \epsilon) - \gamma\} > 0$. On the event $\delta_n < \kappa$, $\hat{H}_n(\xi - \epsilon) < \gamma$ and $\hat{H}_n(\xi + \epsilon) > \gamma$, so $\xi - \epsilon \leq \hat{\xi}_n(\gamma) \leq \xi + \epsilon$. This proves the first claim. For the second,

$$\begin{aligned} \Pr(R_n \leq \hat{\xi}_n) &\geq H_n(\xi - \epsilon) - \Pr(|\hat{\xi}_n - \xi| > \epsilon), \\ \Pr(R_n \leq \hat{\xi}_n) &\leq H_n(\xi + \epsilon) + \Pr(|\hat{\xi}_n - \xi| > \epsilon). \end{aligned}$$

Let $n \rightarrow \infty$ and then $\epsilon \rightarrow 0$, using the continuity of H at ξ .

■

Corollary 23.3.2 — Bootstrap intervals are first-order correct

Under the conditions of [Theorem 23.1.4](#), the percentile and basic intervals built from the residual bootstrap have coverage probability tending to $1 - \alpha$.

Proof. Take $R_n = (\hat{\theta} - \theta)/\|\mathbf{a}_n\|$, with $\hat{H}_n$ the bootstrap distribution of $(\hat{\theta}^* - \hat{\theta})/\|\mathbf{a}_n\|$ and $H(x) = \Phi(x/\sigma)$. [Theorem 23.1.4](#) gives the hypotheses of [Lemma 23.3.1](#). The basic interval covers θ if and only if $\hat{q}(\alpha/2) - \hat{\theta} \leq \hat{\theta} - \theta \leq \hat{q}(1 - \alpha/2) - \hat{\theta}$, that is, $\hat{\xi}_n(\alpha/2) \leq R_n \leq \hat{\xi}_n(1 - \alpha/2)$ with $\hat{\xi}_n$ the quantiles of $\hat{H}_n$. By the lemma the probability tends to $(1 - \alpha/2) - \alpha/2$, the lower endpoint contributing no mass in the limit because H is continuous. The percentile interval covers θ if and only if $-\hat{\xi}_n(1 - \alpha/2) \leq R_n \leq -\hat{\xi}_n(\alpha/2)$. Since H is symmetric, $-\xi(1 - \alpha/2) = \xi(\alpha/2)$, and the same argument applies.

■

The same argument applies to the wild bootstrap under the conditions of [Theorem 23.2.2](#). Since τ_n need not converge, take $R_n = (\hat{\theta} - \theta)/(\|\mathbf{a}_n\|\tau_n)$ and $H = \Phi$; dividing by the constant τ_n leaves the intervals unchanged. It applies also to studentized intervals whenever the standard error is consistent. None of this separates the methods from one another or from the normal interval $\hat{\theta} \pm z_{\alpha/2} \text{se}$.

23.3.2 Pivots and higher-order accuracy

The case for studentizing is clearest when the root is an exact pivot.

Proposition 23.3.3 — The parametric bootstrap in the normal model

In the normal linear model with $\text{rank}(\mathbf{X}) = p < n$, let the **parametric bootstrap** draw $\mathbf{Y}^* \sim N_n(\mathbf{X}\hat{\boldsymbol{\beta}}, s^2\mathbf{I})$. Then for every data set:

- (a) $T^* = (\mathbf{c}^\top \hat{\boldsymbol{\beta}}^* - \mathbf{c}^\top \hat{\boldsymbol{\beta}})/(s^*\|\mathbf{a}\|) \sim t(n - p)$ under Pr_* , so the studentized interval is the t interval of [Corollary 7.5.2](#), apart from Monte Carlo error;
- (b) $\mathbf{c}^\top \hat{\boldsymbol{\beta}}^* \sim N(\mathbf{c}^\top \hat{\boldsymbol{\beta}}, s^2\|\mathbf{a}\|^2)$ under Pr_* , so the percentile and basic intervals are $\hat{\theta} \pm z_{\alpha/2} s\|\mathbf{a}\|$, whose coverage is $\Pr(|T| \leq z_{\alpha/2}) < 1 - \alpha$ with $T \sim t(n - p)$.

Proof. Given the data, $\mathbf{Y}^*$ follows the normal linear model with coefficient vector $\hat{\boldsymbol{\beta}}$ and variance s^2 . (a) is [Corollary 7.5.2](#) applied to that model, with true value $\mathbf{c}^\top \hat{\boldsymbol{\beta}}$. (b) is [Theorem 7.5.1\(a\)](#) for the same model. The interval $\hat{\theta} \pm z_{\alpha/2} s\|\mathbf{a}\|$ covers θ if and only if $|T| \leq z_{\alpha/2}$, where $T = (\hat{\theta} - \theta)/(s\|\mathbf{a}\|) \sim t(n - p)$ by [Corollary 7.5.2](#), and $t(n - p)$ has heavier tails than $N(0, 1)$.

■

The studentized root has the same distribution in both worlds, so the bootstrap reproduces it exactly. The unstudentized root depends on σ , and the bootstrap substitutes s , losing the spread due to estimating σ . The nonparametric bootstrap is never exact, but the same mechanism operates: an **asymptotic pivot** is reproduced more accurately than a root whose distribution depends strongly on the unknown law. Hall (1988) made this precise with Edgeworth expansions. Under smoothness conditions the one-sided studentized interval has coverage error of order n^{-1} , the one-sided percentile and basic intervals of order $n^{-1/2}$. We do not prove these rates (see Hall 1992). The price of studentizing is a standard error recomputed in each resample, and instability when it is poorly estimated.

BCa. Efron (1987) corrected the percentile interval to the same order of accuracy without a standard error. The **bias-corrected and accelerated** (BCa) interval uses the percentile interval at adjusted levels

$$\gamma_k = \Phi\left(\hat{z}_0 + \frac{\hat{z}_0 + z_k}{1 - \hat{a}(\hat{z}_0 + z_k)}\right), \quad z_1 = z_{(\alpha/2)}, \quad z_2 = z_{(1-\alpha/2)},$$

where $z_{(\gamma)} = \Phi^{-1}(\gamma)$, the **bias correction** $\hat{z}_0 = \Phi^{-1}(\Pr_*(\hat{\theta}^* < \hat{\theta}))$ measures median bias, and the **acceleration** $\hat{a}$, the rate at which the standard error changes with θ on a normalizing scale, is usually estimated from the jackknife values $\hat{\theta}_{(i)}$, computed without case i :

$$\hat{a} = \frac{\sum_i d_i^3}{6(\sum_i d_i^2)^{3/2}}, \quad d_i = \bar{\theta}_{(\cdot)} - \hat{\theta}_{(i)}.$$

In regression no refitting is needed: $\hat{\theta}_{(i)} = \hat{\theta} - a_i \hat{\varepsilon}_i / (1 - h_{ii})$ by [Proposition 10.6.2\(a\)](#) ([Exercise \(B2\)](#)). With $\hat{z}_0 = \hat{a} = 0$ BCa is the percentile interval. Its derivation and second-order accuracy are in Efron (1987) and DiCiccio and Efron (1996), for resampling cases, to which the jackknife formula above belongs. Pairing it with the residual bootstrap, as below, is a common heuristic that Efron's proof does not cover.

23.3.3 An example and a simulation

Example. (Intervals for the poverty coefficient)

Return to the state murder rates of [Example \(Poverty and murder rates\)](#), with the District of Columbia omitted, and the coefficient 0.2538 of poverty in the regression on poverty, single parenthood and urbanization. Seven 95% intervals from $B = 9999$ resamples:

method	interval	length
t , classical standard error	(0.066, 0.442)	0.376
residual bootstrap, percentile	(0.064, 0.437)	0.374
residual bootstrap, basic	(0.070, 0.444)	0.374
residual bootstrap, studentized	(0.071, 0.449)	0.378
residual bootstrap, BCa	(0.040, 0.418)	0.378
case bootstrap, percentile	(0.080, 0.428)	0.348
wild bootstrap- t , HC2	(0.079, 0.428)	0.348

The residual bootstrap used leverage-adjusted residuals. The first four intervals agree closely: with fifty states and a well-behaved fit, the classical interval is hard to improve on. BCa is shifted down; its bias correction $\hat{z}_0 = -0.016$ is negligible, but the jackknife acceleration $\hat{a} = -0.0458$ moves both endpoints. The shift comes from that heuristic pairing, not from BCa as such, and opposes the small upward shift of the studentized interval. The case and wild bootstraps give shorter intervals, because the HC2 standard error 0.0869 is smaller than the classical 0.0934 for these data. All seven exclude zero.

Estar = Ystar - (Ystar @ A.T) @ X.T
```

Figure 23.3.1: Coverage of eight nominal 95% intervals for a slope. Circles: skewed errors, constant variance. Squares: normal errors with variance increasing in x . The band is two Monte Carlo standard errors around 0.95.

```
wstar = (Ystar @ a - b) / np.sqrt((Estar ** 2 / (1 - h)) @ a ** 2)
out["wild-t"] = b - np.quantile(wstar, q[::-1]) * se2

for m, (l, u) in out.items():
    print(f"{m:12s} ({l:.3f}, {u:.3f})    length {u - l:.3f}")
```

One data set cannot show which interval is right. Figure 23.3.1 reports coverages for the slope of a line, from 2000 simulated data sets with $B = 999$ resamples each, and Monte Carlo standard error about 0.005. The fixed design is skewed, with largest leverage 0.433 at $n = 20$ and 0.309 at $n = 40$. The errors are either centred exponential with constant variance, or normal with standard deviation proportional to x , so that the largest variances sit at the high-leverage end.

Three lessons stand out.

1. *With constant variance, studentization is what matters.* At $n = 20$ the classical t interval (0.954) and the studentized residual bootstrap (0.953) are on target despite skewed errors. The percentile (0.938) and BCa (0.930) intervals are a little short, as Proposition 23.3.3 predicts for intervals that ignore the variability of s . The robust methods (case 0.912, wild- t 0.918) pay for estimating a variance that did not need estimating.
2. *With heteroscedastic errors the classical t interval and the four residual-bootstrap intervals all fail, and more data do not help:* all five cover between 0.71 and 0.78 at both sample sizes (Exercise (B1)).
3. *The robust methods improve with n but start below nominal.* The case bootstrap, the HC2 t interval and the wild bootstrap- t cover 0.899, 0.852 and 0.868 at $n = 20$, and 0.914, 0.893 and 0.922 at $n = 40$. A high-leverage point with a large error variance is hard for all of them, since one residual carries much of the information about the variance that matters (Example (The wild bootstrap for Engel's data)).

```

With 200 data sets the cell's coverages have Monte Carlo standard errors of about $\sqrt{0.95 \times 0.05/200} = 0.015$.

23.3.4 Bootstrap tests of a linear hypothesis

A test of $H: \Lambda^\top \beta = \mathbf{d}$ can take its critical value from the bootstrap instead of the F table. In each residual-bootstrap resample from the full model, compute F_H^* of Eq. 11.3.1 for the hypothesis $\Lambda^\top \beta = \Lambda^\top \hat{\beta}$, which is true in the bootstrap world, and report the proportion of resamples with $F_H^* \geq F_H$. This is the testing counterpart of the studentized interval (Proposition 12.1.2). Alternatively, resample the residuals of the restricted fit, so that the null hypothesis holds in the bootstrap world; that is the bootstrap analogue of the Freedman–Lane scheme of Section 23.5.

23.3.5 Exercises

23.3.5.1 A. Check your understanding

Exercise A1.

Show that the percentile and basic intervals coincide when the bootstrap distribution of $\hat{\theta}^*$ is symmetric about $\hat{\theta}$. With $\hat{\theta} = 2$, $\hat{q}(0.025) = 1.5$ and $\hat{q}(0.975) = 3.5$, compute both intervals and explain why they lean in opposite directions.

Solution. Symmetry about $\hat{\theta}$ means $\hat{q}(\gamma) - \hat{\theta} = \hat{\theta} - \hat{q}(1 - \gamma)$, so $2\hat{\theta} - \hat{q}(1 - \alpha/2) = \hat{q}(\alpha/2)$, and similarly for the other endpoint. In the example the percentile interval is $[1.5, 3.5]$

and the basic interval is $[4 - 3.5, 4 - 1.5] = [0.5, 2.5]$. The bootstrap distribution has a long right tail. The percentile interval copies it. The basic interval reflects it, reasoning that if $\hat{\theta}$ tends to fall far above θ with some probability, then θ may lie far below $\hat{\theta}$.

23.3.5.2 B. Practice

Exercise B1.

Suppose there is a strictly increasing ϕ such that $\phi(\hat{\theta}) - \phi(\theta)$ has a continuous distribution K , symmetric about zero and the same for every θ , and suppose the bootstrap reproduces it exactly: $\phi(\hat{\theta}^*) - \phi(\hat{\theta})$ has distribution K under Pr_* . Show that the percentile interval has coverage exactly $1 - \alpha$.

Solution. Let k_γ be the γ quantile of K , so $k_{\alpha/2} = -k_{1-\alpha/2}$. Under Pr_* , $\phi(\hat{\theta}^*) = \phi(\hat{\theta}) +$ a K -variable, so the γ quantile of $\hat{\theta}^*$ is $\hat{q}(\gamma) = \phi^{-1}(\phi(\hat{\theta}) + k_\gamma)$. Hence $\hat{q}(\alpha/2) \leq \theta \leq \hat{q}(1 - \alpha/2)$ if and only if $k_{\alpha/2} \leq \phi(\theta) - \phi(\hat{\theta}) \leq k_{1-\alpha/2}$, that is, $-k_{1-\alpha/2} \leq \phi(\hat{\theta}) - \phi(\theta) \leq -k_{\alpha/2}$. By symmetry this is $k_{\alpha/2} \leq \phi(\hat{\theta}) - \phi(\theta) \leq k_{1-\alpha/2}$, which has probability $1 - \alpha$.

Exercise B2.

Show that the jackknife values used in the BCa acceleration satisfy $\hat{\theta}_{(i)} = \hat{\theta} - a_i \hat{\varepsilon}_i / (1 - h_{ii})$, where $\mathbf{a} = \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{c}$. Deduce that the jackknife variance estimate $\frac{n-1}{n} \sum_i (\hat{\theta}_{(i)} - \bar{\theta}_{(\cdot)})^2$ is close to the HC3 variance $\sum_i a_i^2 \hat{\varepsilon}_i^2 / (1 - h_{ii})^2$. (Chapter 21 shows that the uncentred sum $\sum_i (\hat{\theta}_{(i)} - \hat{\theta})^2$ equals it exactly.)

23.3.5.3 C. Going deeper

Exercise C1.

The coverage of a bootstrap interval can itself be estimated by a second level of bootstrapping: treat each first-level resample as data, and ask how often its interval covers $\hat{\theta}$. Describe how this can be used to recalibrate the nominal level, and count the least squares fits needed with $B_1 = B_2 = 999$. How does the design-fixed residual bootstrap reduce the cost?

23.4 Permutation tests for linear hypotheses

The bootstrap replaces an unknown distribution by an estimate. A permutation test instead looks for transformations of the data that leave their distribution unchanged under the null hypothesis, and compares the observed statistic with its values on the transformed data. When such transformations exist the test is exact at every sample size, whatever the error law. The idea is Fisher's (1935), developed by Pitman (1937); in designed experiments the transformations are the rearrangements the randomization could have produced (Section 18.4).

23.4.1 The general construction

Let $\mathcal{G}$ be a finite group of $n \times n$ permutation matrices. A random vector $\mathbf{Y}$ is **$\mathcal{G}$ -invariant in distribution** if $\mathbf{PY}$ has the distribution of $\mathbf{Y}$ for every $\mathbf{P} \in \mathcal{G}$. For the group of all permutations this is exchangeability.

Definition 23.4.1 — Permutation test

Let $T : \mathbb{R}^n \rightarrow \mathbb{R}$ be a statistic, large values of which count against the null hypothesis.

- (a) The **permutation p-value** is $p(\mathbf{y}) = |\mathcal{G}|^{-1} \#\{\mathbf{P} \in \mathcal{G} : T(\mathbf{PY}) \geq T(\mathbf{y})\}$.
- (b) The **Monte Carlo permutation p-value** draws $\mathbf{P}_1, \dots, \mathbf{P}_B$ independently and uniformly from $\mathcal{G}$, independently of $\mathbf{Y}$, and is

$$p_B(\mathbf{y}) = \frac{1 + \#\{b : T(\mathbf{P}_b \mathbf{y}) \geq T(\mathbf{y})\}}{B + 1}. \quad (23.4.1)$$

The test of level α rejects when the p-value is at most α .

The 1 in Eq. 23.4.1 counts the observed arrangement among those compared; without it the p-value can be zero and the test is not exact (Phipson and Smyth 2010). Exactness rests on a counting fact.

Lemma 23.4.1 — Ranks of exchangeable values

For real numbers $t_0, \dots, t_m$, let $R_j = \#\{i : t_i \geq t_j\}$. Then $\#\{j : R_j \leq k\} \leq k$ for every k . Consequently, if $(T_0, \dots, T_m)$ is an exchangeable random vector and $R_0 = \#\{i : T_i \geq T_0\}$, then $\Pr(R_0 \leq k) \leq k/(m+1)$.

Proof. Let $S = \{j : R_j \leq k\}$, and suppose it is not empty. Choose $j^* \in S$ with the smallest t_{j^*} . Every $j \in S$ has $t_j \geq t_{j^*}$, so $R_{j^*} \geq |S|$, and $|S| \leq R_{j^*} \leq k$. For the second claim, exchangeability gives $\Pr(R_j \leq k) = \Pr(R_0 \leq k)$ for every j , so $(m+1)\Pr(R_0 \leq k) = \mathbb{E} \#\{j : R_j \leq k\} \leq k$. ■

Theorem 23.4.2 — Exactness of permutation tests

If $\mathbf{Y}$ is $\mathcal{G}$ -invariant in distribution, then for every statistic T , every $\alpha \in [0, 1]$ and every $B \geq 1$,

$$\Pr(p(\mathbf{Y}) \leq \alpha) \leq \alpha, \quad \Pr(p_B(\mathbf{Y}) \leq \alpha) \leq \alpha.$$

Proof. Let $\mathbf{\Gamma}$ be uniform on $\mathcal{G}$, independent of everything else. Invariance gives $\mathbf{\Gamma Y} \stackrel{d}{=} \mathbf{Y}$, since this holds conditionally on each value of $\mathbf{\Gamma}$.

Full group. $p(\mathbf{Y})$ has the distribution of $p(\mathbf{\Gamma Y})$. As $\mathbf{P}$ runs over $\mathcal{G}$ so does $\mathbf{P}\mathbf{\Gamma}$, so $p(\mathbf{\Gamma Y}) = |\mathcal{G}|^{-1} \#\{\mathbf{P} \in \mathcal{G} : T(\mathbf{PY}) \geq T(\mathbf{\Gamma Y})\}$. Given $\mathbf{Y}$, list the values $t_{\mathbf{P}} = T(\mathbf{PY})$, $\mathbf{P} \in \mathcal{G}$. Then $|\mathcal{G}| p(\mathbf{\Gamma Y}) = R_{\mathbf{\Gamma}}$ in the notation of Lemma 23.4.1, with $\mathbf{\Gamma}$ uniform over the

$|\mathcal{G}|$ indices. By the first part of the lemma, $\Pr(R_{\mathbf{r}} \leq k \mid \mathbf{Y}) \leq k/|\mathcal{G}|$. With $k = \lfloor \alpha|\mathcal{G}| \rfloor$ this gives $\Pr(p \leq \alpha \mid \mathbf{Y}) \leq \alpha$, and we take expectations.

Monte Carlo. Put $\mathbf{P}_0 = \mathbf{I}$ and $T_b = T(\mathbf{P}_b \mathbf{Y})$, so that $(B+1)p_B = R_0$. We show $(T_0, \dots, T_B)$ is exchangeable. Since $\mathbf{Y}$ is independent of $(\mathbf{P}_1, \dots, \mathbf{P}_B)$ and $\mathbf{\Gamma} \mathbf{Y} \stackrel{d}{=} \mathbf{Y}$ with $\mathbf{\Gamma} \mathbf{Y}$ also independent of them, $(T_0, \dots, T_B)$ has the distribution of $(T(\mathbf{\Gamma} \mathbf{Y}), T(\mathbf{P}_1 \mathbf{\Gamma} \mathbf{Y}), \dots, T(\mathbf{P}_B \mathbf{\Gamma} \mathbf{Y}))$. The map $(\mathbf{G}_0, \mathbf{G}_1, \dots, \mathbf{G}_B) \mapsto (\mathbf{G}_0, \mathbf{G}_1 \mathbf{G}_0, \dots, \mathbf{G}_B \mathbf{G}_0)$ is a bijection of $\mathcal{G}^{B+1}$, so $\mathbf{\Gamma}, \mathbf{P}_1 \mathbf{\Gamma}, \dots, \mathbf{P}_B \mathbf{\Gamma}$ are independent and uniform on $\mathcal{G}$, and independent of $\mathbf{Y}$. Given $\mathbf{Y}$, the $B+1$ values are therefore independent and identically distributed, hence exchangeable, and so they are unconditionally. The second part of [Lemma 23.4.1](#) with $k = \lfloor \alpha(B+1) \rfloor$ completes the proof. ■

Nothing about T was used: the statistic affects power, never validity. The full-group test has size exactly α when $\alpha|\mathcal{G}|$ is an integer and the values $T(\mathbf{P} \mathbf{Y})$ are almost surely distinct. In the Monte Carlo test a draw can repeat the identity or another draw, and the resulting ties make R_0 not exactly uniform, so its size is at most α and approaches α as $|\mathcal{G}|$ grows, when $\alpha(B+1)$ is an integer. And the theorem says nothing about β . The hypothesis it tests is the invariance, and translating a regression hypothesis into an invariance is the whole difficulty.

23.4.2 Simple regression

In the straight-line model with fixed x_i and independent, identically distributed errors, $\beta_1 = 0$ says $\mathbf{Y} = \beta_0 \mathbf{1} + \boldsymbol{\varepsilon}$, which is exchangeable, so a permutation test of $\beta_1 = 0$ is exact for any error law. The usual statistics give the same test.

Proposition 23.4.3 — Equivalent statistics for the slope

With $\mathcal{G}$ the group of all permutations, the statistics $|\hat{\beta}_1|$, $|r|$, $|t|$ and $F = t^2$ for the simple regression of $\mathbf{y}$ on $\mathbf{x}$ give the same permutation p-value, for every data set and, in the Monte Carlo version, for every draw of permutations.

Proof. Permuting $\mathbf{y}$ leaves $\bar{y}$ and $S_{yy} = \sum_i (y_i - \bar{y})^2$ unchanged, and S_{xx} does not involve $\mathbf{y}$. Now $\hat{\beta}_1 = S_{xy}/S_{xx}$ and $r = S_{xy}/\sqrt{S_{xx}S_{yy}}$, so $|\hat{\beta}_1|$ and $|r|$ are the same increasing function of $|S_{xy}|$ for every rearrangement. And $t^2 = (n-2)r^2/(1-r^2)$, which increases with r^2 on $[0, 1)$. So all four order the arrangements $\mathbf{P} \mathbf{y}$ in the same way, and the counts in [Definition 23.4.1](#) agree. ■

Example. (Acid concentration and stack loss)

Brownlee's stack loss data ([Example \(Stack loss\)](#)) record 21 days of operation of a plant oxidizing ammonia. Regress stack loss on the acid concentration of the absorbing liquid alone. The slope is 0.7590, with $t = 1.901$ and a two-sided t -test p-value of 0.0725. The 5.11×10^{19} arrangements are too many to enumerate; Monte Carlo with $B = 19999$ permutations gives the p-value 0.0698, with Monte Carlo standard error 0.0018. [Figure](#)

Figure 23.4.1: Permutation distribution of t for stack loss on acid concentration, with the $t(19)$ density and the observed $\pm t$.

23.4.1 shows the permutation distribution of t with the $t(19)$ density. The agreement is close, but the permutation p-value assumes nothing about the error law.

Yperm = y[np.argsort(rng.random((B, n)), axis=1)] # B random permutations of y
b_perm, r_perm, t_perm = slope_stats(Yperm)
p_perm = (1 + np.sum(np.abs(b_perm) >= abs(b_obs))) / (B + 1)
print(f"slope {b_obs:.4f}, t = {t_obs:.3f}, t-test p = {p_t:.4f}, permutation p = {
    p_perm:.4f}")
```

23.4.3 What the permutation test tests

Without identically distributed errors, invariance and $\beta_1 = 0$ come apart. If independent cases have $E(Y | X) = 0$ but $\text{Var}(Y | X)$ depending on X , the slope is zero but the responses are not exchangeable given the x 's. The permutation test tests independence, and rejects too often as a test of zero slope. By the central limit theorem for the sample covariance, when $\text{Cov}(X, Y) = 0$, $\sqrt{n}r \rightarrow N(0, \kappa^2)$ with

$$\kappa^2 = \frac{E[(X - \mu_X)^2(Y - \mu_Y)^2]}{\text{Var}(X) \text{Var}(Y)},$$

which equals 1 under independence but not in general. The permutation distribution of $\sqrt{n}r$ tends to $N(0, 1)$ under mild conditions whatever the dependence, because permuting creates independence; we do not prove this permutation central limit theorem (see Lehmann and Romano 2005, chapter 15). Let $Y = X\varepsilon$, X and ε independent standard normals. Then $\text{Var}(Y) = 1$ and $E(X^2Y^2) = E X^4 E \varepsilon^2 = 3$, so $\kappa^2 = 3$. A nominal 5% permutation test based on $|r|$, or by [Proposition 23.4.3](#) on $|\hat{\beta}_1|$, has limiting size

$$\Pr(|N(0, 3)| > 1.96) = 2(1 - \Phi(1.96/\sqrt{3})) = 2(1 - \Phi(1.1316)) = 0.258.$$

A simulation with 4000 data sets and 399 permutations each gives 0.236 at $n = 20$ and 0.248 at $n = 200$.

The remedy (DiCiccio and Romano 2017) is to studentize: $\hat{\beta}_1/\widehat{\text{se}}_{\text{HC0}}$ has a standard normal limit under zero slope whether or not X and Y are independent ([Exercise \(C1\)](#)), and so does its permutation distribution. The test is exact under independence and asymptotically valid for zero slope. In the simulation its size is 0.117 at $n = 20$ and 0.056 at $n = 200$: much better, though at $n = 20$ still far from exact.

```
import numpy as np

def perm_sizes(n, reps, B, rng, alpha=0.05):
    """Rejection rates of permutation tests of zero slope when y = x * eps (x, eps
    iid normal)."""
    reject = {"raw": 0, "studentized": 0}
    for _ in range(reps):
        x = rng.normal(size=n)
        y = x * rng.normal(size=n) # E(y | x) = 0, Var(y | x) = x^2
        Y = np.vstack([y, y[np.argsort(rng.random((B, n))), axis=1]]]) # row 0: the
        data
        xc = x - x.mean()
        Yc = Y - Y.mean(axis=1, keepdims=True)
        b = Yc @ xc / (xc @ xc)
        e = Yc - b[:, None] * xc
        se_hc0 = np.sqrt((e ** 2) @ xc ** 2) / (xc @ xc)
        for name, T in [("raw", np.abs(b)), ("studentized", np.abs(b / se_hc0))]:
            p = np.mean(T >= T[0]) # (1 + #{T_b >= T_0}) / (B + 1)
            reject[name] += p <= alpha
    return {k: v / reps for k, v in reject.items()}

rng = np.random.default_rng(2305)
for n_sim in (20, 200):
    print(n_sim, perm_sizes(n_sim, reps=400, B=199, rng=rng))
```

23.4.4 Nuisance regressors

Most regression hypotheses concern some coefficients in the presence of others:

$$\mathbf{Y} = \mathbf{Z}\boldsymbol{\gamma} + \mathbf{X}_1\boldsymbol{\beta}_1 + \boldsymbol{\varepsilon}, \quad H_0 : \boldsymbol{\beta}_1 = \mathbf{0}, \quad (23.4.2)$$

with $\mathbf{Z}$ of size $n \times p_0$ containing the nuisance regressors (including the intercept) and $\mathbf{X}_1$ of size $n \times q$. Under H_0 , $\mathbf{Y} = \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\varepsilon}$, which is not exchangeable unless $\mathbf{Z}\boldsymbol{\gamma}$ is a multiple of $\mathbf{1}$. There is an exact test only when some group of permutations leaves the nuisance part alone.

Proposition 23.4.4 — Permutations that fix the nuisance regressors

Suppose $\boldsymbol{\varepsilon}$ is $\mathcal{G}$ -invariant in distribution, and $\mathbf{P}\mathbf{Z} = \mathbf{Z}$ for every $\mathbf{P} \in \mathcal{G}$. Then under H_0 of Eq. 23.4.2 the response $\mathbf{Y}$ is $\mathcal{G}$ -invariant in distribution, and the permutation test over $\mathcal{G}$ with any statistic is exact, whatever the value of $\boldsymbol{\gamma}$.

Proof. $\mathbf{P}\mathbf{Y} = \mathbf{P}\mathbf{Z}\boldsymbol{\gamma} + \mathbf{P}\boldsymbol{\varepsilon} = \mathbf{Z}\boldsymbol{\gamma} + \mathbf{P}\boldsymbol{\varepsilon} \stackrel{d}{=} \mathbf{Z}\boldsymbol{\gamma} + \boldsymbol{\varepsilon} = \mathbf{Y}$. Apply Theorem 23.4.2. ■

The condition $\mathbf{P}\mathbf{Z} = \mathbf{Z}$ says that $\mathbf{P}$ permutes only cases with identical rows of $\mathbf{Z}$. For block indicators, $\mathcal{G}$ is the group of permutations within blocks, and the proposition gives, under errors exchangeable within blocks, the same test as the design-based randomization test of a randomized complete block design (Section 18.4, Definition 18.4.1), which needs no error model at all. When $\mathbf{Z}$ contains a continuous covariate with distinct values only the identity qualifies, and no exact permutation test exists. The schemes of the next section give up exactness for generality.

23.4.5 Exercises

23.4.5.1 A. Check your understanding

Exercise A1.

With $B = 99$ random permutations, what is the smallest possible value of Eq. 23.4.1? For which α between 0.01 and 0.10 is the size of the Monte Carlo test exactly α when there are no ties (ignoring the chance of drawing the same arrangement twice)?

Solution. The smallest value is $1/100$, reached when no permuted statistic reaches the observed one. When there are no ties (ignoring the chance of drawing the same arrangement twice), R_0 is uniform on $\{1, \dots, 100\}$, so $\Pr(p_B \leq \alpha) = \lfloor 100\alpha \rfloor / 100$, which equals α exactly when 100α is an integer: $\alpha = 0.01, 0.02, \dots, 0.10$.

23.4.5.2 B. Practice

Exercise B1.

For $x = (1, 2, 3, 4)$ and $y = (1.2, 0.8, 2.9, 3.1)$, enumerate all 24 arrangements of y and compute the exact two-sided permutation p-value for the slope. Compare it with the t -test p-value, and explain why the permutation p-value cannot be smaller than $2/24$ for any data with $n = 4$ and distinct values.

Solution. By [Proposition 23.4.3](#) it suffices to rank the arrangements by $|S_{xy}|$, where $S_{xy} = \sum_i (x_i - \bar{x})y_{\pi(i)}$ with centred x equal to $(-1.5, -0.5, 0.5, 1.5)$. For the data, $S_{xy} = -1.8 - 0.4 + 1.45 + 4.65 = 3.9$. The largest values of S_{xy} come from putting the two largest responses at $x = 3, 4$ and the two smallest at $x = 1, 2$; the four such arrangements give 3.7, 3.9, 4.1 and 4.3, and every other arrangement gives at most 2.6. Reversing an arrangement negates S_{xy} . So 6 of the 24 arrangements have $|S_{xy}| \geq 3.9$, and the p-value is $6/24 = 0.25$. The t -test gives 0.139: with four points the permutation distribution is coarse. The observed arrangement and its reversal always count, so $p \geq 2/24$.

Exercise B2.

Compute κ^2 when $Y = \varepsilon\sqrt{1 + \lambda X^2}$ with X and ε independent standard normals, and the limiting size of the nominal 5% permutation test of zero slope as a function of λ . What happens as $\lambda \rightarrow \infty$?

23.4.5.3 C. Going deeper**Exercise C1.**

For independent pairs with $\text{Cov}(X, Y) = 0$ and finite fourth moments, show that $\hat{\beta}_1/\widehat{\text{se}}_{\text{HC0}} \rightarrow N(0, 1)$ in distribution. (Use the central limit theorem for $n^{-1/2} \sum_i (X_i - \mu_X)(Y_i - \mu_Y)$ and Slutsky's lemma.)

23.5 Freedman–Lane and related schemes

With a continuous nuisance regressor in [Eq. 23.4.2](#), no permutation of the responses leaves the null distribution unchanged. Several schemes permute something else, or permute the responses and hope. None is exact in general, but their differences can be understood with the projection algebra of [Chapter 6](#).

23.5.1 Five schemes

Keep the notation of [Eq. 23.4.2](#): $\mathbf{Z}$ is $n \times p_0$ with $\mathbf{1} \in \mathcal{C}(\mathbf{Z})$, $\mathbf{X}_1$ is $n \times q$, the full model matrix $[\mathbf{Z}, \mathbf{X}_1]$ has rank $p = p_0 + q < n$, $\mathbf{M}_0$ projects onto $\mathcal{C}(\mathbf{Z})$ and $\mathbf{M}$ onto $\mathcal{C}([\mathbf{Z}, \mathbf{X}_1])$. The statistic for $H_0 : \beta_1 = \mathbf{0}$ is the F statistic of [Theorem 11.1.1](#), written as a function of the response vector:

$$F(\mathbf{u}) = \frac{\|(\mathbf{M} - \mathbf{M}_0)\mathbf{u}\|^2/q}{\|(\mathbf{I} - \mathbf{M})\mathbf{u}\|^2/(n-p)}. \quad (23.5.1)$$

Since $(\mathbf{M} - \mathbf{M}_0)\mathbf{Z} = \mathbf{0}$ and $(\mathbf{I} - \mathbf{M})\mathbf{Z} = \mathbf{0}$, $F(\mathbf{u} + \mathbf{Z}\mathbf{g}) = F(\mathbf{u})$ for every $\mathbf{g}$. Let

$$\hat{\boldsymbol{\varepsilon}}_0 = (\mathbf{I} - \mathbf{M}_0)\mathbf{y}, \quad \hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\mathbf{y}$$

be the residuals of the reduced and the full model. By [Theorem 6.6.2](#), $\mathbf{M} - \mathbf{M}_0$ projects onto $\mathcal{C}(\tilde{\mathbf{X}}_1)$ with $\tilde{\mathbf{X}}_1 = (\mathbf{I} - \mathbf{M}_0)\mathbf{X}_1$.

Definition 23.5.1 — Permutation schemes for a partial hypothesis

For a permutation matrix $\mathbf{P}$, each scheme computes a permuted statistic; its p-value is [Eq. 23.4.1](#) with $T(\mathbf{y})$ the observed $F(\mathbf{y})$ and $T(\mathbf{P}_b\mathbf{y})$ replaced by the scheme's permuted statistic.

- (a) **Raw permutation** (Manly 1997): $F(\mathbf{P}\mathbf{y})$, refitting the full model to permuted responses.
- (b) **Permuting the regressors of interest** (Draper and Stoneman 1966): the F statistic computed from $\mathbf{y}$ with model matrix $[\mathbf{Z}, \mathbf{P}\mathbf{X}_1]$.
- (c) **Kennedy's scheme** (Kennedy 1995): regress $\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0$ on $\tilde{\mathbf{X}}_1$ alone and compute $F_K(\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0)$, where $F_K(\mathbf{u}) = \frac{\|(\mathbf{M} - \mathbf{M}_0)\mathbf{u}\|^2/q}{(\|\mathbf{u}\|^2 - \|(\mathbf{M} - \mathbf{M}_0)\mathbf{u}\|^2)/(n-p)}$.
- (d) **Freedman–Lane** (Freedman and Lane 1983): form $\mathbf{y}^* = \mathbf{M}_0\mathbf{y} + \mathbf{P}\hat{\boldsymbol{\varepsilon}}_0$, the reduced-model fit plus permuted reduced-model residuals, and compute $F(\mathbf{y}^*)$.
- (e) **ter Braak's scheme** (ter Braak 1992): form $\mathbf{y}^* = \mathbf{M}\mathbf{y} + \mathbf{P}\hat{\boldsymbol{\varepsilon}}$, the full-model fit plus permuted full-model residuals, and compute the F statistic for the hypothesis $\boldsymbol{\beta}_1 = \hat{\boldsymbol{\beta}}_1$, which is true in the permuted world.

23.5.2 What can be proved

Proposition 23.5.1 — The Freedman–Lane scheme

In the setting above:

- (a) $F(\mathbf{M}_0\mathbf{y} + \mathbf{P}\hat{\boldsymbol{\varepsilon}}_0) = F(\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0)$ for every $\mathbf{P}$, and $F(\mathbf{y}) = F(\hat{\boldsymbol{\varepsilon}}_0)$. ter Braak's permuted statistic equals $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}})$.
- (b) Under H_0 , $\hat{\boldsymbol{\varepsilon}}_0 = (\mathbf{I} - \mathbf{M}_0)\boldsymbol{\varepsilon}$. The p-values of the Freedman–Lane, ter Braak, Kennedy and Draper–Stoneman schemes depend on $\mathbf{y}$ only through $(\mathbf{I} - \mathbf{M}_0)\mathbf{y}$, so under H_0 their distributions do not depend on $\boldsymbol{\gamma}$. The raw permutation statistic involves $\boldsymbol{\gamma}$.
- (c) Under H_0 , if $\mathbf{P}\mathbf{Z} = \mathbf{Z}$ for every $\mathbf{P}$ in a group $\mathcal{G}$ and $\boldsymbol{\varepsilon}$ is $\mathcal{G}$ -invariant in distribution, then the Freedman–Lane test over $\mathcal{G}$ is exact, and it coincides with the raw permutation test over $\mathcal{G}$.
- (d) Suppose the errors are independent draws from one law with mean zero and variance $\sigma^2 > 0$, $\mathbf{P}$ is uniform over all permutations and independent of $\boldsymbol{\varepsilon}$, and p is fixed as $n \rightarrow \infty$. Then under H_0 , $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0) - F(\mathbf{P}\boldsymbol{\varepsilon}) \rightarrow 0$ in probability, and so does $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}}) - F(\mathbf{P}\boldsymbol{\varepsilon})$.

Proof.

- (a) $\mathbf{M}_0\mathbf{y} \in \mathcal{C}(\mathbf{Z})$, so the invariance of Eq. 23.5.1 gives the first claim, and $\mathbf{y} = \mathbf{M}_0\mathbf{y} + \hat{\boldsymbol{\varepsilon}}_0$ gives the second. In ter Braak's scheme, the F statistic for $\boldsymbol{\beta}_1 = \hat{\boldsymbol{\beta}}_1$ computed from $\mathbf{y}^*$ is the F statistic for $\boldsymbol{\beta}_1 = \mathbf{0}$ computed from $\mathbf{y}^* - \mathbf{X}_1\hat{\boldsymbol{\beta}}_1$, whose reduced model is the set of means $\mathbf{X}_1\hat{\boldsymbol{\beta}}_1 + \mathcal{C}(\mathbf{Z})$: the numerators agree by Theorem 11.3.2(b), and the denominators agree because subtracting $\mathbf{X}_1\hat{\boldsymbol{\beta}}_1 \in \mathcal{C}(\mathbf{X})$ leaves the residuals unchanged. Since $\mathbf{y}^* - \mathbf{X}_1\hat{\boldsymbol{\beta}}_1 = \mathbf{Z}\boldsymbol{\gamma} + \mathbf{P}\hat{\boldsymbol{\varepsilon}}$ with $\mathbf{Z}\boldsymbol{\gamma} \in \mathcal{C}(\mathbf{Z})$, the statistic is $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}})$.
- (b) Under H_0 , $(\mathbf{I} - \mathbf{M}_0)\mathbf{y} = (\mathbf{I} - \mathbf{M}_0)\boldsymbol{\varepsilon}$. Freedman–Lane and Kennedy use $\mathbf{y}$ only through $\hat{\boldsymbol{\varepsilon}}_0$, and ter Braak through $\hat{\boldsymbol{\varepsilon}} = (\mathbf{I} - \mathbf{M})\hat{\boldsymbol{\varepsilon}}_0$. The Draper–Stoneman statistic is unchanged when a vector in $\mathcal{C}(\mathbf{Z})$ is added to $\mathbf{y}$. In each case the observed statistic is $F(\mathbf{y}) = F(\hat{\boldsymbol{\varepsilon}}_0)$ by (a). The raw permutation statistic $F(\mathbf{P}\mathbf{y}) = F(\mathbf{P}\mathbf{Z}\boldsymbol{\gamma} + \mathbf{P}\boldsymbol{\varepsilon})$ involves $\boldsymbol{\gamma}$ whenever $\mathbf{P}\mathbf{Z}\boldsymbol{\gamma} \notin \mathcal{C}(\mathbf{Z})$, and its null distribution in general depends on $\boldsymbol{\gamma}$, as Figure 23.5.1 shows; we do not prove this.
- (c) $\mathbf{P}\mathbf{Z} = \mathbf{Z}$ implies $\mathbf{P}\mathbf{M}_0\mathbf{P}^\top = \mathbf{M}_0$, since $\mathbf{P}\mathbf{M}_0\mathbf{P}^\top$ is the orthogonal projection onto $\mathcal{C}(\mathbf{P}\mathbf{Z}) = \mathcal{C}(\mathbf{Z})$. So $\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0 = \mathbf{P}(\mathbf{I} - \mathbf{M}_0)\boldsymbol{\varepsilon} = (\mathbf{I} - \mathbf{M}_0)\mathbf{P}\boldsymbol{\varepsilon}$ under H_0 , and $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0) = F(\mathbf{P}\boldsymbol{\varepsilon})$ by invariance. Also $F(\mathbf{y}) = F(\boldsymbol{\varepsilon})$. So the Freedman–Lane p-value is the permutation p-value of the statistic F applied to $\boldsymbol{\varepsilon}$, which is exact by Theorem 23.4.2. The raw permutation statistic is $F(\mathbf{Z}\boldsymbol{\gamma} + \mathbf{P}\boldsymbol{\varepsilon}) = F(\mathbf{P}\boldsymbol{\varepsilon})$ as well.
- (d) Put $\mathbf{v} = \mathbf{M}_0\boldsymbol{\varepsilon}$, so $\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0 = \mathbf{P}\boldsymbol{\varepsilon} - \mathbf{P}\mathbf{v}$. For a fixed vector $\mathbf{v}$ and a uniform random permutation, $E(\mathbf{P}\mathbf{v}) = \bar{v}\mathbf{1}$ and $\text{Cov}(\mathbf{P}\mathbf{v}) = \frac{S_v}{n-1}(\mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^\top)$, where $S_v = \sum_i (v_i - \bar{v})^2 \leq \|\mathbf{v}\|^2$ (Exercise (B1)). Since $(\mathbf{M} - \mathbf{M}_0)\mathbf{1} = \mathbf{0}$,

$$\begin{aligned} E[\|(\mathbf{M} - \mathbf{M}_0)\mathbf{P}\mathbf{v}\|^2 \mid \boldsymbol{\varepsilon}] &= \frac{S_v}{n-1} \text{tr}(\mathbf{M} - \mathbf{M}_0) \\ &\leq \frac{q \|\mathbf{M}_0\boldsymbol{\varepsilon}\|^2}{n-1}, \end{aligned}$$

and $E\|\mathbf{M}_0\boldsymbol{\varepsilon}\|^2 = \sigma^2 p_0$, so $\|(\mathbf{M} - \mathbf{M}_0)\mathbf{P}\mathbf{v}\| \rightarrow 0$ in probability. The numerators of the two statistics are $\|\mathbf{N}\|^2/q$ and $\|\mathbf{N} - \boldsymbol{\delta}\|^2/q$ with $\mathbf{N} = (\mathbf{M} - \mathbf{M}_0)\mathbf{P}\boldsymbol{\varepsilon}$ and $\boldsymbol{\delta} = (\mathbf{M} - \mathbf{M}_0)\mathbf{P}\mathbf{v}$. Here $\mathbf{P}\boldsymbol{\varepsilon}$ has the distribution of $\boldsymbol{\varepsilon}$, so $E\|\mathbf{N}\|^2 = q\sigma^2$, and $|\|\mathbf{N} - \boldsymbol{\delta}\|^2 - \|\mathbf{N}\|^2| \leq 2\|\mathbf{N}\|\|\boldsymbol{\delta}\| + \|\boldsymbol{\delta}\|^2 \rightarrow 0$ in probability. For the denominators, $\|(\mathbf{I} - \mathbf{M})\mathbf{P}\hat{\boldsymbol{\varepsilon}}_0\| - \|(\mathbf{I} - \mathbf{M})\mathbf{P}\boldsymbol{\varepsilon}\| \leq \|\mathbf{v}\| = O_p(1)$, while $\|(\mathbf{I} - \mathbf{M})\mathbf{P}\boldsymbol{\varepsilon}\|^2/(n-p)$ has the distribution of s^2 and tends to σ^2 in probability (Corollary 5.6.4 needs fourth moments; the argument of Lemma 23.1.3 needs only the second). Both norms are $O_p(\sqrt{n})$, so the difference of their squares is at most $\|\mathbf{v}\|$ times $O_p(\sqrt{n})$. Dividing by $n-p$, the two denominators differ by a quantity that tends to zero, and both tend to σ^2 . The claim for $F(\mathbf{P}\hat{\boldsymbol{\varepsilon}})$ is the same argument with $\mathbf{v} = \mathbf{M}\boldsymbol{\varepsilon}$, $E\|\mathbf{M}\boldsymbol{\varepsilon}\|^2 = \sigma^2 p$. ■

Part (d) compares Freedman–Lane with an **oracle** that permutes the true errors. The oracle is exact: $F(\mathbf{y}) = F(\boldsymbol{\varepsilon})$ under H_0 , and it compares $F(\boldsymbol{\varepsilon})$ with $F(\mathbf{P}_b\boldsymbol{\varepsilon})$, a permutation test for the exchangeable $\boldsymbol{\varepsilon}$. Freedman–Lane replaces $\mathbf{P}_b\boldsymbol{\varepsilon}$ by $\mathbf{P}_b\hat{\boldsymbol{\varepsilon}}_0$, which changes the statistics by vanishing amounts. To conclude that its size tends to α , one needs also that the oracle statistics have a continuous joint limit, so that vanishing perturbations rarely change their ranks. That holds under conditions like Eq. 23.1.1 by a permutation central limit theorem that we do not prove; Anderson and Robinson (2001) give the argument.

Part (b) is the practical point: four of the schemes see the data only after $\mathbf{Z}$ has been projected

out, while for large $\mathbf{Z}\boldsymbol{\gamma}$ the raw permutation mostly permutes $\mathbf{Z}\boldsymbol{\gamma}$, not the errors. Kennedy's scheme can be pinned down exactly.

Proposition 23.5.2 — Kennedy's scheme is anticonservative relative to Freedman–Lane

For every permutation $\mathbf{P}$, $F_K(\mathbf{P}\hat{\boldsymbol{\epsilon}}_0) \leq F(\mathbf{P}\hat{\boldsymbol{\epsilon}}_0)$, with equality when $\mathbf{P} = \mathbf{I}$. Consequently, for any set of permutations $\mathbf{P}_1, \dots, \mathbf{P}_B$, the Kennedy p-value is at most the Freedman–Lane p-value.

Proof. The two statistics have the same numerator. Write $\mathbf{u} = \mathbf{P}\hat{\boldsymbol{\epsilon}}_0$. Since $\mathbf{I} = \mathbf{M}_0 + (\mathbf{M} - \mathbf{M}_0) + (\mathbf{I} - \mathbf{M})$ with orthogonal ranges,

$$\begin{aligned}\|(\mathbf{I} - \mathbf{M})\mathbf{u}\|^2 &= \|\mathbf{u}\|^2 - \|(\mathbf{M} - \mathbf{M}_0)\mathbf{u}\|^2 - \|\mathbf{M}_0\mathbf{u}\|^2 \\ &\leq \|\mathbf{u}\|^2 - \|(\mathbf{M} - \mathbf{M}_0)\mathbf{u}\|^2,\end{aligned}$$

so Kennedy's denominator is at least as large. For $\mathbf{P} = \mathbf{I}$, $\mathbf{M}_0\hat{\boldsymbol{\epsilon}}_0 = \mathbf{0}$, and the two agree. Each permuted Kennedy statistic is therefore at most the corresponding Freedman–Lane one, while the observed statistics coincide, so fewer permuted values reach the observed one. ■

The discrepancy $\|\mathbf{M}_0\mathbf{P}\hat{\boldsymbol{\epsilon}}_0\|^2$, the part of the permuted residuals that $\mathbf{Z}$ could have explained, has expectation about $(p_0 - 1)\sigma^2$, small beside $(n - p)\sigma^2$ for large n ; so Kennedy's scheme is liberal only in small samples.

23.5.3 Stack loss again, and a simulation

Example. (Acid concentration given air flow and water temperature)

In the full stack loss regression, test whether acid concentration matters once air flow and water temperature are in the model. The F statistic is 0.947 on 1 and 17 degrees of freedom, with p-value 0.344. With 19999 permutations each, the schemes give: raw permutation 0.346, Draper–Stoneman 0.343, Kennedy 0.315, Freedman–Lane 0.345 and ter Braak 0.345. Only Kennedy's differs noticeably, in the direction [Proposition 23.5.2](#) predicts. The marginal association of [Example \(Acid concentration and stack loss\)](#) disappears once the correlated regressors are in the model.

```

Real data with a p-value near 0.34 cannot separate the schemes. The simulation in [Figure 23.5.1](#) is designed to. It has $n = 12$ cases, normal errors, a nuisance regressor z correlated with the regressor of interest x , and one high-leverage value of x . The null hypothesis holds, and the nuisance coefficient γ ranges from 0 to 30. Each point is the rejection rate of a nominal 5% test in 5000 data sets, with 199 permutations each, so the Monte Carlo standard error is about 0.0031.

The same random numbers are used for every γ , so by [Proposition 23.5.1\(b\)](#) five of the six tests

Figure 23.5.1: Null rejection rates of nominal 5% tests of one coefficient, $n = 12$, against the nuisance coefficient γ . The band is two Monte Carlo standard errors around 0.05.

make identical decisions at every γ , and their lines are flat. The F test rejects in 0.048 of the data sets, Freedman–Lane in 0.054, ter Braak and Draper–Stoneman in 0.046, and Kennedy in 0.066, the liberal bias of [Proposition 23.5.2](#) made visible by the small sample. The raw permutation test is exact at $\gamma = 0$ (0.048), but its size moves with γ , reaching 0.064 at $\gamma = 30$.

```
def size_study(gamma, reps, B, seed, n=12, alpha=0.05):
    """Rejection rates at level alpha when beta = 0 and the nuisance coefficient is
    gamma."""
    rng = np.random.default_rng(seed)
    z = np.linspace(-1, 1, n)
    x = 0.8 * z + 0.6 * np.random.default_rng(1).normal(size=n) # fixed,
    # correlated with z
    x[0] = 6.0 # one high-leverage value of x
    Z = np.column_stack([np.ones(n), z])
    rejections = {}
    for _ in range(reps):
        y = 1.0 + gamma * z + rng.normal(size=n) # the null hypothesis beta = 0
        # holds
        for m, pv in perm_pvalues(y, x, Z, B, rng)[0].items():
            rejections[m] = rejections.get(m, 0) + (pv <= alpha)
    return {m: r / reps for m, r in rejections.items()}

for gamma in (0.0, 30.0):
    print(gamma, size_study(gamma, reps=300, B=99, seed=2308))
```

As Anderson and Legendre (1999) concluded from a much larger simulation, Freedman–Lane is the sensible default: exact whenever an exact test exists, blind to the nuisance coefficients, and close to the oracle in large samples. ter Braak’s scheme behaves similarly, and since its reference distribution does not need the null hypothesis, it suits the inversion of tests into intervals. Winkler and coauthors (2014) review the schemes for the general linear model.

23.5.4 Exercises

23.5.4.1 A. Check your understanding

Exercise A1.

Show that when $\mathbf{Z} = \mathbf{1}$ the Freedman–Lane, Kennedy and raw permutation tests all coincide with the permutation test of [Section 23.4](#).

Solution. With $\mathbf{Z} = \mathbf{1}$, every permutation fixes $\mathbf{Z}$, so by [Proposition 23.5.1\(c\)](#) Freedman–Lane and the raw permutation coincide and are exact. Kennedy’s scheme differs only through $\|\mathbf{M}_0 \mathbf{P} \hat{\mathbf{e}}_0\|^2 = n \overline{(\mathbf{P} \hat{\mathbf{e}}_0)^2}$, which is zero because $\hat{\mathbf{e}}_0 = \mathbf{y} - \bar{y} \mathbf{1}$ sums to zero and permuting does not change the sum.

Exercise A2.

In ter Braak’s scheme, what is the permuted statistic for $\mathbf{P} = \mathbf{I}$? Explain why the observed statistic must still be counted in the numerator and denominator of [Eq. 23.4.1](#).

23.5.4.2 B. Practice

Exercise B1.

Let $\mathbf{v} \in \mathbb{R}^n$ be fixed and $\mathbf{P}$ a uniformly random permutation matrix. Show that $E(\mathbf{P}\mathbf{v}) = \bar{v} \mathbf{1}$ and $\text{Cov}(\mathbf{P}\mathbf{v}) = \frac{S_v}{n-1} (\mathbf{I} - n^{-1} \mathbf{1} \mathbf{1}^\top)$ with $S_v = \sum_i (v_i - \bar{v})^2$. (The computation is the one in the proof of [Proposition 18.4.2](#), there for permutations within a block.)

23.5.4.3 C. Going deeper

Exercise C1.

Suppose the errors are independent with variances that depend on $\mathbf{X}_1$. Explain why the schemes of [Definition 23.5.1](#) need not be asymptotically valid for $H_0 : \boldsymbol{\beta}_1 = \mathbf{0}$, and where the argument of [Proposition 23.5.1\(d\)](#) breaks down. Propose a studentized version in the spirit of [Section 23.4](#).

23.6 When resampling fails

The consistency theorems of this chapter assume exchangeable resampled quantities, a smooth statistic, a fixed number of parameters, a finite error variance, no dominant case, independence, and a sample large enough for limits to be relevant. When any of these fails, the bootstrap can fail silently, producing a distribution that looks reasonable and is wrong.

23.6.1 A statistic that is not smooth: the maximum

The cleanest failure is not specific to regression. Let $Y_1, \dots, Y_n$ be independent and uniform on $[0, \theta]$, and estimate θ by the sample maximum $Y_{(n)}$.

Proposition 23.6.1 — The bootstrap of a maximum

- (a) $n(\theta - Y_{(n)})/\theta$ converges in distribution to the standard exponential law.
- (b) For every sample with distinct values, the case bootstrap gives $\Pr_*(Y_{(n)}^* = Y_{(n)}) = 1 - (1 - 1/n)^n \rightarrow 1 - e^{-1}$.

So the bootstrap distribution of $n(Y_{(n)} - Y_{(n)}^*)/Y_{(n)}$ has an atom at zero of mass at least $1 - e^{-1}$ for every sample, and it cannot approach the continuous exponential law.

Proof.

- (a) For $0 \leq t \leq n$, $\Pr(n(\theta - Y_{(n)})/\theta > t) = \Pr(\text{all } Y_i < \theta(1 - t/n)) = (1 - t/n)^n \rightarrow e^{-t}$.
- (b) $Y_{(n)}^* = Y_{(n)}$ unless none of the n draws picks the largest observation, which happens with probability $(1 - 1/n)^n$. And $(1 - 1/n)^n = \exp(n \log(1 - 1/n)) \rightarrow e^{-1}$, from below, since $n \log(1 - 1/n) < -1$.

■

With $n = 50$ the atom is $1 - 0.98^{50} = 0.636$, and a simulation with 20000 resamples finds 0.639. The bootstrap needs the statistic to depend smoothly on the empirical distribution, and extremes do not. The m -out-of- n bootstrap, with resamples of size m and $m/n \rightarrow 0$, repairs many such failures at a price in efficiency (Bickel, Götze and van Zwet 1997). In regression the analogue is any statistic driven by the most extreme residual, such as the largest studentized residual of the outlier test (Theorem 20.3.3).

```
import numpy as np
rng = np.random.default_rng(2310)
n = 50
u = rng.uniform(size=n)
B = 20_000
boot_max = u[rng.integers(0, n, size=(B, n))].max(axis=1)
atom = np.mean(boot_max == u.max())
print(f"bootstrap P*(max* = max) = {atom:.3f}; 1 - (1 - 1/n)^n = {1 - (1 - 1 / n) ** n:.3f}")
```

23.6.2 Heavy tails

Without a finite error variance the sample mean, and any least squares coefficient, is not asymptotically normal. Athreya (1987) showed that the bootstrap of the mean then converges not to the correct stable limit but to a *random* limit that differs from sample to sample: resampling cannot learn a tail that shows up only through a few enormous values.

Figure 23.6.1: (a) Case-bootstrap slopes when one of 15 cases has leverage 0.902, split by whether the resample contains it. (b) Coverage of nominal 95% intervals for a Pareto mean with infinite variance.

Figure 23.6.1(b) shows the consequence for coverage. The data are samples from a Pareto law with tail index 1.5, which has a finite mean and an infinite variance, and the target is the mean. The nominal 95% t interval covers 0.665 of the time at $n = 25$ and 0.758 at $n = 1600$; the bootstrap percentile interval covers 0.673 and 0.780. Neither improves between $n = 400$ and $n = 1600$. The same holds for regression coefficients, which is one reason to prefer estimators less sensitive to extreme errors, such as the least absolute deviations fit of Chapter 45 (Definition 45.2.1), to resampling least squares.

23.6.3 One dominant case

When one case has leverage near one, Eq. 23.1.1 fails and the case bootstrap splits into resamples that contain the case and resamples, about a third of them, that do not.

Example. (A slope determined by one case)

Take 15 cases, fourteen with x spread over $[0, 1]$ and one at $x = 4$, with leverage 0.902, and a response that puts the far case a little below the line of the others. The least squares slope is 0.254. Without the far case it would be 0.437. In 20000 case-bootstrap resamples, a fraction 0.356 omit the far case, close to $(14/15)^{15} = 0.355$. Figure 23.6.1(a) shows the result. The resamples that contain the far case give slopes tightly concentrated near the full-data value, with standard deviation 0.037. Those that omit it give slopes spread around the fourteen-case value, with standard deviation 0.274. The bootstrap distribution mixes two answers to two questions, and neither its spread nor its percentiles describe the uncertainty of $\hat{\beta}_1$.

```
import numpy as np
rng = np.random.default_rng(2313)
n_1 = 15
x_1 = np.append(np.linspace(0, 1, n_1 - 1), 4.0) # one case far from the rest
X_1 = np.column_stack([np.ones(n_1), x_1])
h_1 = np.sum((X_1 @ np.linalg.inv(X_1.T @ X_1)) * X_1, axis=1)
```

```

y_1 = 1 + 0.5 * x_1 + 0.3 * rng.normal(size=n_1)
y_1[-1] -= 1.0                                # and not quite on the line of
                                                the others
idx = rng.integers(0, n_1, size=(20_000, n_1))
xs, ys = x_1[idx], y_1[idx]
xc = xs - xs.mean(axis=1, keepdims=True)
b_case = np.sum(xc * ys, axis=1) / np.sum(xc ** 2, axis=1)
absent = ~np.any(idx == n_1 - 1, axis=1)
print(f"leverage of the far case {h_1[-1]:.3f}; resamples without it: {absent.mean():.3f}")

```

The residual and wild bootstraps keep the far case, but inherit the problem ([Example \(The wild bootstrap for Engel's data\)](#)): its residual has variance $\sigma^2(1 - h_{ii})$, nearly zero, so the data say almost nothing about its error.

23.6.4 Many parameters

With p proportional to n , the plain residual bootstrap underestimates variances by the non-vanishing factor $(n - p)/n$ of [Proposition 23.1.1\(b\)](#). The case bootstrap errs the other way: a resample has only about $0.632n$ distinct cases ([Exercise \(A2\)](#)), and when p/n is not small its design is much worse conditioned than the original.

A simulation with $n = 60$, $p = 30$, a Gaussian design and normal errors shows both effects. The median ratio of bootstrap variance to true variance for one coefficient, over 200 data sets, is 0.47 for the plain residual bootstrap, 0.97 after rescaling the residuals by $\sqrt{n/(n - p)}$, and 3.38 for the case bootstrap. El Karoui and Purdom (2018) study these failures, and Mammen (1993) gives conditions under which the residual and wild bootstraps remain valid as p grows. [Chapter 28](#) takes up regression with more parameters than cases.

```

import numpy as np

def variance_ratios(n, p, reps, B, rng):
    """Bootstrap variance of the first coefficient divided by its true variance (
    errors  $N(0, 1)$ )."""
    X = rng.normal(size=(n, p))                # fixed design
    XtX_inv = np.linalg.inv(X.T @ X)
    true_var = XtX_inv[0, 0]
    H = X @ XtX_inv @ X.T
    out = {"residual": [], "rescaled": [], "case": []}
    for _ in range(reps):
        y = rng.normal(size=n)                # beta = 0
        e = y - H @ y
        fit = H @ y
        for name, r in [("residual", e), ("rescaled", e * np.sqrt(n / (n - p)))]:
            Ys = fit + r[rng.integers(0, n, size=(B, n))]
            out[name].append(np.var(Ys @ (X @ XtX_inv)[: , 0]) / true_var)
        bs = []
        for _ in range(B):
            i = rng.integers(0, n, size=n)
            bs.append(np.linalg.lstsq(X[i], y[i], rcond=None)[0][0])
        out["case"].append(np.var(bs) / true_var)
    return {k: float(np.median(v)) for k, v in out.items()}

rng = np.random.default_rng(2314)
print(variance_ratios(60, 30, reps=20, B=100, rng=rng))

```

23.6.5 Dependence

Resampling independently destroys serial correlation. With positively autocorrelated errors and a smooth regressor, the true variance of a slope far exceeds the independent-errors formula ([Theorem 19.2.2](#)), which every bootstrap of this chapter reproduces. Take a straight line in time with $n = 100$ equally spaced points and AR(1) errors with parameter 0.7. Over 2000 series the slope has standard deviation 1.130, while the residual bootstrap's average standard error is 0.449, a ratio of 0.40.

The **moving-block bootstrap** (Künsch 1989) resamples blocks of consecutive residuals and so keeps the dependence within blocks. With blocks of length 10 its average standard error is 0.818, a ratio of 0.72: better, still short, because dependence between blocks is lost (Lahiri 2003). When the dependence has a known form it is better to model it, as in [Theorem 21.6.1](#), and resample the estimated innovations.

```
import numpy as np

def dependence_study(n, phi, reps, B, block, rng):
    """True sd of the slope, and the average iid and moving-block residual-bootstrap
    standard errors."""
    x = np.linspace(0, 1, n)
    X = np.column_stack([np.ones(n), x])
    A = np.linalg.solve(X.T @ X, X.T)
    slopes, se_iid, se_block = [], [], []
    starts_max = n - block + 1
    for _ in range(reps):
        eps = np.empty(n)
        eps[0] = rng.normal() / np.sqrt(1 - phi ** 2)
        for i in range(1, n):
            eps[i] = phi * eps[i - 1] + rng.normal()    # AR(1) errors
        y = 1 + 2 * x + eps
        b = A @ y
        e = y - X @ b
        slopes.append(b[1])
        Ys = X @ b + e[rng.integers(0, n, size=(B, n))]
        se_iid.append(np.std(Ys @ A[1]))
        starts = rng.integers(0, starts_max, size=(B, n // block))
        idx = (starts[:, :, None] + np.arange(block)).reshape(B, -1)
        Ys = X @ b + e[idx]
        se_block.append(np.std(Ys @ A[1]))
    return np.std(slopes), np.mean(se_iid), np.mean(se_block)

rng = np.random.default_rng(2316)
print(dependence_study(100, 0.7, reps=100, B=200, block=10, rng=rng))
```

23.6.6 Small samples

A bootstrap distribution computed from eight residuals is an estimate from eight numbers. Take a straight line with $n = 8$ equally spaced points and normal errors, the most favourable case. In 4000 simulated data sets, the classical t interval covers 0.953, as it must. The residual

bootstrap percentile interval covers only 0.857. The reason is [Proposition 23.1.1\(b\)](#) combined with [Proposition 23.3.3\(b\)](#). The percentile interval is roughly $\hat{\beta}_1 \pm 1.96\sqrt{(n-2)/n} s \|\mathbf{a}\|$, so its coverage is about

$$\Pr(|t_6| \leq 1.96\sqrt{6/8}) = \Pr(|t_6| \leq 1.697) = 0.859.$$

The studentized residual bootstrap covers 0.952. In small samples, studentize, and compare with the classical interval.

```
import numpy as np
from scipy import stats

def small_n_coverage(n, reps, B, rng):
    """Coverage of 95% intervals for a slope with normal errors: t, residual
    percentile, bootstrap-t."""
    x = np.linspace(0, 1, n)
    X = np.column_stack([np.ones(n), x])
    XtX_inv = np.linalg.inv(X.T @ X)
    A = XtX_inv @ X.T
    c = np.sqrt(XtX_inv[1, 1])
    hits = {"t": 0, "percentile": 0, "studentized": 0}
    for _ in range(reps):
        y = rng.normal(size=n)                # true slope 0
        b = A[1] @ y
        e = y - X @ (A @ y)
        s = np.sqrt(e @ e / (n - 2))
        hits["t"] += abs(b) <= stats.t.ppf(0.975, n - 2) * s * c
        Ys = X @ (A @ y) + e[rng.integers(0, n, size=(B, n))]
        bs = Ys @ A[1]
        ss = np.sqrt(np.sum((Ys - (Ys @ A.T) @ X.T) ** 2, axis=1) / (n - 2))
        lo, hi = np.quantile(bs, [0.025, 0.975])
        hits["percentile"] += lo <= 0 <= hi
        tl, th = np.quantile((bs - b) / (ss * c), [0.025, 0.975])
        hits["studentized"] += b - th * s * c <= 0 <= b - tl * s * c
    return {k: v / reps for k, v in hits.items()}

rng = np.random.default_rng(2318)
print(small_n_coverage(8, reps=300, B=499, rng=rng))
```

Idea. Before trusting a bootstrap, check each assumption listed at the start of this section, and studentize the root. A permutation test needs only exchangeability under the null hypothesis, and is exact or not at all.

23.6.7 Exercises

23.6.7.1 A. Check your understanding

Exercise A1.

Compute $1 - (1 - 1/n)^n$ for $n = 10$ and $n = 1000$. Does the failure of [Proposition 23.6.1](#) become less severe with more data?

Solution. The values are 0.651 and 0.632. The atom decreases slightly toward its limit $1 - e^{-1}$ but never vanishes, so the failure does not go away.

Exercise A2.

In the moving-block bootstrap with blocks of length ℓ , explain why the bootstrap variance of a sample mean tends to be too small when ℓ is much shorter than the range of dependence, and why a very long block makes the estimate noisy.

23.6.7.2 B. Practice**Exercise B1.**

In [Example \(A slope determined by one case\)](#), show that the probability that the far case appears at least twice in a resample is $1 - (1 - 1/n)^n - (1 - 1/n)^{n-1}$, and evaluate it for $n = 15$. What does a resample with the far case drawn three times estimate?

Solution. The number of times the case is drawn is binomial with n trials and probability $1/n$. It is zero with probability $(1 - 1/n)^n$ and one with probability $n(1/n)(1 - 1/n)^{n-1} = (1 - 1/n)^{n-1}$, which gives the formula. For $n = 15$ this is $1 - 0.3553 - 0.3806 = 0.2641$. A resample with the case drawn three times fits a line in which that case has triple weight, a weighted least squares estimate that pulls even harder toward the far case, and not a draw from anything like the sampling distribution of $\hat{\beta}_1$.

23.6.7.3 C. Going deeper**Exercise C1.**

For the uniform maximum of [Proposition 23.6.1](#), show that the m -out-of- n bootstrap with $m \rightarrow \infty$ and $m/n \rightarrow 0$ gives $\Pr_*(Y_{(m)}^* = Y_{(n)}) = 1 - (1 - 1/n)^m \rightarrow 0$, and that the bootstrap distribution of $m(Y_{(n)} - Y_{(m)}^*)/Y_{(n)}$ approaches the standard exponential law.

23.7 Summary and Notes

23.7.1 Summary

Idea.

1. The bootstrap estimates the distribution of $\hat{\theta} - \theta$ by that of $\hat{\theta}^* - \hat{\theta}$ under an estimated mechanism: resampled residuals with the design fixed, or resampled cases ([Definition 23.1.1](#)).
2. The residual bootstrap has covariance $\hat{\sigma}_*^2(\mathbf{X}^\top \mathbf{X})^{-1}$, biased by $(n - p)/n$ ([Proposition 23.1.1](#)), and is consistent for contrasts under exchangeable errors when no case dominates ([Theorem 23.1.4](#)); it fails under heteroscedasticity.
3. The case bootstrap, linearized, has the HC0 sandwich covariance ([Proposition 23.1.5](#)). The wild bootstrap reproduces the sandwich exactly ([Proposition 23.2.1](#)) and is consistent under heteroscedasticity ([Theorem 23.2.2](#)).
4. Percentile, basic and studentized intervals are first-order correct ([Corollary 23.3.2](#));

studentizing reproduces exact pivots exactly ([Proposition 23.3.3](#)) and, by Hall's Edgeworth analysis (not proved here), gives higher-order accuracy.

5. Permutation tests are exact for any statistic under invariance ([Theorem 23.4.2](#)): in simple regression with exchangeable errors, and with nuisance regressors only for permutations that fix them ([Proposition 23.4.4](#)). Heteroscedasticity turns them into tests of independence unless the statistic is studentized.
6. The Freedman–Lane scheme is exact when an exact test exists, ignores the nuisance coefficients, and its permuted statistics are asymptotically those of an exact oracle ([Proposition 23.5.1\(d\)](#)); its asymptotic size is due to Anderson and Robinson (2001). Kennedy's scheme is more liberal ([Proposition 23.5.2](#)).
7. Resampling fails for extremes ([Proposition 23.6.1](#)), heavy tails, dominant cases, large p/n , dependence and, unless studentized, small samples ([Section 23.6](#)).

23.7.2 Notes and sources

The bootstrap. Efron (1979) introduced the bootstrap. Freedman (1981) set out residual and case resampling for regression and proved both consistent; [Theorem 23.1.4](#) is a version for linear contrasts. Bickel and Freedman (1981) developed the general theory, and Wu (1986) showed that the residual bootstrap fails under heteroscedasticity. Efron and Tibshirani (1993) and Davison and Hinkley (1997) are the standard books; the latter uses the leverage-adjusted residuals adopted here. Sen and Srivastava (1990, section 5.4) describe the residual bootstrap test of a linear hypothesis.

The wild bootstrap. The idea is in Wu (1986); Liu (1988) and Mammen (1993) developed its theory, and Mammen introduced the two-point law. Davidson and Flachaire (2008) recommend Rademacher weights with restricted residuals for tests.

Intervals. Hall (1988) compared bootstrap intervals by Edgeworth expansions, and Hall (1992) is the full account, including the iterated bootstrap of [Exercise \(C1\)](#). Efron (1987) introduced BCa; DiCiccio and Efron (1996) review the methods. Prediction intervals for a new response, which add a resampled error to the resampled estimate in place of the normal-theory interval of [Theorem 12.3.1](#), are treated in Davison and Hinkley (1997, chapter 6).

Permutation tests. Fisher (1935) and Pitman (1937) introduced permutation tests. The proof of [Theorem 23.4.2](#) follows Lehmann and Romano (2005, chapter 15); on the Monte Carlo count see Phipson and Smyth (2010). DiCiccio and Romano (2017) proved the validity of studentized permutation tests under dependence without correlation.

Partial tests. The schemes are due to Freedman and Lane (1983), ter Braak (1992), Kennedy (1995), Draper and Stoneman (1966) and Manly (1997). Anderson and Legendre (1999) compared them by simulation, Anderson and Robinson (2001) analytically, and Winkler and coauthors (2014) review them for the general linear model.

Failures. Bickel, Götze and van Zwet (1997) analyse the m -out-of- n bootstrap, Athreya (1987) the infinite-variance mean, and El Karoui and Purdom (2018) large p/n . Künsch (1989) introduced the moving-block bootstrap; Lahiri (2003) treats dependent data at length.

Chapter 24

Errors in Variables

Every earlier chapter takes the regressors as recorded without error. Often they are not: one clinic reading stands in for long-run blood pressure, a questionnaire for usual diet. The scientific model concerns the true value X , but the data contain a noisy W , and least squares on W estimates the best linear predictor from what was recorded. This chapter measures the gap and closes it. Classical error flattens a slope by a factor no sample size removes, makes correctly measured covariates look important, and in the normal model leaves the slope unidentified. Information from outside the regression rescues the analysis: a known error variance, repeated measurements, a known variance ratio, an instrument, or validation data. The moment correction, instrumental variables, regression calibration and SIMEX turn that information into estimates, each with its own conditions and costs.

What you need. [Chapter 6](#) (the population projection, [Theorem 6.11.1](#) and [Proposition 6.11.3](#), and [Theorem 6.3.6](#)). [Chapter 5](#) (moments of least squares under departures, [Proposition 5.5.7](#)). [Chapter 14](#) (random regressors, [Theorem 14.1.2](#), and the limit theorems of [Section 14.4](#)). From this part, [Chapter 19](#) (omitted-variable bias, [Theorem 19.1.2](#)), [Chapter 21](#) (sandwich covariance estimators, [Theorem 21.4.2](#)) and [Chapter 23](#) (the pairs bootstrap, [Definition 23.1.1](#)).

24.0.1 Roadmap

- [Attenuation bias](#)
- [The classical measurement error model](#)
- [Reliability and moment correction](#)
- [Instrumental variables](#)
- [Regression calibration and SIMEX](#)
- [Summary and notes](#)

24.1 Attenuation bias

When a regressor is recorded with error, conditioning on the recorded value is still legitimate, but it describes how the response varies with the *reading*, not with the underlying *quantity*. This section measures the difference.

24.1.1 A running example

One simulated study is used throughout the chapter. For $n = 300$ patients, let x_i be long-run systolic blood pressure, the average that many visits would give, with mean 130 mmHg and standard deviation 12. Age has mean 55 years, standard deviation 10, and correlation 0.5 with x_i . Each patient has two clinic readings, $w_{ij} = x_i + u_{ij}$, with independent errors $u_{ij} \sim N(0, 9^2)$. The outcome is

$$y_i = -4 + 0.08 x_i + 0 \cdot \text{age}_i + \varepsilon_i, \quad \varepsilon_i \sim N(0, 1),$$

so age has no effect given long-run pressure. In a real study x_i is unseen; here it lets every method be checked.

24.1.2 Classical error

Throughout the chapter, a regression model is stated in terms of *true* regressors $\mathbf{x}$ (the ones measured with error) and $\mathbf{z}$ (the ones measured exactly):

$$Y = \alpha + \boldsymbol{\beta}_x^\top \mathbf{x} + \boldsymbol{\beta}_z^\top \mathbf{z} + \varepsilon, \quad (24.1.1)$$

where ε has mean zero and variance σ^2 and is uncorrelated with $(\mathbf{x}, \mathbf{z})$. We write a generic observation without an index. The data are n independent copies of it unless stated otherwise.

Definition 24.1.1 — Classical measurement error

Suppose $\mathbf{x}$ is observed only through $\mathbf{w} = \mathbf{x} + \mathbf{u}$. The error $\mathbf{u}$ is **classical** if $E(\mathbf{u}) = \mathbf{0}$, $\text{Cov}(\mathbf{u}) = \boldsymbol{\Sigma}_{uu}$, and $\mathbf{u}$ is independent of $(\mathbf{x}, \mathbf{z}, \varepsilon)$.

The error is *additive and unrelated to the true value*, and *nondifferential*: independent of ε , so the reading says nothing about the response beyond what $\mathbf{x}$ says. (People with a disease may recall past exposures differently, a differential error.) This section uses only that $\mathbf{u}$ has mean zero and is *uncorrelated* with $\mathbf{x}$, $\mathbf{z}$ and ε .

Definition 24.1.2 — Reliability ratio

The **reliability ratio** of $W = X + U$ is

$$\lambda = \frac{\sigma_x^2}{\sigma_x^2 + \sigma_u^2} = \frac{\text{Var}(X)}{\text{Var}(W)}.$$

If $\mathbf{z}$ is measured exactly, let $\sigma_{x \cdot z}^2 = \sigma_x^2 - \boldsymbol{\sigma}_{zx}^\top \boldsymbol{\Sigma}_{zz}^{-1} \boldsymbol{\sigma}_{zx}$ be the residual variance of X after its best linear prediction from $\mathbf{z}$ (Theorem 6.11.1), where $\boldsymbol{\sigma}_{zx} = \text{Cov}(\mathbf{z}, X)$. The **reliability given $\mathbf{z}$** is

$$\lambda_{x|z} = \frac{\sigma_{x \cdot z}^2}{\sigma_{x \cdot z}^2 + \sigma_u^2}.$$

In the running example a single reading has $\lambda = 144/(144 + 81) = 0.64$. Age explains a quarter of the variance of long-run pressure, leaving $\sigma_{x \cdot z}^2 = 108$, so $\lambda_{x|z} = 108/189 = 0.571$. Covariates remove part of the signal in W and none of the noise, so $\lambda_{x|z} \leq \lambda$.

24.1.3 Least squares on the reading

Substituting $X = W - U$ in $Y = \alpha + \beta X + \varepsilon$ gives

$$Y = \alpha + \beta W + (\varepsilon - \beta U). \quad (24.1.2)$$

Its error is correlated with the regressor, $\text{Cov}(W, \varepsilon - \beta U) = -\beta\sigma_u^2$, so least squares does not estimate β . It estimates the population projection of Y on the recorded regressors ([Proposition 6.11.3](#)), which the next theorem computes.

Theorem 24.1.1 — Attenuation

Let $(\mathbf{x}_{(i)}, \mathbf{z}_{(i)}, \mathbf{u}_{(i)}, \varepsilon_i)$, $i = 1, 2, \dots$, be independent copies of $(\mathbf{x}, \mathbf{z}, \mathbf{u}, \varepsilon)$ with finite second moments, satisfying [Eq. 24.1.1](#) and [Definition 24.1.1](#). Write $\mathbf{t} = (\mathbf{x}^\top, \mathbf{z}^\top)^\top$ for the true regressors, $\mathbf{s} = (\mathbf{w}^\top, \mathbf{z}^\top)^\top$ for the observed ones, $\boldsymbol{\theta} = (\boldsymbol{\beta}_x^\top, \boldsymbol{\beta}_z^\top)^\top$, $\boldsymbol{\Sigma}_{tt} = \text{Cov}(\mathbf{t})$, assumed positive definite, and $\tilde{\boldsymbol{\Sigma}} = \text{diag}(\boldsymbol{\Sigma}_{uu}, \mathbf{0})$ for the covariance matrix of the error in $\mathbf{s}$. Let $\hat{\alpha}_n$ and $\hat{\boldsymbol{\theta}}_n$ be the least squares intercept and slopes from regressing Y on $\mathbf{s}$ in the first n observations. Then, with probability one:

- (a) $\hat{\boldsymbol{\theta}}_n \rightarrow \boldsymbol{\theta}_w = (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}})^{-1} \boldsymbol{\Sigma}_{tt} \boldsymbol{\theta} = \boldsymbol{\theta} - (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}})^{-1} \tilde{\boldsymbol{\Sigma}} \boldsymbol{\theta}$, and $\hat{\alpha}_n \rightarrow \alpha + \boldsymbol{\mu}_t^\top (\boldsymbol{\theta} - \boldsymbol{\theta}_w)$, where $\boldsymbol{\mu}_t = \text{E}(\mathbf{t})$;
- (b) with a single regressor and no $\mathbf{z}$, the slope converges to $\lambda\beta$;
- (c) with a single mismeasured scalar X and exactly measured $\mathbf{z}$, the coefficient of W converges to $\lambda_{x|z}\beta_x$ and the coefficients of $\mathbf{z}$ converge to $\boldsymbol{\beta}_z + (1 - \lambda_{x|z})\beta_x\boldsymbol{\pi}$, where $\boldsymbol{\pi} = \boldsymbol{\Sigma}_{zz}^{-1}\boldsymbol{\sigma}_{zx}$ is the vector of coefficients from the best linear prediction of X from $\mathbf{z}$ ([Theorem 2.5.2](#));
- (d) the residual sum of squares divided by n (or by n minus the number of coefficients) converges to $\sigma^2 + \boldsymbol{\theta}^\top \boldsymbol{\Sigma}_{tt} (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}})^{-1} \tilde{\boldsymbol{\Sigma}} \boldsymbol{\theta}$, which in case (b) equals $\sigma^2 + \lambda\beta^2\sigma_u^2$.

Proof. Because $\mathbf{u}$ is uncorrelated with $\mathbf{t}$, $\text{Cov}(\mathbf{s}) = \boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}}$, which is positive definite as the sum of a positive definite and a nonnegative definite matrix. By [Proposition 6.11.3](#), the least squares coefficients converge with probability one to those of the best linear predictor of Y from $\mathbf{s}$, which by [Theorem 6.11.1](#) has slopes $\text{Cov}(\mathbf{s})^{-1} \text{Cov}(\mathbf{s}, Y)$ and intercept $\text{E}Y - \boldsymbol{\theta}_w^\top \text{E}\mathbf{s}$. Now

$$\text{Cov}(\mathbf{s}, Y) = \text{Cov}(\mathbf{t} + (\mathbf{u}^\top, \mathbf{0}^\top)^\top, \mathbf{t}^\top \boldsymbol{\theta} + \varepsilon) = \boldsymbol{\Sigma}_{tt} \boldsymbol{\theta},$$

since $\mathbf{u}$ is uncorrelated with $\mathbf{t}$ and ε , and ε with $\mathbf{t}$. This is the first form in (a). The second follows from $\boldsymbol{\Sigma}_{tt} = (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}}) - \tilde{\boldsymbol{\Sigma}}$. For the intercept, $\text{E}\mathbf{s} = \boldsymbol{\mu}_t$ and $\text{E}Y = \alpha + \boldsymbol{\theta}^\top \boldsymbol{\mu}_t$.

(b) With scalars, $\theta_w = \sigma_x^2\beta/(\sigma_x^2 + \sigma_u^2) = \lambda\beta$.

(c) Here $\tilde{\boldsymbol{\Sigma}}\boldsymbol{\theta} = \sigma_u^2\beta_x\mathbf{e}_1$, so by the second form in (a) the bias $\boldsymbol{\theta} - \boldsymbol{\theta}_w$ is $\sigma_u^2\beta_x$ times the first column of $\text{Cov}(\mathbf{s})^{-1}$. Order the observed regressors as $(\mathbf{z}, W)$ for the moment, so that

$$\text{Cov}(\mathbf{s}) = \begin{pmatrix} \boldsymbol{\Sigma}_{zz} & \boldsymbol{\sigma}_{zx} \\ \boldsymbol{\sigma}_{zx}^\top & \sigma_x^2 + \sigma_u^2 \end{pmatrix}.$$

The Schur complement of $\boldsymbol{\Sigma}_{zz}$ is $\sigma_x^2 + \sigma_u^2 - \boldsymbol{\sigma}_{zx}^\top \boldsymbol{\Sigma}_{zz}^{-1} \boldsymbol{\sigma}_{zx} = \sigma_{x \cdot z}^2 + \sigma_u^2$. By [Theorem 1.6.4](#) the last column of the inverse is $(-\boldsymbol{\pi}^\top, 1)^\top / (\sigma_{x \cdot z}^2 + \sigma_u^2)$. So the bias in the coefficient of W is

$\sigma_u^2 \beta_x / (\sigma_{x|z}^2 + \sigma_u^2) = (1 - \lambda_{x|z}) \beta_x$, and the bias in the coefficients of $\mathbf{z}$ is $-(1 - \lambda_{x|z}) \beta_x \boldsymbol{\pi}$.

(d) The residual sum of squares over n is $n^{-1} \sum_i (Y_i - \hat{\alpha}_n - \hat{\boldsymbol{\theta}}_n^\top \mathbf{s}_i)^2$. Expanded, it is a continuous function of the coefficients and of second sample moments, which converge by (a) and the strong law, so the limit is $E(Y - \alpha_w - \boldsymbol{\theta}_w^\top \mathbf{s})^2$, the mean squared error of the best linear predictor. By [Eq. 6.11.1](#) it equals $\text{Var}(Y) - \boldsymbol{\theta}_w^\top \text{Cov}(\mathbf{s}) \boldsymbol{\theta}_w$, which is

$$\sigma^2 + \boldsymbol{\theta}^\top \boldsymbol{\Sigma}_{tt} \boldsymbol{\theta} - \boldsymbol{\theta}^\top \boldsymbol{\Sigma}_{tt} (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}})^{-1} \boldsymbol{\Sigma}_{tt} \boldsymbol{\theta} = \sigma^2 + \boldsymbol{\theta}^\top \boldsymbol{\Sigma}_{tt} (\boldsymbol{\Sigma}_{tt} + \tilde{\boldsymbol{\Sigma}})^{-1} \tilde{\boldsymbol{\Sigma}} \boldsymbol{\theta}.$$

In case (b) the last term is $\beta^2 \sigma_x^2 \sigma_u^2 / (\sigma_x^2 + \sigma_u^2) = \lambda \beta^2 \sigma_u^2$.

■

Part (b) is **attenuation**: the slope is shrunk towards zero by the reliability ratio, whatever the sample size. More data give a more precise estimate of the wrong number $\lambda \beta$.

Example. (One reading instead of long-run pressure)

In the running example, regressing y on the true x gives slope 0.0755 (standard error 0.0050). Regressing on the first clinic reading gives 0.0499 (standard error 0.0046), a ratio of 0.661, close to $\lambda = 0.64$; the limit is $\lambda \beta = 0.0512$. The usual 95% interval, [0.0409, 0.0589], misses 0.08, and in 4000 repeated samples the observed coverage was 0.000. The standard error measures variability around $\lambda \beta$, not the distance from $\lambda \beta$ to β . The residual variance tends to $1 + 0.64 \cdot 0.08^2 \cdot 81 = 1.3318$ by [Theorem 24.1.1](#)(d).

24.1.4 Several regressors: bias spreads

Part (c) is more troubling. Correctly measured covariates lower the relevant reliability to $\lambda_{x|z}$, and they inherit part of the effect of X . The part of X that the reading misses acts like an omitted regressor ([Theorem 19.1.2](#)), and covariates correlated with X pick up its effect in proportion to $\boldsymbol{\pi}$. This is **residual confounding**: adjusting for a noisy measurement of a confounder only partly adjusts for it.

Example. (Age looks important)

Add age to the regression on the first reading. Theory predicts a coefficient of $\lambda_{x|z} \beta = 0.0457$ for the reading and $(1 - 0.571) \cdot 0.08 \cdot 0.6 = 0.0206$ per year for age, which truly has no effect. The sample gives 0.0455 for the reading and 0.0182 for age, with standard error 0.0070 and p -value 0.0098. In 4000 repeated samples the t test of “no age effect” rejected at the 5% level in a proportion 0.812 of them. [Figure 24.1.1](#)(b) shows both limits as functions of the reliability.

```
import numpy as np
import statsmodels.api as sm

rng = np.random.default_rng(2401)
n = 300
age = rng.normal(55, 10, n)
x = 130 + 0.6 * (age - 55) + rng.normal(0, np.sqrt(108), n)  # long-run blood
                        pressure, sd 12
```

Figure 24.1.1: (a) The outcomes against true pressure (grey) and one reading (blue), with their least squares lines. (b) Limits of the coefficients of the reading and of age, in units of β_x , against the reliability; dashed, λ itself.

```
w = x[:, None] + rng.normal(0, 9, (n, 2)) # two clinic readings
y = -4 + 0.08 * x + 0.0 * age + rng.normal(0, 1.0, n) # age has no effect
given x

oracle = sm.OLS(y, sm.add_constant(x)).fit() # uses the true x
naive = sm.OLS(y, sm.add_constant(w[:, 0])).fit() # uses one reading
lam = 144 / (144 + 81) # reliability of one
reading

print(f"slope on x: {oracle.params[1]:.4f}")
print(f"slope on reading: {naive.params[1]:.4f} limit lambda*beta = {lam *
0.08:.4f}")
print("naive 95% interval:", naive.conf_int()[1].round(4))

both = sm.OLS(y, sm.add_constant(np.column_stack([w[:, 0], age]))).fit()
print(f"with age: reading {both.params[1]:.4f}, age {both.params[2]:.4f} (p = {both.
pvalues[2]:.4f})")
```

The repeated-sample figures come from this loop (with fewer samples in the cell).

```
def repeat(reps, seed):
    """Coverage of the naive 95% interval for the slope, and the rate at which age
    is 'significant'."""
    r = np.random.default_rng(seed)
    cover = reject = 0
    for _ in range(reps):
        a = r.normal(55, 10, n)
        xx = 130 + 0.6 * (a - 55) + r.normal(0, np.sqrt(108), n)
        ww = xx + r.normal(0, 9, n)
        yy = -4 + 0.08 * xx + r.normal(0, 1.0, n)
        lo, hi = sm.OLS(yy, sm.add_constant(ww)).fit().conf_int()[1]
        cover += lo <= 0.08 <= hi
        reject += sm.OLS(yy, sm.add_constant(np.column_stack([ww, a]))).fit().
        pvalues[2] < 0.05
    return cover / reps, reject / reps

print("coverage of naive interval, rate of rejecting 'no age effect':", repeat(200,
```

2404))

With several mismeasured regressors, $(\Sigma_{tt} + \tilde{\Sigma})^{-1}\Sigma_{tt}$ need not shrink each coefficient. A coefficient can grow, change sign, or appear from nothing ([Exercise \(B3\)](#)).

24.1.5 What survives

Two things survive classical error intact.

Error in the response. Suppose instead that the response is measured with error, $Y^* = Y + V$, where V has mean zero and variance σ_v^2 and is independent of the regressors and of ε .

Proposition 24.1.2 — Error in the response

Under these assumptions $Y^* = \alpha + \beta^\top \mathbf{x} + (\varepsilon + V)$, a linear model with the same coefficients and error variance $\sigma^2 + \sigma_v^2$. If ε and V are normal, so is their sum, and all the exact theory of Parts II and III applies to Y^* with σ^2 replaced by $\sigma^2 + \sigma_v^2$.

The proof is the display. Error in the response costs precision, not bias, unless it depends on the regressors (heavier people under-reporting weight) or is correlated with a regressor's error (both from the same self-report).

Tests of no effect. Since $\lambda\beta = 0$ iff $\beta = 0$, attenuation can hide an effect of the mismeasured regressor but cannot create one. The protection does not extend to the covariates.

Proposition 24.1.3 — Which tests survive classical error

Assume [Eq. 24.1.1](#) and [Definition 24.1.1](#) with a single mismeasured scalar X , $\varepsilon \sim N(0, \sigma^2)$ independent of $(X, \mathbf{z})$, and the covariance matrix of $(X, \mathbf{z}^\top)^\top$ positive definite. Consider the least squares regression of Y on $(1, W, \mathbf{z})$.

- (a) If $\beta_x = 0$, the usual t test of “the coefficient of W is zero” has exactly its nominal level.
- (b) If $\beta_x \neq 0$ and $\boldsymbol{\pi} \neq \mathbf{0}$, the usual F test of “the coefficients of $\mathbf{z}$ equal $\boldsymbol{\beta}_z$ ” rejects with probability tending to one as $n \rightarrow \infty$.

Proof. (a) If $\beta_x = 0$, then $Y = \alpha + \beta_z^\top \mathbf{z} + \varepsilon$, and ε is independent of $(W, \mathbf{z})$ because it is independent of $(X, \mathbf{z}, U)$: it is independent of $(X, \mathbf{z})$ by hypothesis, and U is independent of $(X, \mathbf{z}, \varepsilon)$ by [Definition 24.1.1](#). So, conditionally on the observed regressors, Y follows the normal linear model of [Definition 14.1.1](#) with regressors $(1, W, \mathbf{z})$, in which the coefficient of W is zero. [Theorem 14.1.2](#) gives the exact t distribution.

(b) By [Theorem 24.1.1\(c\)](#), $\hat{\boldsymbol{\beta}}_z - \boldsymbol{\beta}_z \rightarrow \mathbf{c} = (1 - \lambda_{x|z})\beta_x\boldsymbol{\pi} \neq \mathbf{0}$. The F statistic is $n(\hat{\boldsymbol{\beta}}_z - \boldsymbol{\beta}_z)^\top \mathbf{K}_n(\hat{\boldsymbol{\beta}}_z - \boldsymbol{\beta}_z)$, where $\mathbf{K}_n = [n(\mathbf{S}^\top \mathbf{S})^{-1}]_{zz}^{-1}/(qs^2)$, $\mathbf{S}$ is the observed model matrix and q the dimension of $\mathbf{z}$. By the strong law and [Theorem 24.1.1\(d\)](#), $\mathbf{K}_n$ converges to a positive definite limit, so the statistic grows like n , while the critical value tends to a finite limit.

So “is there any association with the underlying quantity?” can be tested with the reading, with reduced power. “Does this covariate matter once the underlying quantity is accounted for?” cannot.

24.1.6 Exercises

24.1.6.1 A. Check your understanding

Exercise A1.

Show that $\lambda = \text{Corr}(W, X)^2$. If $W_1 = X + U_1$ and $W_2 = X + U_2$ are two readings with independent classical errors of the same variance, show that $\text{Corr}(W_1, W_2) = \lambda$. This is why test–retest correlations are used as reliability estimates.

Solution. $\text{Cov}(W, X) = \sigma_x^2$, so $\text{Corr}(W, X)^2 = \sigma_x^4 / \{\sigma_x^2(\sigma_x^2 + \sigma_u^2)\} = \lambda$. For two readings, $\text{Cov}(W_1, W_2) = \text{Var}(X) = \sigma_x^2$ because the errors are independent of each other and of X , and $\text{Var}(W_1) = \text{Var}(W_2) = \sigma_x^2 + \sigma_u^2$. The correlation is $\sigma_x^2 / (\sigma_x^2 + \sigma_u^2) = \lambda$.

24.1.6.2 B. Practice

Exercise B1.

Let $\bar{W}$ be the mean of m readings with independent classical errors of variance σ_u^2 , and let λ be the reliability of one reading. Show that the reliability of $\bar{W}$ is

$$\lambda_m = \frac{m\lambda}{1 + (m-1)\lambda}.$$

How many readings are needed in the running example for the attenuation factor to reach 0.9?

Solution. $\lambda_m = \sigma_x^2 / (\sigma_x^2 + \sigma_u^2/m)$. Dividing through by $\sigma_x^2 + \sigma_u^2$ and using $\sigma_u^2 / (\sigma_x^2 + \sigma_u^2) = 1 - \lambda$ gives $\lambda / \{\lambda + (1 - \lambda)/m\}$, the formula. With $\lambda = 0.64$, $\lambda_m \geq 0.9$ iff $0.64m \geq 0.9 + 0.576(m - 1)$, so $m \geq 5.0625$: six readings (without age in the model).

Exercise B2.

In the setting of [Theorem 24.1.1\(b\)](#), show that the population R^2 of Y on W equals λ times the population R^2 of Y on X . Measurement error lowers the apparent strength of a relation twice: once through the slope and once through the residual variance.

Exercise B3.

Let $\mathbf{t} = (X_1, X_2)$ have unit variances and correlation ρ , let X_1 be measured exactly and X_2 with classical error of variance σ_u^2 , and let $\boldsymbol{\theta} = (\beta_1, \beta_2)$. Show that the limit of the coefficient of X_1 is $\beta_1 + (1 - \lambda_{2|1})\rho\beta_2$, where $\lambda_{2|1} = (1 - \rho^2)/(1 - \rho^2 + \sigma_u^2)$. With $\rho = 0.5$,

$\sigma_u^2 = 1$, $\beta_2 = 1$ and $\beta_1 = -0.2$, show that the sign of the first coefficient is reversed.

Solution. This is [Theorem 24.1.1\(c\)](#) with $\mathbf{z} = X_1$, $X = X_2$ and $\boldsymbol{\pi} = \rho$, since the coefficient of the best linear prediction of X_2 from X_1 is ρ and $\sigma_{x.z}^2 = 1 - \rho^2$. With the numbers given, $\lambda_{2|1} = 0.75/1.75 = 3/7$, so the limit is $-0.2 + (4/7)(0.5) = -0.2 + 2/7 \approx 0.086 > 0$. A regressor with a negative effect acquires a positive coefficient.

24.1.6.3 C. Going deeper

Exercise C1.

Regressors are often recorded after rounding. Model this as $\mathbf{S} = \mathbf{T} + \boldsymbol{\Delta}$ with $\mathbf{T}$ the true model matrix and $\boldsymbol{\Delta}$ a *fixed* matrix of rounding errors, and suppose $E(\mathbf{Y}) = \mathbf{T}\boldsymbol{\theta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}$. Use [Proposition 5.5.7](#) to show that least squares on $\mathbf{S}$ has bias $-(\mathbf{S}^\top\mathbf{S})^{-1}\mathbf{S}^\top\boldsymbol{\Delta}\boldsymbol{\theta}$, that its covariance matrix is exactly $\sigma^2(\mathbf{S}^\top\mathbf{S})^{-1}$, and that the expected residual mean square is at least σ^2 .

Solution. Here $E(\mathbf{Y}) = \mathbf{S}\boldsymbol{\theta} + \boldsymbol{\delta}$ with $\boldsymbol{\delta} = -\boldsymbol{\Delta}\boldsymbol{\theta}$. By [Proposition 5.5.7\(a\)](#) with model matrix $\mathbf{S}$, the expectation is $\boldsymbol{\theta} + (\mathbf{S}^\top\mathbf{S})^{-1}\mathbf{S}^\top\boldsymbol{\delta}$, which gives the bias. The covariance is $\sigma^2(\mathbf{S}^\top\mathbf{S})^{-1}$ by [Proposition 5.5.7\(b\)](#) with $\boldsymbol{\Sigma} = \sigma^2\mathbf{I}$: nothing random has been added. For the residual mean square, [Theorem 2.3.1](#) gives $E\|(\mathbf{I} - \mathbf{M}_S)\mathbf{Y}\|^2 = \sigma^2(n-p) + \boldsymbol{\delta}^\top(\mathbf{I} - \mathbf{M}_S)\boldsymbol{\delta}$, where $\mathbf{M}_S$ projects onto $\mathcal{C}(\mathbf{S})$ and $(\mathbf{I} - \mathbf{M}_S)\mathbf{S}\boldsymbol{\theta} = \mathbf{0}$. The last term is nonnegative. Unlike random error, fixed rounding error does not inflate the variance of the estimator. It only biases it, and the bias is small when rounding is fine compared with the spread of the regressors.

24.2 The classical measurement error model

This section sets up the two versions of the classical model, shows that its normal version cannot identify the slope from the observed data alone, and separates classical error from Berkson error, which does no harm to a linear regression.

24.2.1 Structural and functional models

In a **structural** model the true values are random draws, as in [Theorem 24.1.1](#). In a **functional** model they are fixed unknown constants, one nuisance parameter per observation, which cannot be conditioned on because they are not observed. Attenuation is the same in both.

Proposition 24.2.1 — Attenuation with fixed true values

Let $\mathbf{t}_1, \mathbf{t}_2, \dots \in \mathbb{R}^p$ be fixed vectors with first coordinate 1, such that $n^{-1} \sum_{i=1}^n \mathbf{t}_i \mathbf{t}_i^\top \rightarrow \mathbf{A}$, a positive definite matrix. Let $y_i = \mathbf{t}_i^\top \boldsymbol{\theta} + \varepsilon_i$ and $\mathbf{s}_i = \mathbf{t}_i + \tilde{\mathbf{u}}_i$, where the pairs $(\tilde{\mathbf{u}}_i, \varepsilon_i)$ are independent and identically distributed, $\tilde{\mathbf{u}}_i$ and ε_i are independent with mean zero and finite variances, the first coordinate of $\tilde{\mathbf{u}}_i$ is zero (so that $\mathbf{s}_i$ keeps the constant and $\tilde{\boldsymbol{\Sigma}}$ has zero first row and column), and $\text{Cov}(\tilde{\mathbf{u}}_i) = \tilde{\boldsymbol{\Sigma}}$. Then the least squares coefficient

vector from regressing y on $\mathbf{s}$ converges in probability to $(\mathbf{A} + \tilde{\Sigma})^{-1} \mathbf{A}\theta$.

Proof. Stack the vectors as rows of $\mathbf{T}$, $\mathbf{S}$ and $\tilde{\mathbf{U}}$. Then

$$\frac{1}{n} \mathbf{S}^\top \mathbf{S} = \frac{1}{n} \mathbf{T}^\top \mathbf{T} + \frac{1}{n} (\mathbf{T}^\top \tilde{\mathbf{U}} + \tilde{\mathbf{U}}^\top \mathbf{T}) + \frac{1}{n} \tilde{\mathbf{U}}^\top \tilde{\mathbf{U}}.$$

The last term tends to $\tilde{\Sigma}$ in probability by the weak law of large numbers. An entry $n^{-1} \sum_i t_{ij} \tilde{u}_{ik}$ of $n^{-1} \mathbf{T}^\top \tilde{\mathbf{U}}$ has mean zero and variance $\tilde{\Sigma}_{kk} n^{-2} \sum_i t_{ij}^2 \rightarrow 0$, so it tends to zero by Chebyshev's inequality. Hence $n^{-1} \mathbf{S}^\top \mathbf{S} \rightarrow \mathbf{A} + \tilde{\Sigma}$, which is positive definite. In the same way, $n^{-1} \mathbf{S}^\top \mathbf{y} = n^{-1} \mathbf{S}^\top \mathbf{T}\theta + n^{-1} \mathbf{T}^\top \boldsymbol{\varepsilon} + n^{-1} \tilde{\mathbf{U}}^\top \boldsymbol{\varepsilon}$. Here $n^{-1} \mathbf{S}^\top \mathbf{T} \rightarrow \mathbf{A}$ by the argument just given, $n^{-1} \mathbf{T}^\top \boldsymbol{\varepsilon} \rightarrow \mathbf{0}$ by Chebyshev's inequality, and $n^{-1} \tilde{\mathbf{U}}^\top \boldsymbol{\varepsilon} \rightarrow \mathbf{0}$ by the weak law, since $E(\tilde{u}_i \varepsilon_i) = 0$ by independence. Matrix inversion is continuous at a nonsingular matrix, which finishes the proof. ■

For a straight line the slope tends to $\beta s_x^2 / (s_x^2 + \sigma_u^2)$, where s_x^2 is the limiting variance of the fixed values: what matters is the *spread* of the true values relative to the error. Because the number of parameters grows with n , maximum likelihood can fail in the functional model ([Example \(Many means, one variance\)](#), [Exercise \(C1\)](#)).

24.2.2 What the data cannot tell you

In the **normal structural model**, $X \sim N(\mu_x, \sigma_x^2)$, $U \sim N(0, \sigma_u^2)$ and $\varepsilon \sim N(0, \sigma^2)$ are independent, $W = X + U$ and $Y = \alpha + \beta X + \varepsilon$. Then (W, Y) is bivariate normal ([Theorem 3.3.1](#)) with mean $(\mu_x, \alpha + \beta \mu_x)$ and covariance matrix

$$\begin{pmatrix} \sigma_{ww} & \sigma_{wy} \\ \sigma_{wy} & \sigma_{yy} \end{pmatrix} = \begin{pmatrix} \sigma_x^2 + \sigma_u^2 & \beta \sigma_x^2 \\ \beta \sigma_x^2 & \beta^2 \sigma_x^2 + \sigma^2 \end{pmatrix}. \quad (24.2.1)$$

A bivariate normal distribution is fixed by five numbers, but the model has six parameters $(\mu_x, \alpha, \beta, \sigma_x^2, \sigma_u^2, \sigma^2)$, so data on (W, Y) cannot determine all six.

Proposition 24.2.2 — The slope is identified only up to an interval

Let (W, Y) be bivariate normal with covariance matrix entries $\sigma_{ww}, \sigma_{wy}, \sigma_{yy}$, where $\sigma_{ww} \sigma_{yy} > \sigma_{wy}^2$. If $\sigma_{wy} \neq 0$, a number b is the slope of some normal structural model with $\sigma_x^2 > 0$, $\sigma_u^2 \geq 0$ and $\sigma^2 \geq 0$ that produces this distribution iff b lies in the closed interval with end points

$$b_1 = \frac{\sigma_{wy}}{\sigma_{ww}}, \quad b_2 = \frac{\sigma_{yy}}{\sigma_{wy}}.$$

If $\sigma_{wy} = 0$, the only such slope is $b = 0$.

Proof. A normal distribution is determined by its mean and covariance matrix, so a model reproduces the distribution iff it reproduces both. The means can always be matched by $\mu_x = E W$ and $\alpha = E Y - b \mu_x$. By [Eq. 24.2.1](#) the covariances are matched iff

$$\sigma_x^2 + \sigma_u^2 = \sigma_{ww}, \quad b \sigma_x^2 = \sigma_{wy}, \quad b^2 \sigma_x^2 + \sigma^2 = \sigma_{yy}.$$

Figure 24.2.1: (a) Direct and reverse regression lines and slopes in between (grey), each fitting a normal structural model exactly; dashed, the true slope. (b) The reliability b_1/b and squared correlation b/b_2 that slope b would require.

If $\sigma_{wy} = 0$, the middle equation with $\sigma_x^2 > 0$ forces $b = 0$, and then $\sigma_x^2 \in (0, \sigma_{ww}]$ and $\sigma^2 = \sigma_{yy}$ complete a model. If $\sigma_{wy} \neq 0$, then $b \neq 0$ and the equations force $\sigma_x^2 = \sigma_{wy}/b$, $\sigma_u^2 = \sigma_{ww} - \sigma_{wy}/b$ and $\sigma^2 = \sigma_{yy} - b\sigma_{wy}$. These are admissible iff b has the sign of σ_{wy} (so $\sigma_x^2 > 0$), $|b| \geq |\sigma_{wy}|/\sigma_{ww} = |b_1|$ (so $\sigma_u^2 \geq 0$) and $|b| \leq \sigma_{yy}/|\sigma_{wy}| = |b_2|$ (so $\sigma^2 \geq 0$). Since b_1 and b_2 share the sign of σ_{wy} , these conditions say that b lies between b_1 and b_2 . The interval is not empty, because $|b_1| \leq |b_2|$ is equivalent to $\sigma_{wy}^2 \leq \sigma_{ww}\sigma_{yy}$.

■

The end point b_1 is the least squares slope of Y on W , correct if there is no measurement error. The end point b_2 is the inverted slope of W on Y , correct if there is no equation error. Their ratio is the squared correlation, so the interval is short only when the correlation is high.

Example. (The interval for the blood-pressure study)

For the first reading in the running example, the sample covariances are $s_{ww} = 216.21$, $s_{wy} = 10.786$ and $s_{yy} = 1.889$. The compatible slopes form the interval $[0.0499, 0.1752]$, and the squared correlation is 0.285. It contains the true 0.08, whose implied variances $\sigma_x^2 = 134.8$, $\sigma_u^2 = 81.4$ and $\sigma^2 = 1.026$ are close to the generating 144, 81 and 1, but the data cannot prefer them to those of any other slope in the interval (Figure 24.2.1).

```
import numpy as np

rng = np.random.default_rng(2401)
n = 300
age = rng.normal(55, 10, n)
x = 130 + 0.6 * (age - 55) + rng.normal(0, np.sqrt(108), n)  # long-run blood
                    pressure, sd 12
w = x[:, None] + rng.normal(0, 9, (n, 2))                  # two clinic readings
y = -4 + 0.08 * x + 0.0 * age + rng.normal(0, 1.0, n)      # age has no effect
                    given x

S = np.cov(w[:, 0], y)                                     # sample covariance matrix of (reading,
```

```

outcome)
s_ww, s_wy, s_yy = S[0, 0], S[0, 1], S[1, 1]
b_direct = s_wy / s_ww          # assumes no measurement error (sigma_u
                                ^2 = 0)
b_reverse = s_yy / s_wy         # assumes no equation error (sigma^2 =
                                0)
print(f"slopes compatible with the data: [{b_direct:.4f}, {b_reverse:.4f}]")

for b in [b_direct, 0.08, b_reverse]:          # the variances each slope would imply
    sx2 = s_wy / b
    print(f"b = {b:.4f}: sigma_x^2 = {sx2:7.2f}, sigma_u^2 = {s_ww - sx2:7.2f}, "
          f"sigma^2 = {s_yy - b * s_wy:.4f}")

```

The sign of β , whether $\beta = 0$, and the lower bound $|b_1|$ on $|\beta|$ are identified. Any information that pins down one variance identifies everything: σ_u^2 , λ , the ratio σ^2/σ_u^2 , or a bound $\lambda \geq \lambda_0$ that narrows the interval ([Exercise \(A2\)](#)). The rest of the chapter is about where such information comes from.

Remark (Non-normal true values). Reiersol (1950) showed that when $\beta \neq 0$ and the errors are normal and independent of X , the slope is identified exactly when X is *not* normal; higher moments then carry the missing information. We do not prove this. Estimators based on higher moments are highly variable unless X is far from normal, and rarely replace external information.

24.2.3 Berkson error

Sometimes the truth scatters around the recorded value instead: a furnace set to w degrees, every resident of a district assigned the district monitor's pollution level, a solution prepared at a nominal concentration. Then

$$X = W + U, \quad U \text{ independent of } W,$$

which is **Berkson error** (Berkson, 1950). The difference from classical error is which variable the error is independent of. It cannot be settled from data on (W, Y) , only from how the recorded value was produced. The scalar case with fixed settings appeared in [Section 19.5](#); the proposition below allows several regressors and random recorded values.

Proposition 24.2.3 — Berkson error in linear regression

Let $Y = \alpha + \beta^\top \mathbf{x} + \varepsilon$ and $\mathbf{x} = \mathbf{w} + \mathbf{u}$, where $\mathbf{w}$ is fixed or random and, given $\mathbf{w}$, the errors $\mathbf{u}$ and ε are independent, with means zero, covariance matrix Σ_{uu} and variance σ^2 , not depending on $\mathbf{w}$. Then, given $\mathbf{w}$,

$$E(Y \mid \mathbf{w}) = \alpha + \beta^\top \mathbf{w}, \quad \text{Var}(Y \mid \mathbf{w}) = \sigma^2 + \beta^\top \Sigma_{uu} \beta,$$

and if $\mathbf{u}$ and ε are normal, so is Y given $\mathbf{w}$. Independent observations of this kind therefore satisfy the linear model in the recorded $\mathbf{w}$, with the same coefficients and error variance $\sigma^2 + \beta^\top \Sigma_{uu} \beta$.

Proof. Given $\mathbf{w}$, $Y = \alpha + \beta^\top \mathbf{w} + (\beta^\top \mathbf{u} + \varepsilon)$, and the composite error is a linear combination of the independent $\mathbf{u}$ and ε ([Theorem 2.2.1](#)).

So least squares on the settings is unbiased, and under normality the t and F procedures are exact, with s^2 estimating the enlarged error variance. Nothing needs correcting.

Example. (Concentrations set on a dial)

Five solutions are prepared at each nominal concentration 10, 20, ..., 60 mg/L ($n = 30$); the achieved concentration adds $N(0, 4^2)$ error, and the response is $2 + 0.5x + \varepsilon$, $\varepsilon \sim N(0, 3^2)$. Regressing on the nominal concentrations in 20000 simulated experiments gives a mean slope of 0.4994 and a mean s^2 of 13.01, matching $\sigma^2 + \beta^2 \sigma_u^2 = 9 + 0.25 \cdot 16 = 13$. The nominal 95% t intervals for the slope covered 0.5 in a proportion 0.952 of the experiments.

```
from scipy import stats

rng_b = np.random.default_rng(2410)
settings = np.repeat([10.0, 20.0, 30.0, 40.0, 50.0, 60.0], 5)      # dial settings,
n = 30
Xd = np.column_stack([np.ones(30), settings])
reps = 20_000
achieved = settings + rng_b.normal(0, 4, (reps, 30))              # x = w + u, u
                           independent of w
Y = 2 + 0.5 * achieved + rng_b.normal(0, 3, (reps, 30))
B = np.linalg.solve(Xd.T @ Xd, Xd.T @ Y.T)                       # least squares
                           on the settings
s2 = np.sum((Y.T - Xd @ B) ** 2, axis=0) / 28
se = np.sqrt(s2 * np.linalg.inv(Xd.T @ Xd)[1, 1])
covered = np.abs(B[1] - 0.5) <= stats.t.ppf(0.975, 28) * se
print(f"mean slope {B[1].mean():.4f}, mean s^2 {s2.mean():.2f} (sigma^2 + beta^2
      sigma_u^2 = 13), "
      f"coverage {covered.mean():.3f}")
```

Warning. Berkson error is harmless only because the model is linear in $\mathbf{x}$. For nonlinear g , $E\{g(\mathbf{x}) \mid \mathbf{w}\} \neq g(\mathbf{w})$ in general ([Exercise B1](#)). Real measurements often mix Berkson and classical components, which must then be handled separately.

24.2.4 Exercises

24.2.4.1 A. Check your understanding

Exercise A1.

Classify each regressor error as classical, Berkson or neither, and say whether it biases the slope: (a) weight from a noisy scale; (b) a prescribed dose, when patients take a random fraction of it with mean one; (c) income rounded down to the nearest 10,000.

Exercise A2.

In [Proposition 24.2.2](#), suppose it is known only that the reliability is at least $\lambda_0 \in (0, 1]$. Show that the compatible slopes are those between b_1 and $\min(|b_2|, |b_1|/\lambda_0)$ in magnitude, with the sign of b_1 . Evaluate the interval for [Example \(The interval for the blood-pressure study\)](#) with $\lambda_0 = 0.5$.

Solution. The implied reliability of slope b is $\sigma_x^2/\sigma_{ww} = b_1/b$, so $\lambda \geq \lambda_0$ iff $|b| \leq |b_1|/\lambda_0$. Intersect with the interval of the proposition. For the example, $b_1/\lambda_0 = 0.0499/0.5 = 0.0998 < 0.1752$, so the interval shrinks to $[0.0499, 0.0998]$, which still contains 0.08.

24.2.4.2 B. Practice**Exercise B1.**

Let $Y = \beta_0 + \beta_1 X + \beta_2 X^2 + \beta_3 X^3 + \varepsilon$ and $X = W + U$ with Berkson error $U \sim N(0, \sigma_u^2)$ independent of W and ε . Compute $E(Y | W)$. Which coefficients of a cubic regression on W are biased, and by how much? What happens for a quadratic?

Solution. With $EU = EU^3 = 0$ and $EU^2 = \sigma_u^2$, $E(X^2 | W) = W^2 + \sigma_u^2$ and $E(X^3 | W) = W^3 + 3W\sigma_u^2$. So

$$E(Y | W) = (\beta_0 + \beta_2 \sigma_u^2) + (\beta_1 + 3\beta_3 \sigma_u^2)W + \beta_2 W^2 + \beta_3 W^3.$$

The cubic regression on W estimates the intercept with bias $\beta_2 \sigma_u^2$ and the linear coefficient with bias $3\beta_3 \sigma_u^2$. The top two coefficients are unbiased. For a quadratic ($\beta_3 = 0$) only the intercept is biased. The conditional variance also changes with W , so the errors are heteroscedastic.

Exercise B2.

In the normal structural model, show that the reciprocal of the least squares slope of W on Y converges to $b_2 = \beta + \sigma^2/(\beta\sigma_x^2)$, so that it overstates $|\beta|$ exactly when there is equation error. Evaluate b_2 for the population of the running example and compare it with [Example \(The interval for the blood-pressure study\)](#).

24.2.4.3 C. Going deeper**Exercise C1.**

In the functional model $w_i = x_i + u_i$, $y_i = \alpha + \beta x_i + \varepsilon_i$, with u_i, ε_i independent $N(0, \sigma^2)$ (equal, unknown variances) and $x_1, \dots, x_n$ unknown constants:

- show that, for fixed (α, β) , maximizing the likelihood over each x_i leaves $d_i^2 = (y_i - \alpha - \beta w_i)^2/(1 + \beta^2)$, the squared perpendicular distance from (w_i, y_i) to the line;
- deduce that the maximum likelihood line is the orthogonal regression line of [Section 24.3](#), and that $\hat{\sigma}_{ML}^2 = (2n)^{-1} \sum_i \hat{d}_i^2$;
- show that $\hat{\sigma}_{ML}^2 \rightarrow \sigma^2/2$ in probability, assuming the line is estimated consistently.

Compare [Example \(Many means, one variance\)](#).

Solution. (a) The log likelihood is $-n \log(2\pi\sigma^2) - \sum_i \{(w_i - x_i)^2 + (y_i - \alpha - \beta x_i)^2\} / (2\sigma^2)$. For each i the bracket is the squared distance from (w_i, y_i) to the point $(x_i, \alpha + \beta x_i)$ of the line, and its minimum over x_i is the squared perpendicular distance d_i^2 . (b) The profile log likelihood is $-n \log(2\pi\sigma^2) - \sum_i d_i^2 / (2\sigma^2)$. It is maximized over the line by minimizing $\sum_i d_i^2$, which is orthogonal regression, and over σ^2 by $\sum_i d_i^2 / (2n)$. (c) At the true line, $y_i - \alpha - \beta w_i = \varepsilon_i - \beta u_i$ has variance $\sigma^2(1 + \beta^2)$, so $n^{-1} \sum_i d_i^2 \rightarrow \sigma^2$ by the law of large numbers. A consistent estimate of the line gives the same limit, so $\hat{\sigma}_{\text{ML}}^2 \rightarrow \sigma^2/2$: each nuisance x_i uses up half of its observation's two degrees of freedom.

24.3 Reliability and moment correction

This section supplies the missing information of [Section 24.2](#) directly, as a reliability ratio, an error covariance or a variance ratio, and solves [Theorem 24.1.1](#) for θ .

24.3.1 Correcting with a known reliability

If λ is known, for instance from a test–retest correlation ([Exercise \(A1\)](#) in [Section 24.1](#)), then $\hat{\beta}/\lambda$ is consistent in simple regression. For correlations this is Spearman's (1904) **correction for attenuation**, $\text{Corr}(X_1, X_2) = \text{Corr}(W_1, W_2) / \sqrt{\lambda_1 \lambda_2}$ ([Exercise \(A1\)](#)). With covariates the right divisor is $\lambda_{x|z}$ ([Exercise \(B1\)](#)). Dividing by λ undercorrects and leaves the covariates' bias untouched.

24.3.2 A known error covariance: the corrected estimator

Work with raw second moments, so the intercept needs no special treatment. Collect the true regressors, *including* the constant, in $\mathbf{t} = (1, \mathbf{x}^\top, \mathbf{z}^\top)^\top \in \mathbb{R}^p$, and the observed ones in $\mathbf{s} = \mathbf{t} + \tilde{\mathbf{u}}$, where $\tilde{\mathbf{u}} = (0, \mathbf{u}^\top, \mathbf{0}^\top)^\top$ has zeros for the constant and for the exactly measured $\mathbf{z}$. Write the model as $Y = \mathbf{t}^\top \theta + \varepsilon$. Under classical error,

$$E(\mathbf{s}\mathbf{s}^\top) = E(\mathbf{t}\mathbf{t}^\top) + \tilde{\Sigma}, \quad E(\mathbf{s}Y) = E(\mathbf{t}\mathbf{t}^\top)\theta, \quad \tilde{\Sigma} = E(\tilde{\mathbf{u}}\tilde{\mathbf{u}}^\top),$$

since the cross terms vanish. So $\theta = \{E(\mathbf{s}\mathbf{s}^\top) - \tilde{\Sigma}\}^{-1} E(\mathbf{s}Y)$: subtract the error's share of the moment matrix before inverting. To cover a known $\tilde{\Sigma}$ and one estimated from replicates at once, let observation i carry a matrix $\mathbf{D}_i$, computed from its own data, with expectation $\tilde{\Sigma}$. If $\tilde{\Sigma}$ is known, $\mathbf{D}_i = \tilde{\Sigma}$.

Theorem 24.3.1 — Method-of-moments correction

Let $(\mathbf{t}_i, \tilde{\mathbf{u}}_i, \varepsilon_i, \mathbf{D}_i)$, $i = 1, 2, \dots$, be independent copies of $(\mathbf{t}, \tilde{\mathbf{u}}, \varepsilon, \mathbf{D})$, where $\mathbf{s}_i = \mathbf{t}_i + \tilde{\mathbf{u}}_i$ and $y_i = \mathbf{t}_i^\top \theta + \varepsilon_i$ are observed, and $\mathbf{D}_i$ is a symmetric $p \times p$ matrix computed from the data of observation i . Assume that $E(\varepsilon) = 0$, $E(\mathbf{t}\varepsilon) = \mathbf{0}$, $E(\tilde{\mathbf{u}}\varepsilon) = \mathbf{0}$, $E(\mathbf{t}\tilde{\mathbf{u}}^\top) = \mathbf{0}$, $E(\mathbf{D}) = \tilde{\Sigma} = E(\tilde{\mathbf{u}}\tilde{\mathbf{u}}^\top)$, and that $\mathbf{A} = E(\mathbf{t}\mathbf{t}^\top)$ is positive definite. Let

$$\hat{\mathbf{A}}_n = \frac{1}{n} \sum_{i=1}^n (\mathbf{s}_i \mathbf{s}_i^\top - \mathbf{D}_i), \quad \hat{\boldsymbol{\theta}}_{\text{mm}} = \hat{\mathbf{A}}_n^{-1} \frac{1}{n} \sum_{i=1}^n \mathbf{s}_i y_i. \quad (24.3.1)$$

- (a) With probability one, $\hat{\mathbf{A}}_n$ is nonsingular for all large n and $\hat{\boldsymbol{\theta}}_{\text{mm}} \rightarrow \boldsymbol{\theta}$.
 (b) If $\mathbf{t}$, $\tilde{\mathbf{u}}$ and ε have finite fourth moments and $\mathbf{D}$ has finite second moments, then

$$\sqrt{n}(\hat{\boldsymbol{\theta}}_{\text{mm}} - \boldsymbol{\theta}) \rightarrow N_p(\mathbf{0}, \mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-1}) \quad \text{in distribution,}$$

where $\mathbf{B} = E(\boldsymbol{\psi} \boldsymbol{\psi}^\top)$ and $\boldsymbol{\psi} = \mathbf{s}(y - \mathbf{s}^\top \boldsymbol{\theta}) + \mathbf{D} \boldsymbol{\theta}$.

- (c) Under the conditions of (b), $\hat{\mathbf{A}}_n^{-1} \hat{\mathbf{B}}_n \hat{\mathbf{A}}_n^{-1} \rightarrow \mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-1}$ in probability, where $\hat{\mathbf{B}}_n = n^{-1} \sum_i \hat{\boldsymbol{\psi}}_i \hat{\boldsymbol{\psi}}_i^\top$ and $\hat{\boldsymbol{\psi}}_i$ is $\boldsymbol{\psi}_i$ with $\hat{\boldsymbol{\theta}}_{\text{mm}}$ in place of $\boldsymbol{\theta}$.

Proof. (a) By the strong law of large numbers, $n^{-1} \sum_i \mathbf{s}_i \mathbf{s}_i^\top \rightarrow E(\mathbf{s} \mathbf{s}^\top) = \mathbf{A} + \tilde{\boldsymbol{\Sigma}}$ (the cross terms vanish since $E(\mathbf{t} \tilde{\mathbf{u}}^\top) = \mathbf{0}$) and $n^{-1} \sum_i \mathbf{D}_i \rightarrow \tilde{\boldsymbol{\Sigma}}$. So $\hat{\mathbf{A}}_n \rightarrow \mathbf{A}$, which is nonsingular, and $\hat{\mathbf{A}}_n$ is nonsingular for all large n because the determinant is continuous. Also $n^{-1} \sum_i \mathbf{s}_i y_i \rightarrow E\{(\mathbf{t} + \tilde{\mathbf{u}})(\mathbf{t}^\top \boldsymbol{\theta} + \varepsilon)\} = \mathbf{A} \boldsymbol{\theta}$. By continuity of the inverse, $\hat{\boldsymbol{\theta}}_{\text{mm}} \rightarrow \mathbf{A}^{-1} \mathbf{A} \boldsymbol{\theta} = \boldsymbol{\theta}$.

(b) Directly from the definitions,

$$\frac{1}{n} \sum_i \mathbf{s}_i y_i - \hat{\mathbf{A}}_n \boldsymbol{\theta} = \frac{1}{n} \sum_i \{\mathbf{s}_i y_i - \mathbf{s}_i \mathbf{s}_i^\top \boldsymbol{\theta} + \mathbf{D}_i \boldsymbol{\theta}\} = \frac{1}{n} \sum_i \boldsymbol{\psi}_i,$$

so $\sqrt{n}(\hat{\boldsymbol{\theta}}_{\text{mm}} - \boldsymbol{\theta}) = \hat{\mathbf{A}}_n^{-1} n^{-1/2} \sum_i \boldsymbol{\psi}_i$. The $\boldsymbol{\psi}_i$ are independent and identically distributed with mean

$$E(\boldsymbol{\psi}) = E(\mathbf{s}Y) - E(\mathbf{s} \mathbf{s}^\top) \boldsymbol{\theta} + E(\mathbf{D}) \boldsymbol{\theta} = \mathbf{A} \boldsymbol{\theta} - (\mathbf{A} + \tilde{\boldsymbol{\Sigma}}) \boldsymbol{\theta} + \tilde{\boldsymbol{\Sigma}} \boldsymbol{\theta} = \mathbf{0}.$$

Each entry of $\boldsymbol{\psi}$ is a sum of products of at most two entries of $(\mathbf{t}, \tilde{\mathbf{u}}, \varepsilon)$, plus a linear function of $\mathbf{D}$, so the moment conditions give $\mathbf{B}$ finite entries. By the central limit theorem (the remark in [Section 14.4](#)), $\boldsymbol{\xi}_n = n^{-1/2} \sum_i \boldsymbol{\psi}_i \rightarrow N_p(\mathbf{0}, \mathbf{B})$. Split

$$\hat{\mathbf{A}}_n^{-1} \boldsymbol{\xi}_n = \mathbf{A}^{-1} \boldsymbol{\xi}_n + (\hat{\mathbf{A}}_n^{-1} - \mathbf{A}^{-1}) \boldsymbol{\xi}_n.$$

By continuous mapping ([Section 19.3](#)) the first term converges in distribution to $\mathbf{A}^{-1} N_p(\mathbf{0}, \mathbf{B}) = N_p(\mathbf{0}, \mathbf{A}^{-1} \mathbf{B} \mathbf{A}^{-1})$. Each entry of the second is a sum of products of an entry of $\hat{\mathbf{A}}_n^{-1} - \mathbf{A}^{-1}$, tending to 0, and an entry of $\boldsymbol{\xi}_n$; by the scalar Slutsky lemma it tends to 0 in probability. The sum form of Slutsky's lemma finishes the proof.

(c) Write $\mathbf{G}_i = \mathbf{s}_i \mathbf{s}_i^\top - \mathbf{D}_i$ and $\boldsymbol{\delta} = \hat{\boldsymbol{\theta}}_{\text{mm}} - \boldsymbol{\theta}$. Then $\hat{\boldsymbol{\psi}}_i = \boldsymbol{\psi}_i - \mathbf{G}_i \boldsymbol{\delta}$ and

$$\hat{\mathbf{B}}_n = \frac{1}{n} \sum_i \boldsymbol{\psi}_i \boldsymbol{\psi}_i^\top - \frac{1}{n} \sum_i (\boldsymbol{\psi}_i \boldsymbol{\delta}^\top \mathbf{G}_i^\top + \mathbf{G}_i \boldsymbol{\delta} \boldsymbol{\psi}_i^\top) + \frac{1}{n} \sum_i \mathbf{G}_i \boldsymbol{\delta} \boldsymbol{\delta}^\top \mathbf{G}_i^\top.$$

The first term tends to $\mathbf{B}$ by the strong law. Every entry of the second is at most $2 \|\boldsymbol{\delta}\| n^{-1} \sum_i \|\boldsymbol{\psi}_i\| \|\mathbf{G}_i\|$ in absolute value (with the Frobenius norm for $\mathbf{G}_i$). The average converges to $E(\|\boldsymbol{\psi}\| \|\mathbf{G}\|)$, which is finite by the Cauchy–Schwarz inequality, and $\|\boldsymbol{\delta}\| \rightarrow 0$

by (a). Similarly the third term is at most $\|\delta\|^2 n^{-1} \sum_i \|\mathbf{G}_i\|^2 \rightarrow 0$. Combine with $\hat{\mathbf{A}}_n \rightarrow \mathbf{A}$.

■

In simple regression with known error variance, Eq. 24.3.1 is $s_{wy}/(s_{ww} - \sigma_u^2)$, with sample moments taken with divisor n , the naive slope divided by the estimated reliability. The covariance $\mathbf{A}^{-1}\mathbf{B}\mathbf{A}^{-1}$ has the sandwich form of Theorem 21.4.2, to which it reduces when $\tilde{\mathbf{u}} = \mathbf{0}$ and $\mathbf{D} = \mathbf{0}$. No assumption about the distribution of X or homoscedasticity is needed.

Replicates. Suppose each unit has $m \geq 2$ readings $\mathbf{w}_{ij} = \mathbf{x}_i + \mathbf{u}_{ij}$, $j = 1, \dots, m$, with errors independent across j , independent of $(\mathbf{x}_i, \mathbf{z}_i, \varepsilon_i)$, and with covariance Σ_{uu} . Use the mean $\bar{\mathbf{w}}_i$ as the observed regressor. Its error $\bar{\mathbf{u}}_i$ has covariance Σ_{uu}/m , and an unbiased estimate of that covariance from unit i alone is

$$\frac{1}{m(m-1)} \sum_{j=1}^m (\mathbf{w}_{ij} - \bar{\mathbf{w}}_i)(\mathbf{w}_{ij} - \bar{\mathbf{w}}_i)^\top,$$

padded with zeros to make $\mathbf{D}_i$ (Exercise A2). For $m = 2$ and a scalar regressor this is $(w_{i1} - w_{i2})^2/4$. Because $\mathbf{D}_i$ enters $\boldsymbol{\psi}_i$, the sandwich of (c) includes the uncertainty from estimating the error variance. An external estimate treated as known would need that uncertainty added separately.

Example. (Correcting with two readings)

In the running example, regress y on $(1, \bar{w}, \text{age})$, where $\bar{w}$ is the mean of the two readings. The reliability of the mean is $144/(144 + 40.5) = 0.780$, and given age it is $108/(108 + 40.5) = 0.727$. The naive coefficients are 0.0562 (standard error 0.0054) for blood pressure and 0.0120 (standard error 0.0070) for age. The replicates estimate σ_u^2 as 74.1 (true 81), and Eq. 24.3.1 gives

$$\tilde{\beta}_x = 0.0757 \text{ (0.0076)}, \quad \tilde{\beta}_{\text{age}} = 0.0018 \text{ (0.0076)},$$

with sandwich standard errors. The 95% interval for β_x is [0.0608, 0.0905], and the spurious age effect is gone. The standard error is 1.40 times the naive one: the bias is paid for in variance. With $\sigma_u^2 = 81$ known the estimate would be 0.0782. In 10000 repeated samples the corrected intervals covered 0.08 in a proportion 0.949, the naive ones in 0.013.

        b = np.linalg.lstsq(Wr, yy, rcond=None)[0]
        e = yy - Wr @ b
        sb = np.sqrt(e @ e / (n - 3) * np.linalg.inv(Wr.T @ Wr)[1, 1])
        hits_n += abs(b[1] - 0.08) <= 1.96 * sb
    return hits_c / reps, hits_n / reps

print("coverage (corrected, naive):", coverage(500, 2421))

```

Warning. The theorem is asymptotic, and the correction is fragile when the reliability is low. $\hat{\mathbf{A}}_n$ can fail to be positive definite, and under normality the corrected slope has no finite mean ([Exercise \(C1\)](#)), as with [Proposition 12.5.2](#); Fuller (1987) gives modified estimators. Gleser and Hwang (1987) showed that, as in [Proposition 12.5.4](#), any confidence set with guaranteed coverage has infinite expected length. Wald intervals are reliable only when the estimated reliability is well away from zero.

24.3.3 Deming and orthogonal regression

Sometimes only a *ratio* of error variances is known. In a method-comparison study two instruments measure the same specimens, $W = X + U$ and $Y = \alpha + \beta X + \varepsilon$, with ε the second

instrument's error, and repeatability experiments give

$$\delta = \frac{\text{Var}(\varepsilon)}{\text{Var}(U)}.$$

The question is whether $\alpha = 0$ and $\beta = 1$.

Proposition 24.3.2 — Deming regression

Let (W, Y) have covariances $\sigma_{ww}, \sigma_{wy}, \sigma_{yy}$ with $\sigma_{wy} \neq 0$ and $\sigma_{ww}\sigma_{yy} \geq \sigma_{wy}^2$, and let $\delta > 0$ be known.

- (a) The equations $\sigma_{ww} = \sigma_x^2 + \sigma_u^2$, $\sigma_{wy} = \beta\sigma_x^2$, $\sigma_{yy} = \beta^2\sigma_x^2 + \delta\sigma_u^2$ have exactly one solution with $\sigma_x^2 > 0$, namely

$$\beta_\delta = \frac{\sigma_{yy} - \delta\sigma_{ww} + \sqrt{(\sigma_{yy} - \delta\sigma_{ww})^2 + 4\delta\sigma_{wy}^2}}{2\sigma_{wy}}, \quad (24.3.2)$$

and for it $\sigma_u^2 \geq 0$. The slope β_δ lies in the interval of Proposition 24.2.2. It tends to b_2 as $\delta \rightarrow 0$ and to b_1 as $\delta \rightarrow \infty$.

- (b) For $\delta = 1$, β_1 is the slope of the line that minimizes the mean squared *perpendicular* distance from (W, Y) , whose direction is an eigenvector of the covariance matrix of (W, Y) for its largest eigenvalue. For general δ , β_δ is $\sqrt{\delta}$ times the $\delta = 1$ slope computed for $(W, Y/\sqrt{\delta})$.

Proof. (a) For $\beta \neq 0$ the first two equations give $\sigma_x^2 = \sigma_{wy}/\beta$ and $\sigma_u^2 = \sigma_{ww} - \sigma_{wy}/\beta$. Substituting in the third and multiplying by β ,

$$q(\beta) = \sigma_{wy}\beta^2 + (\delta\sigma_{ww} - \sigma_{yy})\beta - \delta\sigma_{wy} = 0.$$

The product of the roots is $-\delta < 0$, so there is one root of each sign, and $\sigma_x^2 > 0$ selects the root with the sign of σ_{wy} . That root is Eq. 24.3.2. Take $\sigma_{wy} > 0$ (otherwise replace Y by $-Y$). Then

$$q(b_1) = \frac{\sigma_{wy}}{\sigma_{ww}^2}(\sigma_{wy}^2 - \sigma_{ww}\sigma_{yy}) \leq 0, \quad q(b_2) = \frac{\delta}{\sigma_{wy}}(\sigma_{ww}\sigma_{yy} - \sigma_{wy}^2) \geq 0,$$

and q is an upward parabola with $q(0) < 0$, so its positive root lies in $[b_1, b_2]$. Then $\sigma_u^2 = \sigma_{ww}(1 - b_1/\beta_\delta) \geq 0$. As $\delta \rightarrow 0$ the formula tends to $(\sigma_{yy} + \sigma_{yy})/(2\sigma_{wy}) = b_2$. Multiplying the numerator and denominator of Eq. 24.3.2 by the conjugate of the numerator gives $\beta_\delta = 2\delta\sigma_{wy}/\{\sqrt{(\sigma_{yy} - \delta\sigma_{ww})^2 + 4\delta\sigma_{wy}^2} + \delta\sigma_{ww} - \sigma_{yy}\}$, and the denominator is $2\delta\sigma_{ww} + O(1)$, so $\beta_\delta \rightarrow b_1$ as $\delta \rightarrow \infty$.

(b) Let Σ be the covariance matrix of $\mathbf{v} = (W, Y)^\top$. A line through the point $\mathbf{E}\mathbf{v}$ with unit normal vector $\mathbf{n}$ has mean squared perpendicular distance $\mathbf{E}\{\mathbf{n}^\top(\mathbf{v} - \mathbf{E}\mathbf{v})\}^2 = \mathbf{n}^\top \Sigma \mathbf{n}$, and a line through any other point $\mathbf{c}$ adds $\{\mathbf{n}^\top(\mathbf{E}\mathbf{v} - \mathbf{c})\}^2 \geq 0$. By Theorem 1.7.7, $\mathbf{n}^\top \Sigma \mathbf{n}$ is minimized by an eigenvector for the smallest eigenvalue, so the line's direction is an eigenvector (v_1, v_2) for the largest eigenvalue μ . From $(\sigma_{ww} - \mu)v_1 + \sigma_{wy}v_2 = 0$, the slope is $v_2/v_1 = (\mu - \sigma_{ww})/\sigma_{wy}$. Put $b = v_2/v_1$. Then $\mu - \sigma_{ww} = b\sigma_{wy}$, and the second eigenvector equation $\sigma_{wy}v_1 + (\sigma_{yy} - \mu)v_2 = 0$ gives $\mu - \sigma_{yy} = \sigma_{wy}/b$. Subtracting, $\sigma_{yy} - \sigma_{ww} = b\sigma_{wy} - \sigma_{wy}/b$, which is $q(b) = 0$ with $\delta = 1$. Since $\mu \geq \sigma_{ww}$, b has the sign of σ_{wy} , so $b = \beta_1$. For the last claim, substitute σ_{yy}/δ and $\sigma_{wy}/\sqrt{\delta}$ for σ_{yy} and σ_{wy} in Eq. 24.3.2 with $\delta = 1$ and multiply by $\sqrt{\delta}$.

With sample moments, Eq. 24.3.2 is **Deming regression**, consistent because it is continuous where $\sigma_{wy} \neq 0$. With $\delta = 1$ it is **orthogonal regression** (total least squares), whose line is the first principal axis of the scatter.

Warning. Orthogonal regression makes sense only when the errors have equal variances in the units used. Changing the units of Y changes the fitted line by more than a change of scale. Deming regression, with δ rescaled along with the units, does not have this problem.

Example. (Comparing two assays)

Sixty specimens with true concentrations uniform on $[2, 20]$ are measured by method A with error standard deviation 0.8 and by method B, which reads $0.3 + 1.05x$ with error standard deviation 1.0, so $\delta = 1.5625$. The four slopes are

Method	Slope
least squares of B on A	1.0042
Deming, $\delta = 1.5625$	1.0308
orthogonal ($\delta = 1$, unjustified)	1.0382
least squares of A on B, inverted	1.0709

with Deming intercept 0.482. Over 20000 simulated studies the mean slopes were 1.0262 for least squares, attenuated by $27/(27 + 0.64) = 0.9768$, and 1.0505 for Deming. With B in units ten times smaller, orthogonal regression gives 1.0703 (converted back to the original units) instead of 1.0382.

```
import numpy as np

def deming(w, y, delta):
    """Slope and intercept of Deming regression; delta = Var(error in y) / Var(error
    in w)."""
    S = np.cov(w, y)
    s_ww, s_wy, s_yy = S[0, 0], S[0, 1], S[1, 1]
    d = s_yy - delta * s_ww
    b = (d + np.sqrt(d ** 2 + 4 * delta * s_wy ** 2)) / (2 * s_wy)
    return b, y.mean() - b * w.mean()

rng = np.random.default_rng(2430)
x = rng.uniform(2, 20, 60)          # true concentrations
w = x + rng.normal(0, 0.8, 60)      # method A
y = 0.3 + 1.05 * x + rng.normal(0, 1.0, 60)  # method B
delta = 1.0 ** 2 / 0.8 ** 2

b_ls = np.polyfit(w, y, 1)[0]        # regress y on w
b_rev = 1 / np.polyfit(y, w, 1)[0]   # regress w on y, inverted
b_dem, a_dem = deming(w, y, delta)
b_orth, _ = deming(w, y, 1.0)        # orthogonal regression
print(f"least squares {b_ls:.4f}, Deming {b_dem:.4f} (intercept {a_dem:.3f}), "
```

```
f"orthogonal {b_orth:.4f}, reverse {b_rev:.4f}")
```

24.3.4 Exercises

24.3.4.1 A. Check your understanding

Exercise A1.

Prove Spearman's correction: if $W_k = X_k + U_k$ for $k = 1, 2$, with classical errors independent of each other and of (X_1, X_2) , then $\text{Corr}(W_1, W_2) = \sqrt{\lambda_1 \lambda_2} \text{Corr}(X_1, X_2)$.

Exercise A2.

Show that the matrix $\mathbf{D}_i$ defined from m replicates has expectation Σ_{uu}/m , the covariance matrix of $\bar{\mathbf{u}}_i$, padded with zeros.

Solution. $\mathbf{w}_{ij} - \bar{\mathbf{w}}_i = \mathbf{u}_{ij} - \bar{\mathbf{u}}_i$, so $\mathbf{x}_i$ drops out. For independent vectors with common covariance Σ_{uu} , the sample covariance matrix $(m-1)^{-1} \sum_j (\mathbf{u}_{ij} - \bar{\mathbf{u}}_i)(\mathbf{u}_{ij} - \bar{\mathbf{u}}_i)^\top$ is unbiased for Σ_{uu} (Proposition 2.7.1). Dividing by m gives expectation $\Sigma_{uu}/m = \text{Cov}(\bar{\mathbf{u}}_i)$.

24.3.4.2 B. Practice

Exercise B1.

For a scalar X and a scalar exactly measured Z , show that

$$\lambda_{x|z} = \frac{\lambda - \rho_{wz}^2}{1 - \rho_{wz}^2},$$

where ρ_{wz} is the correlation between W and Z . Check the formula on the running example, and deduce that $\lambda_{x|z} < \lambda$ whenever $\rho_{wz} \neq 0$ and $\lambda < 1$.

Solution. $\sigma_{x \cdot z}^2 = \sigma_x^2 - \sigma_{xz}^2/\sigma_z^2$, and since $\sigma_{wz} = \sigma_{xz}$, $\sigma_{xz}^2/\sigma_z^2 = \rho_{wz}^2 \sigma_w^2$. Divide the numerator and the denominator of $\lambda_{x|z} = \sigma_{x \cdot z}^2/(\sigma_{x \cdot z}^2 + \sigma_u^2)$ by σ_w^2 . The numerator becomes $\lambda - \rho_{wz}^2$ and the denominator $\lambda - \rho_{wz}^2 + (1 - \lambda) = 1 - \rho_{wz}^2$. In the example $\rho_{wz}^2 = 60^2/(225 \cdot 100) = 0.16$, so $\lambda_{x|z} = (0.64 - 0.16)/0.84 = 0.571$, as in Section 24.1. Finally $(\lambda - \rho^2)/(1 - \rho^2) < \lambda$ iff $\lambda - \rho^2 < \lambda - \lambda \rho^2$ iff $\rho^2(1 - \lambda) > 0$.

Exercise B2.

In simple regression with centred variables and known σ_u^2 , take $\mathbf{D} = \text{diag}(0, \sigma_u^2)$ in Theorem 24.3.1 and suppose (X, U, ε) are jointly normal and independent. Show that the asymptotic variance of $\sqrt{n}(\hat{\beta} - \beta)$ is

$$\frac{\sigma_w^2 \sigma_v^2 + \beta^2 \sigma_u^4}{\sigma_x^4}, \quad \sigma_v^2 = \sigma^2 + \beta^2 \sigma_u^2.$$

Compare it with σ^2/σ_x^2 , the asymptotic variance when X is observed. What does this

give for the running example with the mean of two readings?

Solution. The slope's estimating function (the intercept decouples for centred variables) is $\psi = W(Y - W\beta) + \sigma_u^2\beta = Wv + \sigma_u^2\beta$ with $v = \varepsilon - \beta U$, and the slope entry of $\mathbf{A}$ is σ_x^2 . Now (W, v) is bivariate normal with $\text{Cov}(W, v) = -\beta\sigma_u^2$, and for such a pair $E(W^2v^2) = \sigma_w^2\sigma_v^2 + 2\text{Cov}(W, v)^2$. So $\text{Var}(\psi) = E(W^2v^2) - \{E(Wv)\}^2 = \sigma_w^2\sigma_v^2 + \beta^2\sigma_u^4$, and the sandwich is $\text{Var}(\psi)/\sigma_x^4$. It exceeds σ^2/σ_x^2 because $\sigma_w^2\sigma_v^2 > \sigma_x^2\sigma^2$. For the example, use $\sigma_u^2 = 40.5$ for the mean of two readings: $\sigma_w^2 = 184.5$, $\sigma_v^2 = 1 + 0.0064 \cdot 40.5 = 1.2592$, and the variance is $(184.5 \cdot 1.2592 + 0.0064 \cdot 1640.25)/144^2 \approx 0.01171$, a standard error of about $\sqrt{0.01171/300} \approx 0.0062$, below the 0.0076 of [Example \(Correcting with two readings\)](#), where σ_u^2 is estimated and age lowers the reliability.

24.3.4.3 C. Going deeper

Exercise C1.

In the normal structural model with known σ_u^2 and $n \geq 3$, show that $\tilde{\beta} = s_{wy}/(s_{ww} - \sigma_u^2)$ has $E|\tilde{\beta}| = \infty$. (Condition on $W_1, \dots, W_n$, and use the fact that s_{ww} has a continuous density that is positive at σ_u^2 .)

Solution. Given the W_i , (W_i, Y_i) is jointly normal and $E(Y | W) = a + \lambda\beta W$ with constant conditional variance $\tau^2 > 0$ ([Theorem 3.5.2](#)). So, given the W_i , $s_{wy} \sim N(\lambda\beta s_{ww}, \tau^2 s_{ww}/(n-1))$, and $E(|s_{wy}| | W) \geq \tau\sqrt{2s_{ww}/\{\pi(n-1)\}}$, because a normal variable's absolute mean is at least that of its centred version. Hence $E|\tilde{\beta}| \geq c E\{\sqrt{s_{ww}}/|s_{ww} - \sigma_u^2|\}$. Here $(n-1)s_{ww}/\sigma_w^2 \sim \chi^2(n-1)$, whose density is continuous and positive on $(0, \infty)$. So the density of s_{ww} is bounded below near σ_u^2 , and the integral of $1/|s - \sigma_u^2|$ diverges there.

24.4 Instrumental variables

The corrections so far used a *number* from outside the regression. Instrumental variables use a *variable*, related to the mismeasured regressor and unrelated to everything that makes least squares fail. The idea goes back to Philip Wright (1928), who used it to estimate supply and demand curves.

24.4.1 Endogeneity

By [Eq. 24.1.2](#), $Y = \alpha + \beta W + e$ with $e = \varepsilon - \beta U$ correlated with W . An omitted common cause ([Theorem 19.1.2](#)) or a regressor partly determined by the response has the same effect. Such regressors are called **endogenous**. In every case the equation

$$y_i = \mathbf{x}_{(i)}^\top \boldsymbol{\beta} + e_i, \quad E(\mathbf{x}_{(i)} e_i) \neq \mathbf{0}, \quad (24.4.1)$$

describes a relation of scientific interest, not the best linear predictor that least squares estimates. Here $\mathbf{x}_{(i)}$ holds all the regressors, including the constant. In this section $\mathbf{x}$ collects all regressors and $\mathbf{z}$ all instruments; the exactly measured covariates of earlier sections appear in both.

Definition 24.4.1 — Instruments

A random q -vector $\mathbf{z}$ is a vector of **instruments** for Eq. 24.4.1, with random regressor p -vector $\mathbf{x}$, if

- (i) *exogeneity*: $E(\mathbf{z}e) = \mathbf{0}$;
- (ii) *relevance*: $\Sigma_{zx} = E(\mathbf{z}\mathbf{x}^\top)$ has rank p , which requires $q \geq p$;

and $\Sigma_{zz} = E(\mathbf{z}\mathbf{z}^\top)$ is positive definite.

Regressors uncorrelated with e , such as the constant, are their own instruments; the rank condition asks the *excluded* instruments to carry extra information about the endogenous regressors. With $q = p$ the equation is **just identified**, and with $q > p$ **overidentified**.

In the blood-pressure study the second reading instruments the first: $\mathbf{x} = (1, W_1, \text{age})$, $\mathbf{z} = (1, W_2, \text{age})$ and $e = \varepsilon - \beta U_1$, which is uncorrelated with $W_2 = X + U_2$. Nothing about σ_u^2 needs to be known, but the two errors must be *independent*, which rules out two readings that share a transient cause (Exercise (A2)).

24.4.2 The estimators

With the $n \times p$ matrix $\mathbf{X}$ of regressors and the $n \times q$ matrix $\mathbf{Z}$ of instruments, the sample version of $E\{\mathbf{z}(y - \mathbf{x}^\top \boldsymbol{\beta})\} = \mathbf{0}$ in the just-identified case is $\mathbf{Z}^\top(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) = \mathbf{0}$, with solution

$$\hat{\boldsymbol{\beta}}_{\text{IV}} = (\mathbf{Z}^\top \mathbf{X})^{-1} \mathbf{Z}^\top \mathbf{y}.$$

When $q > p$ these are more equations than unknowns. **Two-stage least squares** (2SLS) combines them through the projection $\mathbf{M}_Z = \mathbf{Z}(\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{Z}^\top$ onto $\mathcal{C}(\mathbf{Z})$:

$$\hat{\boldsymbol{\beta}}_{\text{2SLS}} = (\mathbf{X}^\top \mathbf{M}_Z \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{M}_Z \mathbf{y}. \quad (24.4.2)$$

The name comes from a two-step computation.

Lemma 24.4.1 — Two-stage least squares as projection

Let $\mathbf{Z}$ have full column rank and $\mathbf{X}^\top \mathbf{M}_Z \mathbf{X}$ be nonsingular, and let $\hat{\mathbf{X}} = \mathbf{M}_Z \mathbf{X}$ be the matrix of first-stage fitted values, obtained by regressing each column of $\mathbf{X}$ on $\mathbf{Z}$.

- (a) $\hat{\boldsymbol{\beta}}_{\text{2SLS}}$ is the least squares coefficient of $\mathbf{y}$ on $\hat{\mathbf{X}}$, and also the IV estimator with instruments $\hat{\mathbf{X}}$: $\hat{\boldsymbol{\beta}}_{\text{2SLS}} = (\hat{\mathbf{X}}^\top \hat{\mathbf{X}})^{-1} \hat{\mathbf{X}}^\top \mathbf{y} = (\hat{\mathbf{X}}^\top \mathbf{X})^{-1} \hat{\mathbf{X}}^\top \mathbf{y}$.
- (b) Columns of $\mathbf{X}$ that are also columns of $\mathbf{Z}$ are unchanged by the first stage.
- (c) If $q = p$ and $\mathbf{Z}^\top \mathbf{X}$ is nonsingular, $\hat{\boldsymbol{\beta}}_{\text{2SLS}} = \hat{\boldsymbol{\beta}}_{\text{IV}}$.

Proof. (a) $\mathbf{M}_Z$ is the orthogonal projection onto $\mathcal{C}(\mathbf{Z})$ (Theorem 6.3.6), so it is symmetric and idempotent (Theorem 6.3.3). Hence $\hat{\mathbf{X}}^\top \hat{\mathbf{X}} = \mathbf{X}^\top \mathbf{M}_Z \mathbf{M}_Z \mathbf{X} = \mathbf{X}^\top \mathbf{M}_Z \mathbf{X}$, and $\hat{\mathbf{X}}^\top \mathbf{X} = \mathbf{X}^\top \mathbf{M}_Z \mathbf{X}$ and $\hat{\mathbf{X}}^\top \mathbf{y} = \mathbf{X}^\top \mathbf{M}_Z \mathbf{y}$ as well. Substitute these in Eq. 24.4.2. (b) A column in $\mathcal{C}(\mathbf{Z})$ is fixed by $\mathbf{M}_Z$. (c) With $\mathbf{Z}^\top \mathbf{X}$ square and invertible, $(\mathbf{X}^\top \mathbf{Z}(\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{Z}^\top \mathbf{X})^{-1} = (\mathbf{Z}^\top \mathbf{X})^{-1} (\mathbf{Z}^\top \mathbf{Z})(\mathbf{X}^\top \mathbf{Z})^{-1}$, and multiplying by $\mathbf{X}^\top \mathbf{Z}(\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{Z}^\top \mathbf{y}$ leaves $(\mathbf{Z}^\top \mathbf{X})^{-1} \mathbf{Z}^\top \mathbf{y}$.

The first stage replaces each endogenous regressor by the part of it that the instruments explain, which is uncorrelated with e . As with the residualized regressions of [Section 6.6](#), the second-stage *coefficients* are right but its *residuals* $\mathbf{y} - \hat{\mathbf{X}}\hat{\boldsymbol{\beta}}$ are not; the equation's residuals are $\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}$.

Theorem 24.4.2 — Consistency and asymptotic normality of IV

Let $(\mathbf{x}_{(i)}, \mathbf{z}_{(i)}, e_i)$ be independent copies of $(\mathbf{x}, \mathbf{z}, e)$ with finite second moments, satisfying [Eq. 24.4.1](#) and [Definition 24.4.1](#). Let $\mathbf{H} = \boldsymbol{\Sigma}_{xz}\boldsymbol{\Sigma}_{zz}^{-1}\boldsymbol{\Sigma}_{zx}$, where $\boldsymbol{\Sigma}_{xz} = \boldsymbol{\Sigma}_{zx}^\top$.

- (a) $\hat{\boldsymbol{\beta}}_{2\text{SLS}} \rightarrow \boldsymbol{\beta}$ with probability one.
- (b) If $E(e^2|\mathbf{z}) < \infty$, then $\sqrt{n}(\hat{\boldsymbol{\beta}}_{2\text{SLS}} - \boldsymbol{\beta}) \rightarrow N_p(\mathbf{0}, \mathbf{V})$ in distribution, where

$$\mathbf{V} = \mathbf{H}^{-1}\boldsymbol{\Sigma}_{xz}\boldsymbol{\Sigma}_{zz}^{-1}\boldsymbol{\Omega}\boldsymbol{\Sigma}_{zz}^{-1}\boldsymbol{\Sigma}_{zx}\mathbf{H}^{-1}, \quad \boldsymbol{\Omega} = E(e^2\mathbf{z}\mathbf{z}^\top).$$

If $E(e^2 | \mathbf{z}) = \sigma_e^2$ is constant, then $\mathbf{V} = \sigma_e^2\mathbf{H}^{-1}$.

- (c) $\hat{\sigma}_e^2 = n^{-1}\|\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{2\text{SLS}}\|^2 \rightarrow \sigma_e^2 = E(e^2)$ with probability one.

Proof. (a) Write $\hat{\mathbf{C}} = n^{-1}\mathbf{Z}^\top\mathbf{X}$ and $\hat{\mathbf{S}} = n^{-1}\mathbf{Z}^\top\mathbf{Z}$. Substituting $\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ in [Eq. 24.4.2](#),

$$\hat{\boldsymbol{\beta}}_{2\text{SLS}} - \boldsymbol{\beta} = (\hat{\mathbf{C}}^\top\hat{\mathbf{S}}^{-1}\hat{\mathbf{C}})^{-1}\hat{\mathbf{C}}^\top\hat{\mathbf{S}}^{-1}\frac{1}{n}\mathbf{Z}^\top\boldsymbol{\varepsilon}.$$

By the strong law, $\hat{\mathbf{C}} \rightarrow \boldsymbol{\Sigma}_{zx}$, $\hat{\mathbf{S}} \rightarrow \boldsymbol{\Sigma}_{zz}$ and $n^{-1}\mathbf{Z}^\top\boldsymbol{\varepsilon} \rightarrow E(\mathbf{z}e) = \mathbf{0}$. The matrix $\mathbf{H}$ is positive definite: for $\mathbf{a} \neq \mathbf{0}$, $\boldsymbol{\Sigma}_{zx}\mathbf{a} \neq \mathbf{0}$ by the rank condition, so $\mathbf{a}^\top\mathbf{H}\mathbf{a} = (\boldsymbol{\Sigma}_{zx}\mathbf{a})^\top\boldsymbol{\Sigma}_{zz}^{-1}(\boldsymbol{\Sigma}_{zx}\mathbf{a}) > 0$. By continuity the right side tends to $\mathbf{H}^{-1}\boldsymbol{\Sigma}_{xz}\boldsymbol{\Sigma}_{zz}^{-1}\mathbf{0} = \mathbf{0}$.

(b) Multiply the display by $\sqrt{n}$. The vectors $\mathbf{z}_{(i)}e_i$ are independent and identically distributed with mean $\mathbf{0}$ and covariance $\boldsymbol{\Omega}$, finite by assumption, so $n^{-1/2}\mathbf{Z}^\top\boldsymbol{\varepsilon} \rightarrow N_q(\mathbf{0}, \boldsymbol{\Omega})$ by the central limit theorem. The matrix in front converges to $\mathbf{L} = \mathbf{H}^{-1}\boldsymbol{\Sigma}_{xz}\boldsymbol{\Sigma}_{zz}^{-1}$, and the splitting used for [Theorem 24.3.1\(b\)](#) gives the limit $\mathbf{L}N_q(\mathbf{0}, \boldsymbol{\Omega}) = N_p(\mathbf{0}, \mathbf{V})$. If $E(e^2 | \mathbf{z}) = \sigma_e^2$, then $\boldsymbol{\Omega} = E\{E(e^2 | \mathbf{z})\mathbf{z}\mathbf{z}^\top\} = \sigma_e^2\boldsymbol{\Sigma}_{zz}$, and $\mathbf{V}$ collapses to $\sigma_e^2\mathbf{H}^{-1}$.

(c) With $\boldsymbol{\delta} = \hat{\boldsymbol{\beta}}_{2\text{SLS}} - \boldsymbol{\beta}$, $\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{2\text{SLS}} = \boldsymbol{\varepsilon} - \mathbf{X}\boldsymbol{\delta}$, so

$$\hat{\sigma}_e^2 = \frac{1}{n}\boldsymbol{\varepsilon}^\top\boldsymbol{\varepsilon} - 2\boldsymbol{\delta}^\top\frac{1}{n}\mathbf{X}^\top\boldsymbol{\varepsilon} + \boldsymbol{\delta}^\top\left(\frac{1}{n}\mathbf{X}^\top\mathbf{X}\right)\boldsymbol{\delta}.$$

The averages converge to $E(e^2)$, $E(\mathbf{x}e)$ and $E(\mathbf{x}\mathbf{x}^\top)$, all finite, and $\boldsymbol{\delta} \rightarrow \mathbf{0}$ by (a).

In practice $\mathbf{V}$ is estimated with sample moments and $\hat{\boldsymbol{\Omega}} = n^{-1}\sum_i \hat{e}_i^2\mathbf{z}_{(i)}\mathbf{z}_{(i)}^\top$, as in [Theorem 21.4.2](#), or under homoscedasticity by $\hat{\sigma}_e^2(\mathbf{X}^\top\mathbf{M}_\mathbf{Z}\mathbf{X})^{-1}$. Among estimators using linear combinations of the instruments, 2SLS has the smallest asymptotic covariance under homoscedasticity ([Exercise \(C2\)](#)).

Example. (The second reading as an instrument)

Instrument the first reading with the second, and let age and the constant instrument themselves. The IV estimates are 0.0708 for blood pressure, with standard error 0.0085

(0.0081 from the sandwich), and 0.0054 for age (standard error 0.0081). The spurious age effect has gone. The first-stage F statistic for the second reading is 160.1, a strong instrument. The correct residuals give $\hat{\sigma}_e^2 = 1.438$, estimating $\sigma^2 + \beta^2 \sigma_u^2 = 1.5184$; the second-stage residuals give 1.376. The moment correction of [Example \(Correcting with two readings\)](#) gave 0.0757 with standard error 0.0076. It uses both readings symmetrically, while IV uses one only as an instrument and pays in precision. But IV needs no estimate of the error variance, and the instrument need only be correlated with X , not a second unbiased reading of it.

```
import numpy as np

rng = np.random.default_rng(2401)
n = 300
age = rng.normal(55, 10, n)
x = 130 + 0.6 * (age - 55) + rng.normal(0, np.sqrt(108), n)  # long-run blood
                        pressure, sd 12
w = x[:, None] + rng.normal(0, 9, (n, 2))                  # two clinic readings
y = -4 + 0.08 * x + 0.0 * age + rng.normal(0, 1.0, n)      # age has no effect
                        given x

X = np.column_stack([np.ones(n), w[:, 0], age])            # regressors: first reading, age
Z = np.column_stack([np.ones(n), w[:, 1], age])            # instruments: second reading,
                        age
b_iv = np.linalg.solve(Z.T @ X, Z.T @ y)                  # residuals use X, not the first
e = y - X @ b_iv                                           -stage fit
ZXinv = np.linalg.inv(Z.T @ X)
cov_h = e @ e / n * ZXinv @ (Z.T @ Z) @ ZXinv.T          # homoscedastic
cov_s = ZXinv @ ((Z * e[:, None] ** 2).T @ Z) @ ZXinv.T   # heteroscedasticity-
                        robust
print("IV (1, x, age):", b_iv.round(4))
print("se, homoscedastic:", np.sqrt(np.diag(cov_h)).round(4))
print("se, sandwich:      ", np.sqrt(np.diag(cov_s)).round(4))

# first stage: regress the first reading on the instruments; F for the excluded
                        instrument
g, rss1 = np.linalg.lstsq(Z, w[:, 0], rcond=None)[:2]
rss0 = np.sum((w[:, 0] - np.column_stack([np.ones(n), age]) @
                        np.linalg.lstsq(np.column_stack([np.ones(n), age]), w[:, 0], rcond=
                        None)[0]) ** 2)
F1 = (rss0 - rss1[0]) / (rss1[0] / (n - 3))
print(f"first-stage F = {F1:.1f}")
```

Wald's (1940) grouping estimator ([Section 7.1](#)) is an IV estimator whose instrument is a group indicator ([Exercise \(B1\)](#)).

24.4.3 Weak instruments

If the instruments explain little of the endogenous regressor, the limit theory of [Theorem 24.4.2](#) is a poor guide at realistic n . The simplest case can be solved exactly.

Proposition 24.4.3 — The exact distribution with one instrument

Let $y_i = \beta x_i + e_i$ and $x_i = \pi z_i + v_i$, $i = 1, \dots, n$, with fixed z_i , $S_{zz} = \sum_i z_i^2 > 0$, and (e_i, v_i) independent bivariate normal with means zero, standard deviations σ_e, σ_v and correlation ρ , $|\rho| < 1$. Let $\hat{\beta} = \sum_i z_i y_i / \sum_i z_i x_i$ and $\mu = \pi \sqrt{S_{zz}} / \sigma_v$.

(a) $\hat{\beta} - \beta$ has the same distribution as

$$\frac{\sigma_e}{\sigma_v} \cdot \frac{\rho\eta + \sqrt{1-\rho^2}\xi}{\mu + \eta}, \quad \eta, \xi \stackrel{\text{iid}}{\sim} N(0, 1). \quad (24.4.3)$$

(b) $E|\hat{\beta}| = \infty$ for every μ .

(c) As $\mu \rightarrow \infty$, $(\mu\sigma_v/\sigma_e)(\hat{\beta} - \beta) \rightarrow N(0, 1)$ in distribution. If $\mu = 0$, $\hat{\beta} - \beta$ has median $\rho\sigma_e/\sigma_v$, which is the large-sample bias of least squares when $\pi = 0$.

(d) $(\sum_i z_i x_i)^2 / (\sigma_v^2 S_{zz}) \sim \chi^2(1, \mu^2)$, with mean $1 + \mu^2$.

Proof. (a) Put $\eta = \sum_i z_i v_i / (\sigma_v \sqrt{S_{zz}})$ and $\zeta = \sum_i z_i e_i / (\sigma_e \sqrt{S_{zz}})$. They are jointly normal (Theorem 3.3.1) with unit variances and covariance $\sum_i z_i^2 \rho \sigma_e \sigma_v / (\sigma_e \sigma_v S_{zz}) = \rho$. By Theorem 3.5.2, $\xi = (\zeta - \rho\eta) / \sqrt{1-\rho^2}$ is standard normal and independent of η . Now $\sum_i z_i x_i = \pi S_{zz} + \sigma_v \sqrt{S_{zz}} \eta = \sigma_v \sqrt{S_{zz}}(\mu + \eta)$, and $\hat{\beta} - \beta = \sum_i z_i e_i / \sum_i z_i x_i = \sigma_e \zeta / \{\sigma_v(\mu + \eta)\}$.

(b) Given η , the numerator $\rho\eta + \sqrt{1-\rho^2}\xi$ is normal with standard deviation $\sqrt{1-\rho^2} > 0$, so its conditional absolute mean is at least $c = \sqrt{2(1-\rho^2)}/\pi$. Hence $E|\hat{\beta} - \beta| \geq (\sigma_e/\sigma_v) c E|\mu + \eta|^{-1} = \infty$, because the density of $\mu + \eta$ is continuous and positive at zero, as in the proof of Proposition 12.5.2. Finally $|\hat{\beta}| \geq |\hat{\beta} - \beta| - |\beta|$.

(c) $(\mu\sigma_v/\sigma_e)(\hat{\beta} - \beta)$ has the law of $(\rho\eta + \sqrt{1-\rho^2}\xi)/(1 + \eta/\mu)$. The numerator is standard normal and $\eta/\mu \rightarrow 0$ in probability, so Slutsky's lemma applies. For $\mu = 0$ the representation is $(\sigma_e/\sigma_v)(\rho + \sqrt{1-\rho^2}\xi/\eta)$, and ξ/η is symmetric about zero, so the median is $\rho\sigma_e/\sigma_v$. When $\pi = 0$, $x = v$ and least squares converges to $\beta + \text{Cov}(v, e)/\sigma_v^2 = \beta + \rho\sigma_e/\sigma_v$.

(d) $\sum_i z_i x_i / (\sigma_v \sqrt{S_{zz}}) = \mu + \eta \sim N(\mu, 1)$, and its square is $\chi^2(1, \mu^2)$, whose mean is $1 + \mu^2$ (the convention of Chapter 4, without a factor $\frac{1}{2}$).

■

The design and π enter only through the **concentration parameter** μ^2 , which acts as a sample size, and by (d) the first-stage statistic estimates $1 + \mu^2$. Hence the rule of thumb of Staiger and Stock (1997): an instrument is weak if the first-stage F is below about 10. A useless instrument ($\mu = 0$) gives an estimator centred on the least squares bias, with Cauchy tails.

Example. (How weak is too weak?)

With $n = 200$, $\beta = 1$, $\sigma_e = \sigma_v = 1$ and $\rho = 0.9$, least squares tends to about 1.9 for a weak instrument. In 20000 samples for each concentration:

Figure 24.4.1: Sampling distributions of the IV estimate of $\beta = 1$ for $\mu^2 = 1, 10, 100$ on $[-1, 3]$; dotted, the least squares limit.

μ^2	median	quartiles	coverage of nominal 95% Wald interval
1	1.298	0.711 to 1.646	0.843
10	1.008	0.740 to 1.181	0.921
100	1.002	0.929 to 1.064	0.947

With $\mu^2 = 1$ the median moves a third of the way to the least squares limit, a proportion 0.200 of estimates fall outside $[-1, 3]$, and the Wald interval undercovers, as it still does at $\mu^2 = 10$ (Figure 24.4.1).

```
def iv_draws(mu2, reps, seed, n=200, rho=0.9):
    """IV estimates of beta = 1 and Wald-interval coverage when the concentration is
    mu2."""
    r = np.random.default_rng(seed)
    z = r.normal(size=n)
    z = z * np.sqrt(n / (z @ z))          # fixed instrument with sum z^2 =
    n
    pi = np.sqrt(mu2 / n)
    ev = r.multivariate_normal([0, 0], [[1, rho], [rho, 1]], size=(reps, n))
    xx = pi * z + ev[:, :, 1]
    yy = 1.0 * xx + ev[:, :, 0]
    b = (yy @ z) / (xx @ z)
    res = yy - b[:, None] * xx
    se = np.sqrt((res ** 2).mean(axis=1) * n / (xx @ z) ** 2)
    return b, np.abs(b - 1) <= 1.96 * se

for mu2 in [1, 10, 100]:
    b, hit = iv_draws(mu2, 2000, 2440)
    print(f"mu^2 = {mu2:3d}: median {np.median(b):.3f}, "
          f"quartiles {np.percentile(b, 25):.3f} to {np.percentile(b, 75):.3f}, "
          f"coverage {hit.mean():.3f}")
```

With many weak instruments, 2SLS is biased towards least squares, and Bound, Jaeger and

Baker (1995) showed that it can nearly reproduce least squares; we do not prove this. For inference, invert a test whose null distribution does not depend on instrument strength, such as the Anderson–Rubin test ([Exercise \(C1\)](#)). Its confidence sets are of Fieller type ([Proposition 12.5.1](#)) and can be unbounded, as they must sometimes be ([Proposition 12.5.4](#)).

Warning. Exogeneity cannot be checked in a just-identified model: all the equations $E(\mathbf{z}e) = \mathbf{0}$ are used to estimate β . With more instruments, tests of overidentifying restrictions (Sargan, 1958) check only that the instruments *agree*. An instrument is justified by knowledge of how the data arose; for replicates, by the independence of their errors. Instruments for causal effects are taken up in [Chapter 25](#).

24.4.4 Exercises

24.4.4.1 A. Check your understanding

Exercise A1.

For $\mathbf{x} = (1, W)$ and $\mathbf{z} = (1, Z)$, show that the IV slope is s_{zy}/s_{zw} , the ratio of two sample covariances. Show that the population ratio equals β when Z is correlated with X and uncorrelated with U and ε .

Exercise A2.

If the errors of two readings are correlated, $\text{Cov}(U_1, U_2) = \kappa$, find the limit of the IV slope in simple regression that instruments W_1 with W_2 . In which direction is it biased when $\kappa > 0$?

Solution. $\text{Cov}(W_2, Y) = \beta\sigma_x^2$ and $\text{Cov}(W_2, W_1) = \sigma_x^2 + \kappa$, so the limit is $\beta\sigma_x^2/(\sigma_x^2 + \kappa)$. With $\kappa > 0$ it is attenuated, though less than least squares unless $\kappa = \sigma_u^2$. The instrument is not exogenous: $\text{Cov}(W_2, \varepsilon - \beta U_1) = -\beta\kappa$.

24.4.4.2 B. Practice

Exercise B1.

Let $g_i \in \{0, 1\}$ be a group indicator, and let $\mathbf{z}_{(i)} = (1, g_i)$ instrument $\mathbf{x}_{(i)} = (1, w_i)$. Show that the IV slope is $(\bar{y}_1 - \bar{y}_0)/(\bar{w}_1 - \bar{w}_0)$, the difference of group means of y divided by that of w . This is Wald's (1940) estimator. Show that it is consistent if g is independent of (U, ε) and $E(X | g)$ differs between the groups. Explain why forming the groups by splitting at the median of w itself, as Wald proposed, does not satisfy these conditions under classical error.

Solution. By [Exercise \(A1\)](#) the slope is s_{gy}/s_{gw} . For a binary g with n_1 ones, $\sum_i (g_i - \bar{g})y_i = n_1(\bar{y}_1 - \bar{y})$ and $\bar{y}_1 - \bar{y} = (n_0/n)(\bar{y}_1 - \bar{y}_0)$. The same holds for w , and the factors cancel. Exogeneity needs $\text{Cov}(g, \varepsilon - \beta U) = 0$, which holds when g is independent of (U, ε) . Relevance needs $\text{Cov}(g, W) = \text{Cov}(g, X) \neq 0$, that is, different group means of X . If the groups are formed from w , membership depends on U : readings with large positive errors tend to land in the upper group, so $\text{Cov}(g, U) > 0$ and exogeneity fails. The grouping must come from information independent of the measurement error, such

as a second reading or a design variable.

24.4.4.3 C. Going deeper

Exercise C1.

In [Eq. 24.4.1](#) with $\mathbf{x} = (1, W)$, let $\mathbf{z} = (1, \mathbf{z}_1)$ with $\mathbf{z}_1$ a k -vector of excluded instruments, and suppose e is independent of $\mathbf{z}$ and $N(0, \sigma_e^2)$. To test $H_0 : \beta = \beta_0$, regress $y - \beta_0 w$ on $\mathbf{z}$ and compute the F statistic for $\mathbf{z}_1$. Show that under H_0 it has an exact $F(k, n - k - 1)$ distribution, whatever the strength of the instruments. This is the test of Anderson and Rubin (1949). Inverting it gives a confidence set for β . Show that for $k = 1$ the set is of the form in [Proposition 12.5.1](#).

Solution. Under H_0 , $y - \beta_0 w = \alpha + e$ with e normal and independent of $\mathbf{z}$: given $\mathbf{Z}$, a normal linear model in which the coefficients of $\mathbf{z}_1$ are zero. The F statistic of [Theorem 11.1.1](#) is exactly $F(k, n - k - 1)$ given $\mathbf{Z}$, hence unconditionally, and w plays no role. For $k = 1$, let $\hat{a}$ and $\hat{b}$ be the slopes of y and of w on $(1, z)$, let $v = 1 / \sum_i (z_i - \bar{z})^2$, and let s_{11} , s_{12} , s_{22} be the residual mean squares and mean cross-product of y and w from these two regressions. The regression of $y - \beta_0 w$ on $(1, z)$ has slope $\hat{a} - \beta_0 \hat{b}$ and residual mean square $s_{11} - 2\beta_0 s_{12} + \beta_0^2 s_{22}$, so $F = t^2$ and the acceptance region is

$$(\hat{a} - \beta_0 \hat{b})^2 \leq t_{n-2, \alpha/2}^2 v (s_{11} - 2\beta_0 s_{12} + \beta_0^2 s_{22}).$$

This is [Eq. 12.5.1](#) with $s^2 v_{ij}$ replaced by $v s_{ij}$: a quadratic inequality in β_0 . Like Fieller's set, it can be an interval, the complement of an interval, or the whole line.

Exercise C2.

Let $\mathbf{F}$ be a fixed $q \times p$ matrix with $\Sigma_{zx}^\top \mathbf{F}$ nonsingular, and consider the IV estimator with instruments $\mathbf{ZF}$. Under homoscedasticity its asymptotic covariance is $\sigma_e^2 (\mathbf{F}^\top \Sigma_{zx})^{-1} \mathbf{F}^\top \Sigma_{zz} \mathbf{F} (\Sigma_{zx}^\top \mathbf{F})^{-1}$. Show that this is never smaller, in the nonnegative definite ordering, than $\sigma_e^2 \mathbf{H}^{-1}$, with equality when $\mathbf{F} = \Sigma_{zz}^{-1} \Sigma_{zx}$, which is the population version of 2SLS.

24.5 Regression calibration and SIMEX

The moment correction and IV are tied to linear moment equations. Two more portable ideas were designed for logistic, Cox and other nonlinear regressions, where they are approximations. **Regression calibration** replaces the unobserved regressor by its best prediction from what was observed. **SIMEX** watches the naive estimate deteriorate as error is added, and extrapolates back to no error. In the linear model both can be exact.

24.5.1 Regression calibration

Error is **nondifferential** if the distribution of Y given $(\mathbf{x}, \mathbf{z}, \mathbf{w})$ does not depend on $\mathbf{w}$, as for classical error.

Proposition 24.5.1 — Regression calibration

Suppose $E(Y | \mathbf{x}, \mathbf{z}) = \alpha + \beta_x^\top \mathbf{x} + \beta_z^\top \mathbf{z}$ and the error is nondifferential, and let $\mathbf{m}(\mathbf{w}, \mathbf{z}) = E(\mathbf{x} | \mathbf{w}, \mathbf{z})$.

- (a) $E(Y | \mathbf{w}, \mathbf{z}) = \alpha + \beta_x^\top \mathbf{m}(\mathbf{w}, \mathbf{z}) + \beta_z^\top \mathbf{z}$.
- (b) If moreover $\text{Var}(Y | \mathbf{x}, \mathbf{z}) = \sigma^2$ and $\text{Cov}(\mathbf{x} | \mathbf{w}, \mathbf{z}) = \mathbf{C}$ does not depend on $(\mathbf{w}, \mathbf{z})$, as when $(\mathbf{x}, \mathbf{z}, \mathbf{u})$ is jointly normal, then $\text{Var}(Y | \mathbf{w}, \mathbf{z}) = \sigma^2 + \beta_x^\top \mathbf{C} \beta_x$. The regression of Y on $(1, \mathbf{m}(\mathbf{w}, \mathbf{z}), \mathbf{z})$ is then a homoscedastic linear model with the original coefficients.
- (c) Without distributional assumptions, let the error be classical with finite second moments. With $\mathbf{t} = (1, \mathbf{x}^\top, \mathbf{z}^\top)^\top$, $\mathbf{s} = (1, \mathbf{w}^\top, \mathbf{z}^\top)^\top$, $\mathbf{A} = E(\mathbf{t}\mathbf{t}^\top)$ positive definite and $\mathbf{S} = E(\mathbf{s}\mathbf{s}^\top)$, the best linear predictor of $\mathbf{t}$ from $\mathbf{s}$ is $\hat{\mathbf{t}} = \mathbf{A}\mathbf{S}^{-1}\mathbf{s}$, and the best linear predictor of Y from $\hat{\mathbf{t}}$ is $\boldsymbol{\theta}^\top \hat{\mathbf{t}}$, where $\boldsymbol{\theta} = (\alpha, \beta_x^\top, \beta_z^\top)^\top$.
- (d) The sample version of (c) reproduces the method-of-moments estimator exactly. If $\hat{\mathbf{S}} = n^{-1} \sum_i \mathbf{s}_i \mathbf{s}_i^\top$, $\hat{\mathbf{A}} = \hat{\mathbf{S}} - \mathbf{D}$ for a symmetric matrix $\mathbf{D}$ with $\hat{\mathbf{A}}$ nonsingular, and $\hat{\mathbf{t}}_i = \hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}\mathbf{s}_i$, then the least squares coefficients of y on the $\hat{\mathbf{t}}_i$ are $\hat{\mathbf{A}}^{-1}n^{-1} \sum_i \mathbf{s}_i y_i$, which is [Eq. 24.3.1](#) with $\mathbf{D}_i = \mathbf{D}$.

Proof. (a) By the tower property and nondifferential error, $E(Y | \mathbf{w}, \mathbf{z}) = E\{E(Y | \mathbf{x}, \mathbf{z}, \mathbf{w}) | \mathbf{w}, \mathbf{z}\} = E\{\alpha + \beta_x^\top \mathbf{x} + \beta_z^\top \mathbf{z} | \mathbf{w}, \mathbf{z}\}$, which is the claim.

(b) The law of total variance, conditioning on $\mathbf{x}$ inside $(\mathbf{w}, \mathbf{z})$, gives $\text{Var}(Y | \mathbf{w}, \mathbf{z}) = E\{\text{Var}(Y | \mathbf{x}, \mathbf{z}, \mathbf{w}) | \mathbf{w}, \mathbf{z}\} + \text{Var}\{E(Y | \mathbf{x}, \mathbf{z}, \mathbf{w}) | \mathbf{w}, \mathbf{z}\} = \sigma^2 + \beta_x^\top \mathbf{C} \beta_x$. Under joint normality the conditional covariance of $\mathbf{x}$ given $(\mathbf{w}, \mathbf{z})$ does not depend on the conditioning values ([Theorem 3.5.2](#)).

(c) The best linear predictor ([Definition 6.11.1](#), [Theorem 2.5.2](#)), with the constant among the predictors, is the projection in L^2 onto the span of the entries of $\mathbf{s}$, so it is $E(\mathbf{t}\mathbf{s}^\top)\mathbf{S}^{-1}\mathbf{s}$. Under classical error $E(\mathbf{t}\mathbf{s}^\top) = E\{\mathbf{t}(\mathbf{t} + \tilde{\mathbf{u}})^\top\} = \mathbf{A}$, and $\mathbf{A}\mathbf{S}^{-1}\mathbf{s}$ follows. The entries of $\hat{\mathbf{t}}$ span the same space as those of $\mathbf{s}$, since $\mathbf{A}\mathbf{S}^{-1}$ is nonsingular. Their second-moment matrix is $\mathbf{A}\mathbf{S}^{-1}\mathbf{S}\mathbf{S}^{-1}\mathbf{A} = \mathbf{A}\mathbf{S}^{-1}\mathbf{A}$, and $E(\hat{\mathbf{t}}Y) = \mathbf{A}\mathbf{S}^{-1}E(\mathbf{s}Y) = \mathbf{A}\mathbf{S}^{-1}\mathbf{A}\boldsymbol{\theta}$, because $E(\mathbf{s}Y) = \mathbf{A}\boldsymbol{\theta}$ as in [Section 24.3](#). The projection coefficients are $(\mathbf{A}\mathbf{S}^{-1}\mathbf{A})^{-1}\mathbf{A}\mathbf{S}^{-1}\mathbf{A}\boldsymbol{\theta} = \boldsymbol{\theta}$.

(d) With the calibrated regressors $\hat{\mathbf{t}}_i = \hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}\mathbf{s}_i$, the normal equations ([Theorem 6.4.2](#)) have matrix $n^{-1} \sum_i \hat{\mathbf{t}}_i \hat{\mathbf{t}}_i^\top = \hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}\hat{\mathbf{A}}$ and right side $\hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}n^{-1} \sum_i \mathbf{s}_i y_i$. Solving, $(\hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}\hat{\mathbf{A}})^{-1}\hat{\mathbf{A}}\hat{\mathbf{S}}^{-1}n^{-1} \sum_i \mathbf{s}_i y_i = \hat{\mathbf{A}}^{-1}n^{-1} \sum_i \mathbf{s}_i y_i$.

■

The coordinates of $\hat{\mathbf{t}}$ for the constant and $\mathbf{z}$ reproduce them, so only the mismeasured regressors are replaced. By (c) and (d), linear regression calibration needs no distributional assumption and is the moment correction, with the standard errors of [Theorem 24.3.1](#). Second-stage standard errors, which treat the calibrated values as data, are too small. A **validation subsample** in which $\mathbf{x}$ is measured identifies the calibration directly, by regressing $\mathbf{x}$ on $(\mathbf{w}, \mathbf{z})$ there, and needs only (a): nondifferential error and a correct model for $E(\mathbf{x} | \mathbf{w}, \mathbf{z})$. In a logistic regression, (a) gives $E\{G(\alpha + \beta X) | w\}$, not $G(\alpha + \beta m(w))$, so calibration is an approximation, good when $\text{Var}(X | W)$ is small (Carroll, Ruppert, Stefanski and Crainiceanu, 2006).

Remark (Two meanings of “calibration”). In [Section 12.5](#) *calibration* meant inverse prediction of x_0 from a new response. Regression calibration instead predicts the regressor from its measurement.

Example. (Calibrating the mean reading)

The replicates estimate the error variance of the mean reading as 37.04. The calibrated pressure $\hat{x}_i$ has standard deviation 10.36, against 13.11 for the mean reading: each reading is shrunk towards what age predicts. Regressing y on $(1, \hat{x}, \text{age})$ gives 0.0757 and 0.0018, exactly the moment correction of [Example \(Correcting with two readings\)](#), by [Proposition 24.5.1\(d\)](#).

```
import numpy as np

rng = np.random.default_rng(2401)
n = 300
age = rng.normal(55, 10, n)
x = 130 + 0.6 * (age - 55) + rng.normal(0, np.sqrt(108), n)  # long-run blood
                        pressure, sd 12
w = x[:, None] + rng.normal(0, 9, (n, 2))                  # two clinic readings
y = -4 + 0.08 * x + 0.0 * age + rng.normal(0, 1.0, n)      # age has no effect
                        given x

wbar = w.mean(axis=1)
s2_ubar = np.mean((w[:, 0] - w[:, 1]) ** 2) / 4              # error variance of
                        the mean reading
W = np.column_stack([np.ones(n), wbar, age])
S = W.T @ W / n                                             # raw second moments
                        of (1, wbar, age)
Suu = np.diag([0.0, s2_ubar, 0.0])

# calibration: best linear predictor of (1, x, age) from (1, wbar, age), using E(w x
# ^T) = S - Suu
Gamma = np.linalg.solve(S, S - Suu)
x_hat = (W @ Gamma)[:, 1]                                  # predicted long-run
                        pressure
b_rc = np.linalg.lstsq(np.column_stack([np.ones(n), x_hat, age]), y, rcond=None)[0]
b_mom = np.linalg.solve(S - Suu, W.T @ y / n)              # method of moments,
                        Section 24.3
print("regression calibration:", b_rc.round(4))
print("method of moments:      ", b_mom.round(4))
```

24.5.2 SIMEX

Cook and Stefanski (1994) treat the naive estimator as a black box. Data cannot be made more accurate, but they can be made *less* accurate by adding simulated error; watching the naive estimate move as the error variance grows, we extrapolate back to zero. Let σ_u^2 be the known or estimated error variance of W .

1. **Simulation.** For each ζ in a grid such as $\{0.5, 1, 1.5, 2\}$ and $b = 1, \dots, B$, form remeasured data $W_{b,i}(\zeta) = W_i + \sqrt{\zeta} \sigma_u V_{b,i}$, with $V_{b,i} \stackrel{\text{iid}}{\sim} N(0, 1)$ independent of the data, and compute

the naive estimate $\hat{\theta}_b(\zeta)$ from $(W_b(\zeta), \mathbf{z}, Y)$. Average over b to get $\hat{\theta}(\zeta)$, and put $\hat{\theta}(0)$ equal to the naive estimate.

2. **Extrapolation.** Fit a function $g(\zeta; \gamma)$ of ζ to the points $(\zeta, \hat{\theta}(\zeta))$, one coefficient at a time, and report $g(-1; \hat{\gamma})$.

The remeasured error $U + \sqrt{\zeta}\sigma_u V$ is still classical, with variance $(1 + \zeta)\sigma_u^2$, so $\zeta = -1$ means no error. Averaging over b removes simulation noise only.

Proposition 24.5.2 — SIMEX in the linear model

Assume the conditions of [Theorem 24.1.1\(c\)](#), with one mismeasured scalar regressor of error variance σ_u^2 , and fix $\zeta \geq 0$. For each b , the naive least squares coefficients from the remeasured data converge with probability one to $\mathbf{g}(\zeta) = (g_x(\zeta), \mathbf{g}_z(\zeta))$, where

$$g_x(\zeta) = \frac{\beta_x \sigma_{x \cdot z}^2}{\sigma_{x \cdot z}^2 + (1 + \zeta)\sigma_u^2}, \quad \mathbf{g}_z(\zeta) = \boldsymbol{\beta}_z + \frac{(1 + \zeta)\sigma_u^2}{\sigma_{x \cdot z}^2 + (1 + \zeta)\sigma_u^2} \beta_x \boldsymbol{\pi}, \quad (24.5.1)$$

and so does their average over b . Moreover:

- (a) $g_x(-1) = \beta_x$ and $\mathbf{g}_z(-1) = \boldsymbol{\beta}_z$;
- (b) every coefficient has the form $a + b/(c + \zeta)$ with $c = 1 + \sigma_{x \cdot z}^2/\sigma_u^2$; in particular $1/g_x(\zeta)$ is linear in ζ when $\beta_x \neq 0$;
- (c) if a polynomial of fixed degree is fitted by least squares to the points $(\zeta_k, \hat{\theta}(\zeta_k))$ on a fixed grid, the SIMEX estimate converges to the value at -1 of the polynomial fitted in the same way to $(\zeta_k, \mathbf{g}(\zeta_k))$, which in general differs from $\mathbf{g}(-1)$.

Proof. The remeasured data satisfy [Definition 24.1.1](#) with error $U + \sqrt{\zeta}\sigma_u V$, whose variance is $(1 + \zeta)\sigma_u^2$, and the observations $(X_i, \mathbf{z}_i, U_i, V_{b,i}, \varepsilon_i)$ are independent over i . By [Theorem 24.1.1\(c\)](#), with σ_u^2 replaced by $(1 + \zeta)\sigma_u^2$, the coefficients converge to $\lambda_\zeta \beta_x$ and $\boldsymbol{\beta}_z + (1 - \lambda_\zeta)\beta_x \boldsymbol{\pi}$, where $\lambda_\zeta = \sigma_{x \cdot z}^2 / \{\sigma_{x \cdot z}^2 + (1 + \zeta)\sigma_u^2\}$. This is [Eq. 24.5.1](#). A finite average of sequences converging with probability one converges to the average of the limits. (a) At $\zeta = -1$, $\lambda_\zeta = 1$. (b) The denominator is $\sigma_u^2(c + \zeta)$. So $g_x(\zeta) = (\beta_x \sigma_{x \cdot z}^2 / \sigma_u^2) / (c + \zeta)$, and $(1 + \zeta)/(c + \zeta) = 1 - (c - 1)/(c + \zeta)$ gives $\mathbf{g}_z(\zeta) = \boldsymbol{\beta}_z + \beta_x \boldsymbol{\pi} - (c - 1)\beta_x \boldsymbol{\pi} / (c + \zeta)$. (c) On a fixed grid the fitted polynomial's coefficients are a fixed linear function of the fitted points (the least squares solution with a fixed model matrix), so its value at -1 is a continuous function of the points, and the points converge. ■

So the rational form matches the limit exactly, and the rational SIMEX estimate is consistent provided the nonlinear fit is unique and continuous in the points, which we do not verify. The quadratic, a common default because it is linear in its parameters, recovers only part of the attenuation ([Exercise \(B1\)](#)). With several mismeasured regressors, or in nonlinear models, no simple extrapolant is exact and SIMEX is only approximately consistent. Its appeal is that it needs nothing but the naive estimator.

Example. (SIMEX for the blood-pressure study)

Apply SIMEX to the regression on the mean reading and age, with error variance 37.04,

Figure 24.5.1: SIMEX: averaged naive coefficients (dots), quadratic and rational extrapolants with their values at $\zeta = -1$ (diamonds), the limits Eq. 24.5.1 (dotted) and the truth (dashed).

grid $\{0, 0.5, 1, 1.5, 2\}$ and $B = 200$ (Figure 24.5.1). Extrapolating to $\zeta = -1$:

Coefficient	naive	SIMEX, quadratic	SIMEX, $a + b/(c + \zeta)$	moment correction	truth
blood pressure	0.0562	0.0709	0.0744	0.0757	0.08
age	0.0120	0.0042	0.0024	0.0018	0

The rational extrapolant nearly reproduces the moment correction; the quadratic stops short, and by Proposition 24.5.2(c) its large-sample limit is 0.0749, only 0.77 of the way from the naive limit 0.0582 to 0.08, and 0.0030 for age. A pairs bootstrap (Definition 23.1.1) over patients, re-estimating the error variance and rerunning SIMEX ($B = 50, 200$ resamples), gives standard error 0.0076 for the rational SIMEX slope, as for the moment correction.

```
from scipy.optimize import curve_fit

def naive_fits(wcol, age, y):
    """Least squares coefficients of y on (1, wcol, age) for a stack of remeasured
    columns."""
    m, k = wcol.shape # m remeasured data
    # sets of size k
    Xs = np.stack([np.ones((m, k)), wcol, np.broadcast_to(age, (m, k))], axis=2)
    XtX = np.einsum("mki,mkj->mij", Xs, Xs)
    Xty = np.einsum("mki,k->mi", Xs, y)
    return np.linalg.solve(XtX, Xty[:, :, None])[ :, :, 0]

def simex(wbar, age, y, s2_ubar, zetas, B, rng):
    """Average naive coefficients after adding error of variance zeta * s2_ubar."""
    out = [naive_fits(wbar[None, :], age, y)[0]]
    for z in zetas[1:]:
        extra = rng.normal(0, np.sqrt(z * s2_ubar), (B, len(y)))
        out.append(naive_fits(wbar + extra, age, y).mean(axis=0))
    return np.array(out) # one row per zeta
```

```

print("SIMEX, rational:   ", np.round(est_rat, 4))

```

24.5.3 Which correction?

In the linear model the moment correction and regression calibration coincide, rational SIMEX agrees up to simulation noise, and IV trades precision for not needing an error variance. Beyond it, only regression calibration and SIMEX carry over. All rest on information from outside the regression of Y on W . Without it, [Proposition 24.2.2](#) is the honest summary: a range of slopes, with the naive estimate at one end.

24.5.4 Exercises

24.5.4.1 A. Check your understanding

Exercise A1.

In simple regression without $\mathbf{z}$, show directly that regression calibration ([Proposition 24.5.1](#)) with the linear calibration $\hat{x} = \bar{w} + \hat{\lambda}(w - \bar{w})$, $\hat{\lambda} = (s_{ww} - \sigma_u^2)/s_{ww}$, gives the slope $\hat{\beta}/\hat{\lambda}$, where $\hat{\beta}$ is the naive slope.

24.5.4.2 B. Practice

Exercise B1.

In simple regression with reliability λ , write $g(\zeta) = \lambda\beta/\{1 + \zeta(1 - \lambda)\}$. Show that the quadratic through $(\zeta, g(\zeta))$ for $\zeta = 0, 1, 2$ takes the value $3g(0) - 3g(1) + g(2)$ at $\zeta = -1$. Evaluate it for $\lambda = 0.5$ and $\lambda = 0.64$, as fractions of β .

Solution. The quadratic through three equally spaced points is determined by the forward differences. Written as $p(\zeta) = g_0 + \zeta\Delta g_0 + \frac{1}{2}\zeta(\zeta - 1)\Delta^2 g_0$, it gives $p(-1) = g_0 - \Delta g_0 + \Delta^2 g_0 = g_0 - (g_1 - g_0) + (g_2 - 2g_1 + g_0) = 3g_0 - 3g_1 + g_2$. With $\lambda = 0.5$: $g_0 = \beta/2$, $g_1 = \beta/3$, $g_2 = \beta/4$, so $p(-1) = \beta(3/2 - 1 + 1/4) = 0.75\beta$. With $\lambda = 0.64$: $g_0 = 0.64\beta$, $g_1 = 0.64\beta/1.36$, $g_2 = 0.64\beta/1.72$, so $p(-1) = \beta(1.92 - 1.4118 + 0.3721) \approx 0.880\beta$. The

quadratic removes most of the attenuation but not all of it, and it does worse as the reliability falls.

Exercise B2.

A validation subsample of n_v patients has the true x measured along with (w, z) , and the main sample has only (w, z, y) . Describe regression calibration using the validation data. Which of the assumptions of [Proposition 24.5.1](#) does it need, and which does it avoid? Why does using the validation patients' x directly in the outcome regression not help if their y is not recorded?

24.5.4.3 C. Going deeper

Exercise C1.

Simulate a logistic regression $\Pr(Y = 1 \mid X) = 1/(1 + e^{-(\alpha + \beta X)})$ with $X \sim N(0, 1)$, $\beta = 1$, $n = 2000$, and a reading $W = X + U$ with $\sigma_u^2 = 0.5$. Compare the naive estimate, regression calibration ([Proposition 24.5.1](#): replace W by $E(X \mid W)$), and SIMEX with quadratic and rational extrapolants, over repeated samples. Which is closest to β ?

24.6 Summary and Notes

24.6.1 Summary

Idea.

1. Under classical, nondifferential error, least squares estimates the best linear predictor from the *reading*. A simple-regression slope is attenuated by the reliability λ , whatever n ([Theorem 24.1.1](#)).
2. Exactly measured covariates absorb part of the effect and can look important when they are not ([Example \(Age looks important\)](#)). Error in the response only adds variance ([Proposition 24.1.2](#)). The test of no effect of the mismeasured regressor keeps its level; tests on correlated, correctly measured covariates do not ([Proposition 24.1.3](#)).
3. Attenuation is the same with fixed true values ([Proposition 24.2.1](#)). The normal structural model identifies the slope only up to the interval between the direct and reverse regressions ([Proposition 24.2.2](#)). Berkson error causes no bias in a linear model ([Proposition 24.2.3](#)).
4. A known or replicate-estimated error covariance gives the moment correction, with a sandwich covariance ([Theorem 24.3.1](#)); a known variance ratio gives Deming regression ([Proposition 24.3.2](#)).
5. IV and two-stage least squares are consistent under exogeneity and relevance ([Lemma 24.4.1](#), [Theorem 24.4.2](#)); with weak instruments they have no mean, drift towards least squares, and Wald intervals undercover ([Proposition 24.4.3](#)).
6. Linear regression calibration is exact and equals the moment correction ([Proposi-](#)

tion 24.5.1). SIMEX extrapolates the naive estimate to zero error; in the linear model the rational form matches the limit exactly, so the rational extrapolant is consistent under regularity conditions for its fit ([Proposition 24.5.2](#)).

24.6.2 Notes and sources

Sources. None of the six source books treats errors in variables at length. Seber and Lee (2003, section 9.6) surveys random regressors, fixed regressors measured with error, the structural identification problem, rounding errors and Berkson’s model, covered here in [Theorem 24.1.1](#), [Proposition 24.2.1](#), [Proposition 24.2.2](#), [Exercise \(C1\)](#) and [Proposition 24.2.3](#). Fuller (1987) is the classical treatment of linear measurement error models, including moment estimators, their asymptotics and small-sample modifications. Carroll, Ruppert, Stefanski and Crainiceanu (2006) is the standard reference for nonlinear models, regression calibration and SIMEX, and discusses the choice of SIMEX extrapolant. All data in the chapter are simulated.

Attenuation and identification. Spearman (1904) introduced the correction for attenuation in mental testing. Reiersol (1950) proved that non-normality of the true regressor restores identification. The functional model’s incidental parameters are an instance of Neyman and Scott (1948). Gleser and Hwang (1987) proved that errors-in-variables confidence sets with guaranteed coverage have infinite expected length. Berkson (1950) distinguished controlled regressors from classical error.

Orthogonal and Deming regression. Orthogonal regression goes back to Adcock in the 1870s; the version with a known variance ratio carries Deming’s name from Deming (1943). In numerical analysis it is total least squares (Golub and Van Loan, 1980). Wald (1940) proposed the grouping estimator of [Exercise \(B1\)](#).

Instrumental variables. Instrumental variables go back to Wright (1928). Two-stage least squares was developed in the 1950s by Theil and by Basmann (1957), among others, and Sargan (1958) gave the general theory, including the test of overidentifying restrictions. Anderson and Rubin (1949) introduced the test of [Exercise \(C1\)](#). Bound, Jaeger and Baker (1995) showed the practical danger of weak instruments, and Staiger and Stock (1997) gave the asymptotics behind the first-stage F rule of thumb. Angrist and Pischke (2009) give a modern treatment, including the causal use of IV taken up in [Chapter 25](#).

Regression calibration and SIMEX. Regression calibration developed in epidemiology in the 1980s to correct relative risks for exposure measurement error. SIMEX is due to Cook and Stefanski (1994).

Chapter 25

Causal Interpretation of Coefficients

Earlier chapters treated a regression coefficient as a feature of a joint distribution. People who fit regressions usually want more: what would happen to the response if a regressor were *changed*, if a patient took the drug or a school hired more teachers. No amount of data on the undisturbed system answers that without further assumptions. This chapter states the assumptions and proves what they buy: potential outcomes and randomization, graphs and the back-door criterion for observational data, the bias from adjusting for mediators and colliders, and covariate adjustment in experiments, which can hurt unless the regression is interacted. This makes precise the warnings of [Section 5.7](#), of the remark after the Frisch–Waugh–Lovell theorem ([Section 6.6](#)) and of [Section 18.1](#).

What you need. 25.1 Prediction versus intervention

A regression of Y on X answers a question about *seeing*: among units in which $X = x$ was observed, what is Y typically? The answer is $E(Y \mid X = x)$, or its best linear approximation

$L(Y | X)$ (Theorem 6.11.1), which least squares estimates whatever produced the data (Proposition 6.11.3). A decision asks about *doing*: if X were set to x by an outside agent, what would Y typically be? This section makes the second question precise and shows, in the simplest model, that the answers differ, that more data do not close the gap, and that the better predictor can be the worse guide to action.

25.1.1 Structural causal models

A joint distribution says how variables co-vary, not which would move if another were changed. For that we need a model of the mechanism, a list of the processes that generate each variable. The following definition goes back to Wright (1921) and Haavelmo (1943).

Definition 25.1.1 — Structural causal model

Let $V_1, \dots, V_m$ be random variables. A **structural causal model** (SCM) for them consists of

- (a) for each j , a set $\text{pa}(j) \subseteq \{1, \dots, j-1\}$ of indices, the **parents** of V_j ;
- (b) for each j , a function f_j , and mutually independent random variables $U_1, \dots, U_m$, the **disturbances**, such that

$$V_j = f_j(V_{\text{pa}(j)}, U_j), \quad j = 1, \dots, m, \quad (25.1.1)$$

where $V_{\text{pa}(j)}$ is the vector of parents of V_j .

Each line of Eq. 25.1.1 is an **assignment**: it says how nature sets V_j , not merely that an equation holds. Solving the assignments in the order $j = 1, \dots, m$ writes every V_j as a function of $U_1, \dots, U_j$. For a variable $X = V_k$ and a value x , the **intervention** $\text{do}(X = x)$ replaces the k th assignment by $V_k = x$ and keeps every other assignment and every disturbance unchanged. The distribution of the variables in the modified model is the **interventional distribution**, and expectations under it are written $E(Y | \text{do}(X = x))$. The model is **linear** if each $f_j(\mathbf{v}, u) = c_j + \sum_{l \in \text{pa}(j)} b_{jl}v_l + u$ with constants c_j, b_{jl} , and disturbances with mean zero and finite variance.

Section 25.3 draws the parent sets as a graph. The substantive assumption is that an intervention changes one assignment and leaves the other mechanisms intact. Conditioning and intervening are then different operations: $E(Y | X = x)$ looks at the part of the *original* distribution where $X = x$ happened, while $E(Y | \text{do}(X = x))$ describes a *new* distribution in which $X = x$ was imposed.

25.1.2 A common cause

The simplest model in which the two differ has a background variable Z that influences both X and Y :

$$Z = c_Z + U_Z, \quad X = c_X + \alpha Z + U_X, \quad Y = c_Y + \theta X + \gamma Z + U_Y, \quad (25.1.2)$$

with independent disturbances of variances $\sigma_Z^2 > 0$, $\sigma_X^2 > 0$ and σ_Y^2 (Figure 25.1.1). The

coefficient θ is what the assignment for Y does with its argument X .

Figure 25.1.1. The model [Eq. 25.1.2](#). An arrow points from each parent to its child and is labelled with its coefficient. The dashed circle marks a variable that is not recorded in [Example \(Clinic visits and health\)](#).

Proposition 25.1.1 — Seeing and doing with a common cause

In the model [Eq. 25.1.2](#):

- (a) $E(Y \mid \text{do}(X = x)) = c_Y + \gamma c_Z + \theta x$, so the interventional slope is θ ;
- (b) the best linear predictor $L(Y \mid X)$ has slope

$$\beta^* = \theta + \frac{\gamma \alpha \sigma_Z^2}{\alpha^2 \sigma_Z^2 + \sigma_X^2}; \quad (25.1.3)$$

- (c) the coefficient of X in $L(Y \mid X, Z)$ is θ ;
- (d) if the disturbances are normal, $E(Y \mid X = x) = L(Y \mid X)$ evaluated at x , so the slopes of seeing and doing differ whenever $\gamma \alpha \neq 0$.

Proof.

- (a) Under $\text{do}(X = x)$ the assignment for Z is unchanged and does not involve X , so $Z = c_Z + U_Z$ still, and $Y = c_Y + \theta x + \gamma Z + U_Y$. Take expectations.
- (b) By [Theorem 6.11.1](#) the slope is $\text{Cov}(X, Y) / \text{Var}(X)$. Here $\text{Var}(X) = \alpha^2 \sigma_Z^2 + \sigma_X^2$ and $\text{Cov}(X, Y) = \theta \text{Var}(X) + \gamma \text{Cov}(X, Z) = \theta \text{Var}(X) + \gamma \alpha \sigma_Z^2$.
- (c) The error $Y - c_Y - \theta X - \gamma Z = U_Y$ has mean zero and is uncorrelated with X and Z , which are functions of U_Z and U_X . So $c_Y + \theta X + \gamma Z$ satisfies the population normal equations of [Theorem 6.11.1](#) and is the projection.
- (d) (X, Y) is a linear function of the normal vector (U_Z, U_X, U_Y) , hence bivariate normal, and its conditional mean is the best linear predictor ([Theorem 3.5.2](#)).

■

The extra term in [Eq. 25.1.3](#) is association that X borrows from Z . Part (c) is the familiar remedy, including the common cause as a regressor, and it needs Z to be recorded. [Section 25.4](#) says in general which variables must be included.

Example. (Clinic visits and health)

In a synthetic population, Z is the severity of a chronic illness, which nobody records; X is the number of clinic visits in a year; and Y is a health score measured at the end of the year. Sicker people visit more ($\alpha = 1.5$) and end the year less healthy ($\gamma = -6$),

Figure 25.1.1: The model of [Example \(Clinic visits and health\)](#). (a) Observational data: the fitted line slopes down. (b) Data in which the number of visits is set at random by the analyst: the same mechanism for Y , but now X carries no information about illness. The solid line is the observational fit in both panels; the dashed line has the causal slope $\theta = 2$.

and each visit helps ($\theta = 2$). With $\sigma_Z = \sigma_X = 1$ and $\sigma_Y = 2$, [Eq. 25.1.3](#) gives

$$\beta^* = 2 + \frac{(-6)(1.5)}{1.5^2 + 1} = 2 - \frac{9}{3.25} = -0.769.$$

In a sample of $n = 2000$ people the least squares slope is -0.790 : each extra visit goes with a *lower* health score. A second data set in which visits are assigned at random, which is an intervention on X , has least squares slope 1.999 ([Figure 25.1.2](#)). A health authority that capped visits on the strength of the first regression would harm its patients.

```
import numpy as np

rng = np.random.default_rng(2501)
n = 2000
alpha, theta, gamma = 1.5, 2.0, -6.0          # Z -> X, X -> Y, Z -> Y

def draw(n, do_x=None):
    """Draw from the model; with do_x, X is set by the analyst instead of by Z."""
    Z = rng.normal(size=n)                    # illness severity, never recorded
    X = 4 + alpha * Z + rng.normal(size=n) if do_x is None else do_x
    Y = 50 + theta * X + gamma * Z + rng.normal(scale=2.0, size=n)
    return X, Y

x_obs, y_obs = draw(n)                        # observational data
x_do = rng.uniform(x_obs.min(), x_obs.max(), size=n) # X assigned at random
x_int, y_int = draw(n, do_x=x_do)            # interventional data

slope_obs, icpt_obs = np.polyfit(x_obs, y_obs, 1)
slope_int, icpt_int = np.polyfit(x_int, y_int, 1)
print(f"slope from observational data: {slope_obs:.3f}")
print(f"slope from interventional data: {slope_int:.3f} (theta = {theta})")
```

25.1.3 A good predictor can be a bad causal model

The observational line in [Example \(Clinic visits and health\)](#) is the best linear predictor of health from visits in the population that generated the data, and the causal line, with slope θ through the same means, predicts *worse* there. On the observational data the fitted line has mean squared error 15.0 and the causal line 40.7, which is worse than predicting every person by the sample mean (the variance of Y is 17.1). On the interventional data the positions reverse: 123.3 for the fitted line and 39.2 for the causal line.

```
def mse(x, y, slope, icpt):
    return np.mean((y - icpt - slope * x) ** 2)

causal_icpt = np.mean(y_obs) - theta * np.mean(x_obs)  # causal slope, fitted level
for label, x, y in [("observational", x_obs, y_obs), ("interventional", x_int, y_int)]:
    print(f"{label:15s} MSE: regression line {mse(x, y, slope_obs, icpt_obs):6.2f}, "
          f" causal line {mse(x, y, theta, causal_icpt):6.2f}")
```

Observationally, any line through the means other than the projection loses exactly $(\text{slope} - \beta^*)^2 \text{Var}(X)$ ([Exercise \(B1\)](#)). Under intervention a large X no longer signals a large Z , so the part of the slope borrowed from Z becomes pure error: the causal line describes the mechanism both regimes share, the regression line a distribution that the intervention destroys.

Confounding by a common cause is one of three standard ways in which a predictor misleads about action. In **reverse causation** Y causes X , and X can predict Y perfectly while setting it does nothing ([Exercise \(B2\)](#)): a thermometer predicts the temperature, but moving its needle does not warm the room. In **selection** the data contain only units selected by a common effect of X and Y , which creates association without effect ([Section 25.5](#)).

More data do not help: the least squares slope converges to β^* , not θ ([Proposition 6.11.3](#)), and no procedure using only the distribution of (X, Y) can do better, because models with different θ can produce the same distribution ([Exercise \(B3\)](#)). Causal conclusions need either an intervention, as in panel (b) of [Figure 25.1.2](#), or assumptions about the mechanism that link the interventional distribution to the observational one.

25.1.4 When seeing is doing

Conditioning and intervening agree for every mechanism when nothing in the model influences X .

Proposition 25.1.2 — An exogenous cause

In a structural causal model, suppose $X = V_k$ has no parents, so that $X = f_k(U_k)$. Then a version of the conditional distribution of the other variables given $X = x$ is their distribution under $\text{do}(X = x)$; in particular, when $E|Y| < \infty$, $E(Y \mid X = x) = E(Y \mid \text{do}(X = x))$ for almost every x (with respect to the distribution of X), and for every x with $\Pr(X = x) > 0$.

Proof. Solve the assignments in order. Every variable is a function $h(X, \mathbf{U}_{-k})$ of X and the disturbances $\mathbf{U}_{-k}$ other than U_k , because U_k enters the other assignments only

through X . The same function describes the model under $\text{do}(X = x)$, with x in place of X , since only the k th assignment changed. Now $X = f_k(U_k)$ is independent of $\mathbf{U}_{-k}$, and for independent X and $\mathbf{U}_{-k}$ a version of the conditional distribution of $h(X, \mathbf{U}_{-k})$ given $X = x$ is the distribution of $h(x, \mathbf{U}_{-k})$ (Billingsley 1995), which is the interventional distribution.

■

A randomized experiment makes the treatment exogenous by construction: the random device is the only parent of X and influences nothing else, so what is seen is what would be done. [Section 25.2](#) turns this into exact finite-sample statements that need no structural model.

25.1.5 Exercises

25.1.5.1 A. Check your understanding

Exercise A1.

In the model [Eq. 25.1.2](#) with $\theta = 2$, $\gamma = -6$ and $\sigma_Z = \sigma_X = 1$, for which values of α is the observational slope β^* exactly zero? What would an analyst who saw $\beta^* = 0$ be tempted to conclude?

25.1.5.2 B. Practice

Exercise B1.

Let (x_i, y_i) , $i = 1, \dots, n$, be any data with least squares slope $\hat{\beta}$. For a number b , let $\ell_b(x) = \bar{y} + b(x - \bar{x})$ be the line with slope b through the means. Show that

$$\frac{1}{n} \sum_i (y_i - \ell_b(x_i))^2 = \frac{1}{n} \sum_i (y_i - \ell_{\hat{\beta}}(x_i))^2 + (b - \hat{\beta})^2 \frac{1}{n} \sum_i (x_i - \bar{x})^2,$$

and deduce the ordering of the two observational mean squared errors in [Example \(Clinic visits and health\)](#).

Solution. Write $y_i - \ell_b(x_i) = (y_i - \ell_{\hat{\beta}}(x_i)) + (\hat{\beta} - b)(x_i - \bar{x})$. The cross term is $(\hat{\beta} - b) \sum_i \hat{e}_i (x_i - \bar{x})$, where $\hat{e}_i$ are the least squares residuals. The residuals are orthogonal to $\mathbf{1}$ and to $\mathbf{x}$ ([Theorem 6.4.1](#)), so the cross term is zero, and squaring gives the identity. With $b = \theta = 2$ the causal line through the means loses $(2 - \hat{\beta})^2$ times the variance of the visits, which is why its mean squared error exceeds that of the fitted line. The script checks the identity to rounding error.

Exercise B2.

Let $Y = c + U_Y$ and $X = \delta Y + U_X$, with independent disturbances of variances σ_Y^2 and σ_X^2 . Find the slope of $L(Y | X)$, the squared correlation of X and Y , and $E(Y | \text{do}(X = x))$. Show that the squared correlation can be arbitrarily close to one while setting X has no effect on Y .

Exercise B3.

Take $c_Z = c_X = c_Y = 0$ in Eq. 25.1.2 with normal disturbances, and suppose only (X, Y) is observed. Show that the parameter values

$$(\alpha, \theta, \gamma, \sigma_Z^2, \sigma_X^2, \sigma_Y^2) = (1, 1, 0, 1, 1, 1) \quad \text{and} \quad (1, 0, \frac{4}{3}, \frac{3}{2}, \frac{1}{2}, \frac{1}{3})$$

give the same distribution of (X, Y) , although X has an effect on Y in the first model and none in the second.

Solution. Both distributions are bivariate normal with mean zero, so it suffices to compare covariance matrices, using $\text{Var}(X) = \alpha^2 \sigma_Z^2 + \sigma_X^2$, $\text{Cov}(X, Y) = \theta \text{Var}(X) + \gamma \alpha \sigma_Z^2$ and $\text{Var}(Y) = \theta^2 \text{Var}(X) + \gamma^2 \sigma_Z^2 + 2\theta \gamma \alpha \sigma_Z^2 + \sigma_Y^2$. In the first model these are 2, 2 and $2 + 1 = 3$. In the second they are $\frac{3}{2} + \frac{1}{2} = 2$, $\frac{4}{3} \cdot \frac{3}{2} = 2$ and $\frac{16}{9} \cdot \frac{3}{2} + \frac{1}{3} = 3$. The covariance matrices agree, so no function of the (X, Y) data can distinguish $\theta = 1$ from $\theta = 0$.

25.2 Potential outcomes and the regression coefficient

Whether a treatment works needs much less than a model of the whole mechanism. Each unit has two possible responses, with and without the treatment, and the effect on that unit is their difference. This language of potential outcomes, due to Neyman (1923) for field trials and extended to observational studies by Rubin (1974), needs no model for the responses, and under randomization it gives exact results. The regression coefficient of a treatment indicator is the natural estimator; its usual standard error is wrong in a specific way.

25.2.1 Potential outcomes

Definition 25.2.1 — Potential outcomes and average effects

Consider n units and a binary treatment. Unit i has two **potential outcomes**: $y_i(1)$, the response it would show if treated, and $y_i(0)$, the response it would show if not. With $T_i \in \{0, 1\}$ the treatment it actually receives, the observed response is

$$Y_i = T_i y_i(1) + (1 - T_i) y_i(0). \quad (25.2.1)$$

The **unit effect** is $\tau_i = y_i(1) - y_i(0)$, and the **average treatment effect** of the n units is

$$\tau = \frac{1}{n} \sum_{i=1}^n \tau_i = \bar{y}(1) - \bar{y}(0).$$

When the units are instead drawn at random from a population, so that $(Y(0), Y(1), T)$ is a random vector, the population **average treatment effect** is $E(Y(1) - Y(0))$ and the **average effect on the treated** is $E(Y(1) - Y(0) \mid T = 1)$.

Equation [Eq. 25.2.1](#) assumes that unit i 's response depends only on its own treatment (**no interference**, which fails for vaccines) and that there is one version of each treatment: Rubin's *stable unit treatment value assumption*. In a structural causal model, $Y(t)$ is the value of Y , as a function of the disturbances, in the model modified by $\text{do}(T = t)$, so $E Y(t) = E(Y \mid \text{do}(T = t))$. On the event $T = t$, solving the original and the modified assignments in order gives every variable the same value, so $Y = Y(t)$ there, which is [Eq. 25.2.1](#).

For each unit one potential outcome is observed and the other is **counterfactual**, so no unit effect is ever observed (Holland's (1986) fundamental problem of causal inference). Averages can still be estimated from *different* units, if treated and untreated units are comparable.

Proposition 25.2.1 — Selection bias

Let $(Y(0), Y(1), T)$ be random with finite means and $0 < \Pr(T = 1) < 1$. Then

$$E(Y \mid T = 1) - E(Y \mid T = 0) = E(Y(1) - Y(0) \mid T = 1) + [E(Y(0) \mid T = 1) - E(Y(0) \mid T = 0)]. \quad (25.2.2)$$

Proof. By [Eq. 25.2.1](#), $E(Y \mid T = 1) = E(Y(1) \mid T = 1)$ and $E(Y \mid T = 0) = E(Y(0) \mid T = 0)$. Add and subtract $E(Y(0) \mid T = 1)$. ■

The observed difference is the effect on the treated plus a **selection bias**, the difference between treated and untreated units in the response they would have shown untreated. In [Example \(Clinic visits and health\)](#) heavy users of the clinic would have been less healthy than light users even without their visits. The data on (T, Y) cannot reveal the bias, because $Y(0)$ is never observed for the treated.

25.2.2 Randomization

A **completely randomized experiment** treats n_1 of the n units, every subset of size n_1 being equally likely, and leaves the other $n_0 = n - n_1$ as controls. In Neyman's framework the potential outcomes are fixed numbers and the only randomness is the assignment: no linearity, normality or common variance is assumed, and the units need not be a sample from anything.

Write $\bar{Y}_1$ and $\bar{Y}_0$ for the mean observed responses of the treated and control units, s_1^2 and s_0^2 for their sample variances, and

$$S_t^2 = \frac{1}{n-1} \sum_{i=1}^n (y_i(t) - \bar{y}(t))^2, \quad S_\tau^2 = \frac{1}{n-1} \sum_{i=1}^n (\tau_i - \tau)^2$$

for the variances of the potential outcomes and of the unit effects over the n units. The treated units are a simple random sample from the n units, and the moments of such samples are as follows (compare [Lemma 18.4.3](#)).

Lemma 25.2.2 — Means of a simple random sample

Let $u_1, \dots, u_N$ and $v_1, \dots, v_N$ be fixed numbers with means $\bar{u}$, $\bar{v}$ and $S_{uv} = \sum_a (u_a - \bar{u})(v_a - \bar{v})/(N-1)$. If $\mathcal{S}$ is a simple random sample of m of the indices, $1 \leq m \leq N$, with sample means $\bar{u}_\mathcal{S}$ and $\bar{v}_\mathcal{S}$, then

$$E \bar{u}_\mathcal{S} = \bar{u}, \quad \text{Cov}(\bar{u}_\mathcal{S}, \bar{v}_\mathcal{S}) = \left(\frac{1}{m} - \frac{1}{N} \right) S_{uv}.$$

Proof. Let W_a indicate that $a \in \mathcal{S}$. Then $E W_a = m/N$, and for $a \neq c$, $E W_a W_c = m(m-1)/\{N(N-1)\}$. Hence $\text{Var } W_a = q$ and $\text{Cov}(W_a, W_c) = m(m-1)/\{N(N-1)\} - m^2/N^2 = -q/(N-1)$, where $q = (m/N)(1 - m/N)$. Put $\tilde{u}_a = u_a - \bar{u}$ and $\tilde{v}_a = v_a - \bar{v}$. Since $\sum_a W_a = m$, $\bar{u}_\mathcal{S} - \bar{u} = m^{-1} \sum_a W_a \tilde{u}_a$, whose mean is $N^{-1} \sum_a \tilde{u}_a = 0$. For the covariance,

$$m^2 \text{Cov}(\bar{u}_\mathcal{S}, \bar{v}_\mathcal{S}) = \sum_{a,c} \text{Cov}(W_a, W_c) \tilde{u}_a \tilde{v}_c = q \left(\sum_a \tilde{u}_a \tilde{v}_a - \frac{1}{N-1} \sum_{a \neq c} \tilde{u}_a \tilde{v}_c \right).$$

Because $\sum_a \tilde{u}_a = 0$, $\sum_{a \neq c} \tilde{u}_a \tilde{v}_c = -\sum_a \tilde{u}_a \tilde{v}_a$, and the bracket is $\sum_a \tilde{u}_a \tilde{v}_a N/(N-1) = N S_{uv}$. So the covariance is $q N S_{uv} / m^2 = (1/m - 1/N) S_{uv}$. ■

Theorem 25.2.3 — Randomization and the difference in means

In a completely randomized experiment with $n_1 \geq 1$ and $n_0 \geq 1$, let $\hat{\tau} = \bar{Y}_1 - \bar{Y}_0$.

- (a) $\hat{\tau}$ is unbiased for the average treatment effect: $E \hat{\tau} = \tau$.
- (b) Its variance over the randomization is

$$\text{Var}(\hat{\tau}) = \frac{S_1^2}{n_1} + \frac{S_0^2}{n_0} - \frac{S_\tau^2}{n}. \quad (25.2.3)$$

- (c) If $n_1, n_0 \geq 2$, the estimator $\hat{V} = s_1^2/n_1 + s_0^2/n_0$ has $E \hat{V} = \text{Var}(\hat{\tau}) + S_\tau^2/n \geq \text{Var}(\hat{\tau})$, with equality iff the unit effects are all equal.
- (d) $\hat{\tau}$ is the least squares coefficient of T in the regression of the observed responses on an intercept and the treatment indicator.
- (e) If instead the units are independent copies of $(Y(0), Y(1), T)$ with T independent of $(Y(0), Y(1))$, $0 < \Pr(T=1) < 1$ and finite means, then $E(Y | T=1) - E(Y | T=0) = E(Y(1) - Y(0))$, and the average effect on the treated equals the average treatment effect.

Proof. Let $\mathcal{S}$ be the set of treated units, a simple random sample of size n_1 . Then $\bar{Y}_1$ is the sample mean of the $y_i(1)$ over $\mathcal{S}$, and $\bar{Y}_0$ is the mean of the $y_i(0)$ over the complement.

- (a) The complement of $\mathcal{S}$ is a simple random sample of size n_0 . By [Lemma 25.2.2](#), $E \bar{Y}_1 = \bar{y}(1)$ and $E \bar{Y}_0 = \bar{y}(0)$.
- (b) Let $\bar{y}_\mathcal{S}(0)$ be the mean of the $y_i(0)$ over $\mathcal{S}$. The control mean is $\bar{Y}_0 = (n \bar{y}(0) - n_1 \bar{y}_\mathcal{S}(0)) / n_0$, so

$$\hat{\tau} = \bar{u}_S - \frac{n}{n_0} \bar{y}(0), \quad u_i = y_i(1) + \frac{n_1}{n_0} y_i(0). \quad (25.2.4)$$

By [Lemma 25.2.2](#), $\text{Var}(\hat{\tau}) = (1/n_1 - 1/n)S_u^2 = \{n_0/(nn_1)\}S_u^2$. Expanding, $S_u^2 = S_1^2 + (n_1/n_0)^2 S_0^2 + 2(n_1/n_0)S_{10}$, where S_{10} is the covariance of the two potential outcomes over the units, and $S_\tau^2 = S_1^2 + S_0^2 - 2S_{10}$. Eliminating S_{10} ,

$$S_u^2 = \frac{n}{n_0} S_1^2 + \frac{nn_1}{n_0^2} S_0^2 - \frac{n_1}{n_0} S_\tau^2,$$

and multiplying by $n_0/(nn_1)$ gives [Eq. 25.2.3](#).

- (c) The treated responses are a simple random sample of $n_1 \geq 2$ of the numbers $y_i(1)$, so $E s_1^2 = S_1^2$ by [Lemma 18.4.3](#); likewise $E s_0^2 = S_0^2$. Hence $E \hat{V} = S_1^2/n_1 + S_0^2/n_0$, which exceeds [Eq. 25.2.3](#) by S_τ^2/n . This is zero iff $\tau_i = \tau$ for every i .
- (d) This is [Proposition 5.4.4](#) with two groups and control as the reference.
- (e) By [Eq. 25.2.1](#) and independence, $E(Y \mid T = 1) = E(Y(1) \mid T = 1) = E Y(1)$, and likewise for $T = 0$. The same independence gives $E(Y(1) - Y(0) \mid T = 1) = E(Y(1) - Y(0))$.

■

Part (e) shows randomization removing the selection bias of [Eq. 25.2.2](#); part (a) needs no sampling model at all. The last term of (b) cannot be estimated, because it depends on how $y_i(1)$ is paired with $y_i(0)$ within units, which no unit reveals. Part (c) accepts a conservative answer, exact when the treatment adds the same amount to every unit.

Example. (All randomizations of twenty units)

A synthetic population of $n = 20$ units has $\tau = 2.100$, $S_1^2 = 12.129$, $S_0^2 = 5.678$ and $S_\tau^2 = 1.698$; the effect grows with $y_i(0)$. With $n_1 = 8$ there are 125970 assignments, few enough to enumerate. Over all of them $\hat{\tau}$ has mean 2.100 and variance 1.9043, which is [Eq. 25.2.3](#) to every digit. Neyman's $\hat{V}$ has mean 1.9892, too large by $S_\tau^2/n = 0.0849$. The pooled least squares variance estimate averages 1.7055, below the true variance, because it gives the more variable treated arm the weight of the smaller arm ([Exercise \(B1\)](#)). [Figure 25.2.1](#) shows the distribution of $\hat{\tau}$.

```
import itertools
import numpy as np

rng = np.random.default_rng(2502)
n, n1 = 20, 8
n0 = n - n1
y0 = np.round(rng.normal(10, 3, size=n), 1) # potential outcome
      , control
y1 = np.round(y0 + 2 + 0.5 * (y0 - 10) + rng.normal(0, 1, n), 1) # potential
      outcome, treated
tau = np.mean(y1 - y0) # the sample
      average effect
S1, S0, St = np.var(y1, ddof=1), np.var(y0, ddof=1), np.var(y1 - y0, ddof=1)
print(f"tau = {tau:.3f}; S1^2 = {S1:.3f}, S0^2 = {S0:.3f}, S_tau^2 = {St:.3f}")
```

```
idx = np.array(list(itertools.combinations(range(n), n1))) # every possible
```

Figure 25.2.1: The randomization distribution of the difference in means in [Example \(All randomizations of twenty units\)](#), over all 125970 assignments of 8 of the 20 units to treatment. The dashed line is τ ; the curve is the normal density with Neyman’s variance [Eq. 25.2.3](#).

```

    treated set
treated = np.zeros((len(idx), n), dtype=bool)
treated[np.arange(len(idx))[:, None], idx] = True                # one row per
    assignment                                                    # arm means, one
m1, m0 = (treated @ y1) / n1, (~treated @ y0) / n0              # difference in
    row per assignment                                           # means
diff = m1 - m0                                                    # within-arm
    means                                                        # variances
s1 = (treated @ y1 ** 2 - n1 * m1 ** 2) / (n1 - 1)
s0 = (~treated @ y0 ** 2 - n0 * m0 ** 2) / (n0 - 1)
V_hat = s1 / n1 + s0 / n0                                        # Neyman's
    variance estimate
V_neyman = S1 / n1 + S0 / n0 - St / n
print(f"{len(diff)} assignments")
print(f"mean of difference in means {diff.mean():.3f}    (tau = {tau:.3f})")
print(f"variance over assignments {diff.var():.4f}    (Neyman's formula {V_neyman:.4f})")
print(f"mean of variance estimate {V_hat.mean():.4f}    (excess S_tau^2/n = {St / n:.4f})")

```

Finite-population central limit theorems (Hájek 1960; Li and Ding 2017), whose proofs are beyond this chapter, make $(\hat{\tau} - \tau) / \sqrt{\widehat{\text{Var}} \hat{\tau}}$ asymptotically standard normal under conditions on the potential outcomes, so $\hat{\tau} \pm 1.96 \sqrt{\widehat{V}}$ has coverage at least 95% in the limit. In the example, with twenty units, it covers τ for a fraction 0.931 of the assignments.

25.2.3 What the regression coefficient estimates

By part (d), the least squares coefficient of T is unbiased for the average effect because of the design, not because the model $E(Y_i) = \beta_0 + \beta_1 T_i$ is true: its “errors” are not random draws and have different variances in the two arms. What the model gets wrong is the standard error. The pooled estimate of $\sigma^2(1/n_1 + 1/n_0)$ ([Theorem 5.5.1](#)) can be too small or too large when $n_1 \neq n_0$ ([Exercise \(B1\)](#)), while Neyman’s $\widehat{V}$ is exactly the HC2 sandwich estimate of [Chapter 21](#) ([Exercise \(B2\)](#), [Theorem 21.4.2](#)). Covariates measured before randomization can be added

to this regression to gain precision; [Section 25.6](#) shows how, and finds a surprise.

Remark (Fisher's sharp null). Fisher (1935) tested the *sharp* null $y_i(1) = y_i(0)$ for every unit, under which the randomization distribution of any statistic is known exactly. [Chapter 23](#) develops these permutation tests ([Theorem 23.4.2](#)).

25.2.4 Exercises

25.2.4.1 A. Check your understanding

Exercise A1.

Four units have potential outcomes $(y_i(0), y_i(1)) = (1, 4), (3, 3), (5, 9), (7, 8)$. Two are treated by complete randomization. List the six possible values of $\hat{\tau}$, and verify [Theorem 25.2.3](#)(a) and (b) directly.

Solution. The unit effects are 3, 0, 4, 1, so $\tau = 2$. For the treated pairs $\{1, 2\}, \{1, 3\}, \{1, 4\}, \{2, 3\}, \{2, 4\}, \{3, 4\}$ the treated means are 3.5, 6.5, 6, 6, 5.5, 8.5 and the control means 6, 5, 4, 4, 3, 2, giving $\hat{\tau} = -2.5, 1.5, 2, 2, 2.5, 6.5$. Their mean is $12/6 = 2 = \tau$. Their squared deviations from 2 sum to $20.25 + 0.25 + 0 + 0 + 0.25 + 20.25 = 41$, so $\text{Var } \hat{\tau} = 41/6$. The formula: $S_1^2 = 26/3$, $S_0^2 = 20/3$, $S_\tau^2 = 10/3$, and $(26/3)/2 + (20/3)/2 - (10/3)/4 = 46/6 - 5/6 = 41/6$.

25.2.4.2 B. Practice

Exercise B1.

Let $s_p^2 = \{(n_1 - 1)s_1^2 + (n_0 - 1)s_0^2\}/(n - 2)$ and $\hat{V}_{\text{OLS}} = s_p^2(1/n_1 + 1/n_0)$, the least squares variance estimate for the coefficient of T . Show that $\hat{V}_{\text{OLS}} = \hat{V}$ when $n_1 = n_0$, and that in general

$$\text{E } \hat{V}_{\text{OLS}} - \text{E } \hat{V} = \frac{(n - 1)(n_1 - n_0)(S_1^2 - S_0^2)}{n_1 n_0 (n - 2)}.$$

Conclude that when the smaller arm has the more variable potential outcomes, the least squares variance estimate is smaller on average than Neyman's, and it can be smaller than the true variance.

Solution. If $n_1 = n_0 = m$, then $s_p^2 = (s_1^2 + s_0^2)/2$ and $\hat{V}_{\text{OLS}} = s_p^2 \cdot 2/m = \hat{V}$. In general $\text{E } s_t^2 = S_t^2$ ([Lemma 18.4.3](#)), so $\text{E } \hat{V}_{\text{OLS}} = n\{(n_1 - 1)S_1^2 + (n_0 - 1)S_0^2\}/\{n_1 n_0 (n - 2)\}$. The coefficient of S_1^2 in $\text{E } \hat{V}_{\text{OLS}} - \text{E } \hat{V}$ is

$$\frac{n(n_1 - 1) - n_0(n - 2)}{n_1 n_0 (n - 2)} = \frac{n(n_1 - n_0) - (n_1 - n_0)}{n_1 n_0 (n - 2)} = \frac{(n - 1)(n_1 - n_0)}{n_1 n_0 (n - 2)},$$

using $n = n_1 + n_0$; by symmetry the coefficient of S_0^2 is its negative. If $n_1 < n_0$ and $S_1^2 > S_0^2$, the difference is negative. Since $\text{E } \hat{V}$ exceeds $\text{Var } \hat{\tau}$ only by S_τ^2/n , the least squares estimate underestimates the variance on average whenever the negative difference is larger than that. In [Example \(All randomizations of twenty units\)](#), $\text{E } \hat{V}_{\text{OLS}} = 1.7055$ while $\text{Var } \hat{\tau} = 1.9043$.

Exercise B2.

In the regression of the observed Y_i on $\mathbf{1}$ and the treatment indicator, the leverages are $h_{ii} = 1/n_1$ for treated units and $1/n_0$ for controls (Proposition 6.8.1). The HC2 estimate of $\text{Cov}(\hat{\beta})$ is $(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \text{diag}(\hat{e}_i^2 / (1 - h_{ii})) \mathbf{X} (\mathbf{X}^\top \mathbf{X})^{-1}$. Show that its entry for the coefficient of T is exactly Neyman's $\hat{V}$.

Solution. Reparameterize with the two arm indicators as columns, which changes neither the fit nor the estimate of the difference of the arm means (Proposition 5.7.1). Then $\mathbf{X}^\top \mathbf{X} = \text{diag}(n_1, n_0)$, the residuals are $Y_i - \bar{Y}_1$ and $Y_i - \bar{Y}_0$, and the sandwich is diagonal with entries $n_1^{-2} \sum_{\text{treated}} \hat{e}_i^2 / (1 - 1/n_1) = s_1^2 / n_1$ and similarly s_0^2 / n_0 . The variance of the difference of the two coefficients is their sum, $\hat{V}$.

25.2.4.3 C. Going deeper**Exercise C1.**

Show that $S_\tau^2 \geq (S_1 - S_0)^2$, and hence that

$$\text{Var}(\hat{\tau}) \leq \frac{S_1^2}{n_1} + \frac{S_0^2}{n_0} - \frac{(S_1 - S_0)^2}{n},$$

a bound that is attained when $y_i(1)$ is an increasing affine function of $y_i(0)$. Propose a conservative variance estimator that is never larger than $\hat{V}$.

25.3 Confounding and causal graphs

The functions and disturbances of a structural causal model are usually unknown; its parent sets, saying which variables can influence which, are qualitative and best displayed as a graph. This section shows how the graph constrains the joint distribution and identifies confounding as a property of paths. For linear models the connection is exact, and the omitted-variable bias of Proposition 5.7.2 becomes a sum over paths.

25.3.1 Graphs

Definition 25.3.1 — Directed acyclic graph

A **directed graph** on nodes $1, \dots, m$ is a set of ordered pairs (l, j) , $l \neq j$, drawn as arrows $l \rightarrow j$. It is **acyclic** (a DAG) if no sequence of arrows leads from a node back to itself. In a DAG:

- (a) l is a **parent** of j , and j a **child** of l , if $l \rightarrow j$;
- (b) a **path** between l and j is a sequence of distinct nodes, starting at l and ending at j , in which consecutive nodes are joined by an arrow in either direction;
- (c) a path is **directed** (from l to j) if every arrow on it points towards j ; then l is an **ancestor** of j , and j a **descendant** of l ;

- (d) an interior node c of a path is a **collider** on the path if both arrows of the path that meet at c point into it, $\rightarrow c \leftarrow$; every other interior node is a **non-collider** on the path.

The **graph of a structural causal model** has an arrow $l \rightarrow j$ iff $l \in \text{pa}(j)$. It is acyclic because parents have smaller indices.

Being a collider is a property of a node *on a given path*: in Figure 25.3.1(c), C is a collider on $X \rightarrow C \leftarrow Y$ but not on a path that continues along an arrow $C \rightarrow D$.

25.3.2 What the graph says about the distribution

Assume that for each j and each value $\mathbf{v}$ of the parents, the variable $f_j(\mathbf{v}, U_j)$ has a density $p_j(\cdot \mid \mathbf{v})$ with respect to Lebesgue or counting measure.

Proposition 25.3.1 — Markov factorization and truncated factorization

Under this assumption:

- (a) $(V_1, \dots, V_m)$ has density

$$p(v_1, \dots, v_m) = \prod_{j=1}^m p_j(v_j \mid v_{\text{pa}(j)}), \quad (25.3.1)$$

and $p_j(\cdot \mid v_{\text{pa}(j)})$ is the conditional density of V_j given $V_1, \dots, V_{j-1}$, which depends on them only through the parents;

- (b) under $\text{do}(V_k = x)$, the other variables have density $\prod_{j \neq k} p_j(v_j \mid v_{\text{pa}(j)})$, evaluated with $v_k = x$.

Proof.

- (a) The variables $V_1, \dots, V_{j-1}$ are functions of $U_1, \dots, U_{j-1}$, which are independent of U_j . For independent inputs, the conditional distribution of $f_j(V_{\text{pa}(j)}, U_j)$ given $(V_1, \dots, V_{j-1}) = (v_1, \dots, v_{j-1})$ is the distribution of $f_j(v_{\text{pa}(j)}, U_j)$ (Billingsley 1995), whose density is $p_j(\cdot \mid v_{\text{pa}(j)})$. The factorization follows by multiplying these conditional densities in the order $j = 1, \dots, m$.
- (b) The modified model is a structural causal model for the variables other than V_k , in which V_k is the constant x and every other assignment and disturbance is unchanged. Apply (a) to it.

■

So an intervention deletes one factor and keeps the others, which are observational conditional densities; with every variable observed, the interventional distribution is computable from the observational one.

The linear case has an explicit form. Write a linear model as $\mathbf{V} = \mathbf{c} + \mathbf{B}\mathbf{V} + \mathbf{U}$, where $\mathbf{B} = (b_{jl})$ has $b_{jl} \neq 0$ only if $l \in \text{pa}(j)$, so $\mathbf{B}$ is strictly lower triangular, and $\mathbf{\Omega} = \text{Cov}(\mathbf{U}) =$

$\text{diag}(\omega_1, \dots, \omega_m)$. The coefficient b_{jl} labels the arrow $l \rightarrow j$.

Proposition 25.3.2 — Path tracing

In a linear structural causal model:

- (a) $\mathbf{I} - \mathbf{B}$ is invertible, $\mathbf{V} = \mathbf{A}(\mathbf{c} + \mathbf{U})$ with $\mathbf{A} = (\mathbf{I} - \mathbf{B})^{-1}$, and $\text{Cov}(\mathbf{V}) = \mathbf{A}\mathbf{\Omega}\mathbf{A}^\top$;
- (b) for $j \neq l$, the entry a_{jl} of $\mathbf{A}$ is the sum, over all directed paths from l to j , of the products of the coefficients on the arrows of the path (zero if there is none), and $a_{jj} = 1$;
- (c) $E(V_j \mid \text{do}(V_l = x)) = E(V_j \mid \text{do}(V_l = 0)) + a_{jl}x$.

The number a_{jl} is the **total effect** of V_l on V_j : the change in the interventional mean of V_j per unit change in the value imposed on V_l .

Proof.

- (a) $\mathbf{I} - \mathbf{B}$ is unit lower triangular, hence invertible, and $(\mathbf{I} - \mathbf{B})\mathbf{V} = \mathbf{c} + \mathbf{U}$. The covariance follows from [Theorem 2.2.1](#).
- (b) $\mathbf{B}$ is strictly lower triangular, so $\mathbf{B}^m = \mathbf{0}$ and $(\mathbf{I} - \mathbf{B})(\mathbf{I} + \mathbf{B} + \dots + \mathbf{B}^{m-1}) = \mathbf{I} - \mathbf{B}^m = \mathbf{I}$. The (j, l) entry of $\mathbf{B}^r$ is $\sum b_{jk_1}b_{k_1k_2} \dots b_{k_{r-1}l}$ over all $k_1, \dots, k_{r-1}$; a term is nonzero only if $l \rightarrow k_{r-1} \rightarrow \dots \rightarrow k_1 \rightarrow j$ are arrows, which is a directed path of length r (its nodes are distinct because the graph is acyclic). Summing over r gives (b).
- (c) The intervened model is linear with $\mathbf{B}$ replaced by $\tilde{\mathbf{B}}$, in which row l is zero, and with $c_l + U_l$ replaced by x . A directed path out of l never uses an arrow into l , so the directed paths from l in the graph of $\tilde{\mathbf{B}}$ are those of $\mathbf{B}$, and by (b) the (j, l) entry of $(\mathbf{I} - \tilde{\mathbf{B}})^{-1}$ is a_{jl} . By (a) applied to the intervened model, V_j is $a_{jl}x$ plus terms not involving x .

■

This is Wright's method of path coefficients (Wright 1921, 1934); the covariance formula in (a) gives his rule for correlations ([Exercise \(C1\)](#)).

25.3.3 Chains, forks and colliders

Three configurations of three variables are the building blocks of everything the graph says about conditional independence ([Figure 25.3.1](#)).

Figure 25.3.1. The three structures of [Proposition 25.3.3](#). In (a) and (b) the middle node

transmits association between X and Y , and conditioning on it removes the association. In (c) the middle node transmits nothing until it is conditioned on.

Proposition 25.3.3 — Chains, forks and colliders

Consider linear models with independent disturbances, $\text{Var } U_X = \sigma_X^2 > 0$ and so on, and write $\sigma_{XY \cdot W}$ for the partial covariance of X and Y given W (Definition 3.6.1).

- (a) **Chain** $X = U_X$, $M = aX + U_M$, $Y = bM + U_Y$: $\text{Cov}(X, Y) = ab\sigma_X^2$ and $\sigma_{XY \cdot M} = 0$.
- (b) **Fork** $Z = U_Z$, $X = aZ + U_X$, $Y = bZ + U_Y$: $\text{Cov}(X, Y) = ab\sigma_Z^2$ and $\sigma_{XY \cdot Z} = 0$.
- (c) **Collider** $X = U_X$, $Y = U_Y$, $C = aX + bY + U_C$: $\text{Cov}(X, Y) = 0$ and

$$\sigma_{XY \cdot C} = -\frac{ab\sigma_X^2\sigma_Y^2}{a^2\sigma_X^2 + b^2\sigma_Y^2 + \sigma_C^2}. \quad (25.3.2)$$

With normal disturbances, a zero partial covariance means conditional independence (Proposition 3.6.1), so in (a) and (b) X and Y are dependent but conditionally independent given the middle node, and in (c) they are independent but, if $ab \neq 0$, conditionally dependent given C .

Proof. The covariances follow from Proposition 25.3.2(a). (a) $Y - bM = U_Y$ is uncorrelated with X and M , so $L(Y | M, X) = bM$ has no X term, and by Proposition 14.5.2 $\sigma_{XY \cdot M} = 0$. (b) The same argument with $Y - bZ = U_Y$. (c) By definition,

$$\sigma_{XY \cdot C} = \text{Cov}(X, Y) - \frac{\text{Cov}(X, C)\text{Cov}(Y, C)}{\text{Var}(C)} = 0 - \frac{(a\sigma_X^2)(b\sigma_Y^2)}{\text{Var}(C)}.$$

■

In the collider, independent causes become dependent once their common effect is held fixed. In the listing, with $a = b = 1$ and unit variances, the correlations of X and Y in the chain and the fork are 0.577 and 0.500 (simulated: 0.582 and 0.505), and both partial correlations given the middle node are zero. In the collider the correlation is zero and the partial correlation given C is -0.500 (simulated -0.501).

```
import numpy as np

rng = np.random.default_rng(2503)
n = 100_000
a, b = 1.0, 1.0                                     # the two edge coefficients

def corr_and_partial(x, y, w):
    """Correlation of x and y, and their partial correlation given w (residuals on
    1, w)."""
    W = np.column_stack([np.ones(len(w)), w])
    rx = x - W @ np.linalg.lstsq(W, x, rcond=None)[0]
    ry = y - W @ np.linalg.lstsq(W, y, rcond=None)[0]
    return np.corrcoef(x, y)[0, 1], np.corrcoef(rx, ry)[0, 1]

U = rng.normal(size=(3, n))
x = U[0]; m = a * x + U[1]; y = b * m + U[2]          # chain    X -> M -> Y
```

```

chain = corr_and_partial(x, y, m)
z = U[0]; x = a * z + U[1]; y = b * z + U[2]          # fork      X <- Z -> Y
fork = corr_and_partial(x, y, z)
x = U[0]; y = U[1]; c = a * x + b * y + U[2]          # collider  X -> C <- Y
collider = corr_and_partial(x, y, c)
for name, (r, rp) in [("chain", chain), ("fork", fork), ("collider", collider)]:
    print(f"{name:9s} corr {r:6.3f}    partial corr given middle {rp:6.3f}")

```

25.3.4 d-separation

In a larger graph association can travel along many paths at once; d-separation combines the three structures.

Definition 25.3.2 — d-separation

Let $\mathcal{Z}$ be a set of nodes. A path is **blocked** by $\mathcal{Z}$ if

- (i) some non-collider on the path is in $\mathcal{Z}$, or
- (ii) some collider on the path is not in $\mathcal{Z}$ and has no descendant in $\mathcal{Z}$.

Otherwise the path is **open** given $\mathcal{Z}$. Disjoint sets of nodes $\mathcal{A}$ and $\mathcal{B}$ are **d-separated** by $\mathcal{Z}$ (disjoint from both) if every path between a node of $\mathcal{A}$ and a node of $\mathcal{B}$ is blocked by $\mathcal{Z}$.

A path is open when each non-collider is left free and each collider is conditioned on, directly or through a descendant, a noisy measurement of it ([Exercise \(B1\)](#)).

Theorem 25.3.4 — d-separation and conditional independence

Let $\mathbf{V}$ follow a structural causal model with graph G , and let $\mathcal{A}, \mathcal{B}, \mathcal{Z}$ be disjoint sets of nodes.

- (a) If $\mathcal{Z}$ d-separates $\mathcal{A}$ and $\mathcal{B}$ in G , then $\mathbf{V}_{\mathcal{A}}$ and $\mathbf{V}_{\mathcal{B}}$ are conditionally independent given $\mathbf{V}_{\mathcal{Z}}$.
- (b) If $\mathcal{Z}$ does not d-separate them, there is a linear structural causal model on G with normal disturbances in which they are conditionally dependent; in fact this holds for all edge coefficients and disturbance variances outside a set of Lebesgue measure zero.

Proof. Sketch; full proofs are in the references. For (a) with densities (Lauritzen, Dawid, Larsen and Leimer 1990): the nodes of $\mathcal{A} \cup \mathcal{B} \cup \mathcal{Z}$ and their ancestors form a set $\mathcal{N}$ whose density, by [Proposition 25.3.1](#), is a product of functions of the sets $\{j\} \cup \text{pa}(j)$, $j \in \mathcal{N}$. These sets are complete in the *moral graph* on $\mathcal{N}$, which joins each node to its parents and any two parents of a common child. If $\mathcal{Z}$ separates $\mathcal{A}$ from $\mathcal{B}$ there, the factors split into two groups, giving the conditional independence; a combinatorial lemma shows that d-separation in G is equivalent to this separation. Geiger, Verma and Pearl (1990) give another proof. For (b), partial correlations of a linear normal model are rational functions of the parameters, not identically zero along an open path, and so vanish only

on a set of measure zero (Spirtes, Glymour and Scheines 2000).

■

Part (b) says the converse of (a) fails only by accident, as in [Exercise \(A1\)](#), where the effect of visits and the association through illness cancel exactly. Distributions with no such cancellation are called **faithful** to the graph.

25.3.5 Confounding as an open path

Definition 25.3.3 — Back-door paths and confounding

A **back-door path** from X to Y is a path between them whose arrow at X points into X , $X \leftarrow \cdots Y$. The effect of X on Y is **confounded** if some back-door path from X to Y is open given the empty set, that is, contains no collider.

Directed paths from X to Y carry the effect of X ; back-door paths carry association that reflects whatever caused X . In a linear model the split is exact.

Proposition 25.3.5 — Confounding bias in a linear model

In a linear structural causal model with disturbances of positive variance, let $X = V_k$, $Y = V_j$, and let $\tau = a_{jk}$ be the total effect of X on Y . For each l , let d_l be the sum over the directed paths from V_l to Y that do not pass through X of the products of coefficients (so $d_k = 0$, and $d_j = 1$ from the trivial path of Y to itself).

- (a) $Y = \tau X + R$, where $R = \sum_l d_l(c_l + U_l)$ is the value of Y under $\text{do}(X = 0)$. Under $\text{do}(X = x)$, $Y = \tau x + R$.
- (b) The slope of the best linear predictor $L(Y | X)$ is

$$\tau + \frac{\text{Cov}(R, X)}{\text{Var}(X)}, \quad \text{Cov}(R, X) = \sum_l \omega_l d_l a_{kl}. \quad (25.3.3)$$

- (c) If the effect of X on Y is not confounded, the slope of $L(Y | X)$ is τ .

Proof.

- (a) A directed path from V_l to Y either avoids X or passes through it exactly once, and a path of the second kind splits at X into a directed path from V_l to X and one from X to Y . Summing products over paths with [Proposition 25.3.2\(b\)](#), $a_{jl} = d_l + a_{kl}\tau$ for every l (for $l = k$, $a_{kk} = 1$ and $d_k = 0$; for $l = j$, $a_{jj} = 1 = d_j$ and $a_{kj} = 0$). Hence $Y = \sum_l a_{jl}(c_l + U_l) = \tau \sum_l a_{kl}(c_l + U_l) + R = \tau X + R$. Under $\text{do}(X = x)$, as in the proof of [Proposition 25.3.2\(c\)](#), the arrows into X are removed, so the directed paths from V_l , $l \neq k$, to Y in the intervened graph are exactly those that avoid X . Thus $Y = \tau x + \sum_{l \neq k} d_l(c_l + U_l) = \tau x + R$.
- (b) The slope is $\text{Cov}(X, Y) / \text{Var}(X) = \tau + \text{Cov}(R, X) / \text{Var}(X)$ by [Theorem 6.11.1](#), and $\text{Cov}(R, X) = \sum_{l, l'} d_l a_{kl'} \text{Cov}(U_l, U_{l'}) = \sum_l \omega_l d_l a_{kl}$, since the disturbances are uncorrelated.

- (c) Suppose $\omega_l d_l a_{kl} \neq 0$ for some l . Then $l \neq k$, and there are a directed path π_1 from V_l to X and a directed path π_2 from V_l to Y that avoids X . Let w be the node of π_1 closest to X that also lies on π_2 ; it exists because V_l lies on both, and $w \neq X$ because π_2 avoids X . Follow π_1 backwards from X to w , then π_2 forwards from w to Y . By the choice of w the nodes are distinct, so this is a path. Its arrow at X is the last arrow of π_1 , which points into X , and every arrow on it points away from w , so it has no collider. The effect is therefore confounded. Contrapositively, if it is not confounded, every term of $\text{Cov}(R, X)$ vanishes.

■

Part (a) is the potential outcome $Y(x) = \tau x + Y(0)$: linear structural models have constant effects. Part (b) writes the regression slope as the effect plus one contribution for each common ancestor of X and Y . In the model of [Figure 25.1.1](#), $R = c_Y + \gamma Z + U_Y$ and the only term comes from Z : $\omega da = \sigma_Z^2 \cdot \gamma \cdot \alpha$, which is [Eq. 25.1.3](#).

This is the omitted-variable bias of least squares: by [Proposition 5.7.2](#) the short regression estimates $\theta + \pi\gamma$, with π the sample slope of $\mathbf{z}$ on $\mathbf{x}$, whose limit is $\alpha\sigma_Z^2/\text{Var}(X)$ (see also [Theorem 19.1.2](#) in [Chapter 19](#)). The graph adds that an omitted variable causes bias only if it lies on an open back-door path; an omitted mediator should stay omitted ([Section 25.5](#)).

25.3.6 Exercises

25.3.6.1 A. Check your understanding

Exercise A1.

A DAG has arrows $A \rightarrow X$, $A \rightarrow B$, $B \rightarrow Y$, $X \rightarrow Y$, $X \rightarrow C$, $Y \rightarrow C$ and $D \rightarrow C$. List every path between X and Y , mark the back-door paths, and say which paths are open given $\emptyset$, given $\{B\}$ and given $\{C\}$.

Solution. There are three paths: $X \rightarrow Y$; $X \leftarrow A \rightarrow B \rightarrow Y$, a back-door path; and $X \rightarrow C \leftarrow Y$, with collider C . (The arrow $D \rightarrow C$ gives no path to Y except through C , where $D \rightarrow C \leftarrow Y$ would require revisiting C .) Given $\emptyset$: the first two are open and the third is blocked by the collider. Given $\{B\}$: only $X \rightarrow Y$ is open. Given $\{C\}$: all three are open, since conditioning on the collider opens the third.

25.3.6.2 B. Practice

Exercise B1.

Extend the collider by $D = C + U_D$, with $\text{Var } U_D = \delta$ and all other variances one. Compute $\sigma_{XY \cdot D}$ and show that it lies between 0 and $\sigma_{XY \cdot C}$, approaching them as $\delta \rightarrow \infty$ and $\delta \rightarrow 0$.

Solution. $\text{Cov}(X, D) = a$, $\text{Cov}(Y, D) = b$ and $\text{Var } D = a^2 + b^2 + 1 + \delta$, so $\sigma_{XY \cdot D} = -ab/(a^2 + b^2 + 1 + \delta)$. At $\delta = 0$ this is [Eq. 25.3.2](#), and it decreases in absolute value to zero as δ grows. A proxy for a collider opens the path partially, the more so the better the proxy.

25.3.6.3 C. Going deeper

Exercise C1.

Show from [Proposition 25.3.2\(a\)](#) that in a linear model $\text{Cov}(V_j, V_k) = \sum_l \omega_l a_{jl} a_{kl}$. Interpret each term as a sum over pairs of directed paths from V_l to V_j and to V_k , and use this to compute $\text{Cov}(X, Y)$ in the chain of [Proposition 25.3.3](#).

25.4 Adjustment sets and the back-door criterion

If confounding is association along back-door paths, the remedy is to block them by conditioning on variables on them, that is, by including those variables as regressors. This section says which sets do the job, proves that they do, and compares their precision.

25.4.1 The criterion

Definition 25.4.1 — Back-door criterion

Let X and Y be nodes of a DAG. A set $\mathcal{Z}$ of nodes, containing neither X nor Y , satisfies the **back-door criterion** relative to (X, Y) if

- (i) no node in $\mathcal{Z}$ is a descendant of X , and
- (ii) $\mathcal{Z}$ blocks every back-door path from X to Y ([Definition 25.3.3](#)).

Such a set is called a (back-door) **adjustment set**.

Condition (ii) closes the non-causal routes. Condition (i) protects the causal ones: a descendant of X may be a mediator, whose conditioning removes part of the effect, or a collider, whose conditioning opens a path ([Section 25.5](#)). The empty set qualifies exactly when the effect is not confounded, and the parents of X always qualify, provided Y is not one of them, since every back-door path begins $X \leftarrow P$ with P a parent and a non-collider. The graph itself is an assumption that the data cannot check ([Exercise \(B3\)](#)); the criterion turns it into a precise statement about which regression to run.

Recall from [Section 25.2](#) that $Y(x)$ is the value of Y in the model modified by $\text{do}(X = x)$, and that $Y = Y(x)$ on the event $X = x$. Conditional independence of $Y(x)$ and X given $\mathbf{Z}$ is the potential-outcome form of “no confounding given $\mathbf{Z}$ ”, which Rosenbaum and Rubin (1983), adding positivity, called *strong ignorability*.

Theorem 25.4.1 — Back-door adjustment

Let $\mathbf{V}$ follow a structural causal model with graph G , let X and Y be two of its variables, and let $\mathbf{Z}$ be the vector of the variables in a set $\mathcal{Z}$ of other nodes.

- (a) **Adjustment formula.** Suppose X takes finitely many values, $\Pr(X = x \mid \mathbf{Z}) > 0$ with probability one, $E|Y(x)| < \infty$, and $Y(x)$ is conditionally independent of X given $\mathbf{Z}$. Then

$$E(Y \mid \text{do}(X = x)) = E[E(Y \mid X = x, \mathbf{Z})], \quad (25.4.1)$$

where the outer expectation is over the distribution of $\mathbf{Z}$.

- (b) **The criterion gives ignorability.** If $\mathcal{Z}$ satisfies the back-door criterion relative to (X, Y) , then $Y(x)$ is conditionally independent of X given $\mathbf{Z}$, for every x .
- (c) **Linear models.** In a linear structural causal model whose disturbances have finite positive variances, if $\mathcal{Z}$ satisfies the back-door criterion, the coefficient of X in $L(Y \mid X, \mathbf{Z})$ is the total effect τ of X on Y . Consequently, for independent copies of $\mathbf{V}$, the least squares coefficient of X in the regression of Y on 1, X and $\mathbf{Z}$ converges to τ with probability one.

The proofs of (b) and (c) below are complete when $\mathcal{Z}$ contains every parent of X ; for general adjustment sets they are sketches, since the proof of (c) uses (b).

Proof.

- (a) Using the tower rule, then the conditional independence together with positivity, then $Y = Y(x)$ on $\{X = x\}$,

$$\begin{aligned} E Y(x) &= E[E(Y(x) \mid \mathbf{Z})] \\ &= E[E(Y(x) \mid X = x, \mathbf{Z})] = E[E(Y \mid X = x, \mathbf{Z})], \end{aligned}$$

and $E Y(x) = E(Y \mid \text{do}(X = x))$ by definition.

- (b) *When $\mathcal{Z}$ contains the parents of X .* Let $X = V_k$, and write $\mathbf{U}_{-k}$ for the disturbances other than U_k . A node that is not a descendant of X has no directed path from X , so solving the assignments shows that it is a function of $\mathbf{U}_{-k}$ alone; by (i), so is $\mathbf{Z}$. In the model modified by $\text{do}(X = x)$, the disturbance U_k appears nowhere, so $Y(x)$ is also a function of $\mathbf{U}_{-k}$. Hence U_k is independent of $(Y(x), \mathbf{Z})$, and given $\mathbf{Z}$ it remains independent of $Y(x)$, with its unconditional distribution. Finally $X = f_k(\mathbf{Z}_{\text{pa}}, U_k)$, where $\mathbf{Z}_{\text{pa}}$ is the part of $\mathbf{Z}$ formed by the parents of X . Given $\mathbf{Z}$, X is a function of U_k alone, and so is conditionally independent of $Y(x)$. *General adjustment sets (sketch).* Form a graph containing both the original variables and their counterparts in the model modified by $\text{do}(X = x)$, joined through shared disturbance nodes (a *twin network*); $Y(x)$ is a node of it, and X has no arrows into the counterpart variables. A path from X to $Y(x)$ that leaves X through a child of X must turn back somewhere, at the latest at a disturbance node shared with a counterpart variable, so it meets a collider that is a descendant of X ; by (i) neither that collider nor its descendants are in $\mathcal{Z}$, and the path is blocked. A path that leaves X through a parent starts like a back-door path, and one checks, using (ii) and again (i), that $\mathcal{Z}$ blocks it. So $\mathcal{Z}$ d-separates X from $Y(x)$, and [Theorem 25.3.4\(a\)](#) gives the conditional independence. Pearl (1995, 2009) gives the criterion and its proof in the language of interventions, and Shpitser, VanderWeele and Robins (2010) characterize exactly which sets satisfy [Eq. 25.4.1](#) for every model on G .
- (c) By [Proposition 25.3.5\(a\)](#), $Y = \tau X + R$, where R is the value of Y under $\text{do}(X = 0)$, that is, $R = Y(0)$. The variables R , X and $\mathbf{Z}$ are linear functions of the disturbances with coefficients determined by $\mathbf{B}$, so their covariance matrix depends

only on $\mathbf{B}$ and $\mathbf{\Omega}$. The covariance matrix of $(X, \mathbf{Z})$ is positive definite, because $\text{Cov}(\mathbf{V}) = \mathbf{A}\mathbf{\Omega}\mathbf{A}^\top$ with $\mathbf{A}$ invertible and $\mathbf{\Omega}$ positive definite. By [Proposition 14.5.2](#) the coefficient of X in $L(Y \mid X, \mathbf{Z})$ is

$$\frac{\sigma_{YX \cdot Z}}{\sigma_{XX \cdot Z}} = \tau + \frac{\sigma_{RX \cdot Z}}{\sigma_{XX \cdot Z}},$$

with $\sigma_{XX \cdot Z} > 0$. Consider the linear model with the same $\mathbf{B}$ and $\mathbf{\Omega}$ but normal disturbances. It has the same covariance matrix of $(R, X, \mathbf{Z})$, hence the same partial covariance $\sigma_{RX \cdot Z}$. In it $(R, X, \mathbf{Z})$ is jointly normal and, by (b), $R = Y(0)$ is conditionally independent of X given $\mathbf{Z}$, so $\sigma_{RX \cdot Z} = 0$ by [Proposition 3.6.1\(b\)](#). Therefore the coefficient is τ . (This step is complete when $\mathcal{Z}$ contains the parents of X , and otherwise inherits the sketch of (b).) The last statement is [Proposition 6.11.3](#). ■

Part (a) averages the conditional mean at $X = x$ over the population distribution of $\mathbf{Z}$, not over its distribution among units with $X = x$ (direct standardization), and needs positivity: where $X = x$ never occurs, the data say nothing about $E(Y \mid X = x, \mathbf{Z})$. Part (c) answers the question left open after the Frisch–Waugh–Lovell theorem: the multiple-regression coefficient of X in a linear model is the effect of changing X whenever the other regressors form an adjustment set.

Warning. Only the coefficient of X acquires a causal meaning. The coefficients of the adjustment variables are generally not their effects, because X may mediate them; reporting them as effects is the “Table 2 fallacy” (Westreich and Greenland 2013), computed in [Exercise \(B2\)](#).

25.4.2 An example with eight variables

Example. (Choosing an adjustment set)

[Figure 25.4.1](#) shows a linear model with unit-variance disturbances and

$$\begin{aligned} W_2 &= 0.8W_1 + U, & X &= 0.7W_1 + 0.6W_3 + 0.9I + U, & M &= 0.8X + U, \\ Y &= 0.5X + 0.6M + 0.7W_2 + 0.8W_3 + P + U, \end{aligned}$$

with a separate disturbance U in each equation and W_1, W_3, I, P parentless. Summing over the two directed paths, $\tau = 0.5 + 0.8 \times 0.6 = 0.98$. The back-door paths $X \leftarrow W_1 \rightarrow W_2 \rightarrow Y$ and $X \leftarrow W_3 \rightarrow Y$ are blocked by W_1 or W_2 , and by W_3 , and M is a descendant of X . So a set is valid iff it contains W_3 and one of W_1, W_2 , and not M ; I and P are optional.

The listing computes the coefficient of X in $L(Y \mid X, \mathbf{Z})$ exactly from $\text{Cov}(\mathbf{V}) = \mathbf{A}\mathbf{A}^\top$, with the factor $\sigma_{Y \cdot XZ}/\sigma_{X \cdot Z}$ that governs precision (see below), and the standard deviation over 4000 simulated samples of size $n = 500$:

adjustment set	valid	coefficient of X	$\sigma_{Y \cdot XZ}/\sigma_{X \cdot Z}$	simulated sd
none	no	1.308	1.15	0.052
W_3	no	1.150	1.16	0.052

W_1, W_3	yes	0.980	1.25	0.056
W_2, W_3	yes	0.980	1.06	0.047
W_2, W_3, P	yes	0.980	0.80	0.036
W_1, W_3, I	yes	0.980	1.69	0.076
W_1, W_3, M	no	0.500	1.72	0.077
W_1, W_2, W_3, I, P	yes	0.980	1.17	0.052

Every valid set gives τ ; the invalid sets leave a back-door path open or, with M , keep only the direct effect 0.5. Among valid sets the standard deviation varies by a factor of two (Figure 25.4.2).

Figure 25.4.1. The graph of Example (Choosing an adjustment set). Blue arrows form the directed paths from X to Y ; brown arrows form the two back-door paths. I influences only X , and P only Y .

```
import numpy as np

names = ["W1", "W3", "I", "P", "W2", "X", "M", "Y"]      # a topological order

```

25.4.3 Which adjustment set is most precise

All valid sets estimate τ , so the choice among them is a question of variance. With normal disturbances, Y given $(X, \mathbf{Z})$ follows a linear model with variance $\sigma_{Y \cdot XZ}^2$, and given the regressors the coefficient of X has variance $\sigma_{Y \cdot XZ}^2 / \|(\mathbf{I} - \mathbf{M}_Z)\mathbf{x}\|^2$, where $\mathbf{M}_Z$ projects onto the span of $\mathbf{1}$ and the columns of $\mathbf{Z}$ ([Theorem 6.6.2](#) and [Eq. 6.6.2](#)). Divided by n , the squared length in the denominator is the residual mean square of the regression of X on $\mathbf{Z}$, which converges to $\sigma_{X \cdot Z}^2$ with probability one ([Proposition 6.11.3](#)). So n times the variance tends to

$$v(\mathcal{Z}) = \frac{\sigma_{Y \cdot XZ}^2}{\sigma_{X \cdot Z}^2}, \quad (25.4.2)$$

the square of the factor in the table. A good adjustment set explains much of Y and little of X .

Proposition 25.4.2 — Adding a variable to an adjustment set

Let $\mathcal{Z}$ and $\mathcal{Z} \cup \{W\}$ both satisfy the back-door criterion, with all covariance matrices positive definite.

- (a) If $\sigma_{YW \cdot XZ} = 0$, then $v(\mathcal{Z} \cup \{W\}) \geq v(\mathcal{Z})$.
- (b) If $\sigma_{XW \cdot Z} = 0$, then $v(\mathcal{Z} \cup \{W\}) \leq v(\mathcal{Z})$.

Proof. Partial variances are the mean squared errors of best linear predictors, and projecting onto a larger space can only reduce them ([Theorem 2.5.2\(c\)](#)). (a) By [Proposition 14.5.2](#) applied with $(X, \mathbf{Z})$ as conditioning variables, $\sigma_{YW \cdot XZ} = 0$ means that W has coefficient zero in $L(Y \mid X, \mathbf{Z}, W)$, so this predictor equals $L(Y \mid X, \mathbf{Z})$ and the numerator of [Eq. 25.4.2](#) is unchanged; the denominator can only decrease. (b) Likewise $\sigma_{XW \cdot Z} = 0$ means $L(X \mid \mathbf{Z}, W) = L(X \mid \mathbf{Z})$, so the denominator is unchanged, while the numerator can only decrease. ■

In [Example \(Choosing an adjustment set\)](#), a direct computation from $\text{Cov}(\mathbf{V}) = \mathbf{A}\mathbf{A}^\top$ gives $\sigma_{YI \cdot XW_1W_3} = 0$ and $\sigma_{XP \cdot W_2W_3} = 0$: the pure cause I of X satisfies (a) and the pure cause P of Y satisfies (b). Accordingly, adding I to $\{W_1, W_3\}$ raises the factor from 1.25 to 1.69; adding P to $\{W_2, W_3\}$ lowers it from 1.06 to 0.80. Replacing W_1 by W_2 , closer to Y on the back-door path, also helps. Henckel, Perković and Maathuis (2022) turn these observations into a graphical rule for the valid set of smallest asymptotic variance in linear models: roughly, the parents of Y and of the mediators, other than the mediators and X .

If every adjustment set contains an unrecorded variable, as in [Example \(Clinic visits and health\)](#), other structure must be used: an instrumental variable ([Theorem 24.4.2](#) in [Chapter 24](#)), or the front-door criterion of Pearl (1995), which uses an observed mediator; or a sensitivity analysis asks how strong an unobserved confounder would have to be, using formulas such as [Eq. 25.3.3](#).

25.4.4 Exercises

25.4.4.1 A. Check your understanding

Exercise A1.

In [Example \(Choosing an adjustment set\)](#), decide which of $\{W_1, W_2\}$, $\{W_3, P\}$ and $\{W_2, W_3, M\}$ satisfy the back-door criterion, and explain the coefficients of X that the listing gives for them: 1.201, 1.150 and 0.500.

Solution. None does. $\{W_1, W_2\}$ leaves $X \leftarrow W_3 \rightarrow Y$ open, and $\{W_3, P\}$ leaves $X \leftarrow W_1 \rightarrow W_2 \rightarrow Y$ open, so both coefficients exceed $\tau = 0.98$. The set $\{W_2, W_3, M\}$ blocks both back-door paths but contains the mediator M , violating (i); holding M fixed leaves only the direct arrow, with coefficient 0.5.

25.4.4.2 B. Practice

Exercise B1.

Let $X \in \{0, 1\}$ and let Z take values $1, \dots, K$. In a sample, stratum z has n_z units, a fraction $\hat{p}_z \in (0, 1)$ of them with $X = 1$, and difference of mean responses $\hat{\delta}_z = \bar{y}_{1z} - \bar{y}_{0z}$. Show that the sample version of [Eq. 25.4.1](#) for the effect $E(Y \mid \text{do}(X = 1)) - E(Y \mid \text{do}(X = 0))$ is $\sum_z (n_z/n) \hat{\delta}_z$, while the coefficient of X in the least squares regression of

Y on X and the K stratum indicators is

$$\hat{\beta}_X = \frac{\sum_z n_z \hat{p}_z (1 - \hat{p}_z) \hat{\delta}_z}{\sum_z n_z \hat{p}_z (1 - \hat{p}_z)}.$$

When do they agree?

Solution. Replacing $E(Y \mid X = x, Z = z)$ by $\bar{y}_{xz}$ and the distribution of Z by the sample fractions n_z/n gives the first expression. For the second, apply [Theorem 6.6.2](#) with $\mathbf{X}_2$ the stratum indicators. Projecting onto their span replaces each value by its stratum mean ([Example \(The one-way layout\)](#)), so $\tilde{x}_i = x_i - \hat{p}_{z(i)}$. Then $\hat{\beta}_X = \sum_i \tilde{x}_i y_i / \sum_i \tilde{x}_i^2$. Within stratum z , $\sum_i \tilde{x}_i^2 = n_z \hat{p}_z (1 - \hat{p}_z)$ and $\sum_i \tilde{x}_i y_i = n_z \hat{p}_z (1 - \hat{p}_z) (\bar{y}_{1z} - \bar{y}_{0z})$, since the treated contribute $(1 - \hat{p}_z) n_z \hat{p}_z \bar{y}_{1z}$ and the untreated $-\hat{p}_z n_z (1 - \hat{p}_z) \bar{y}_{0z}$. The two agree when the $\hat{\delta}_z$ are all equal or when $\hat{p}_z$ is the same in every stratum. Otherwise the regression weights strata by the variance of X within them, not by their size, and estimates a weighted average effect that is not the average effect (Angrist 1998).

Exercise B2.

In [Example \(Choosing an adjustment set\)](#), show that the coefficient of W_3 in $L(Y \mid X, W_1, W_3)$ is 0.80, the coefficient of the arrow $W_3 \rightarrow Y$, while the total effect of W_3 on Y is 1.388. Which set of variables would one adjust for to estimate the effect of W_3 ?

Solution. Write $Y = 0.5X + 0.6(0.8X + U_M) + 0.7(0.8W_1 + U_{W_2}) + 0.8W_3 + P + U_Y = 0.98X + 0.56W_1 + 0.8W_3 + E$, where $E = 0.6U_M + 0.7U_{W_2} + P + U_Y$ is uncorrelated with X , W_1 and W_3 (none of these depends on the disturbances in E). So $L(Y \mid X, W_1, W_3) = 0.98X + 0.56W_1 + 0.8W_3$. The total effect of W_3 is the sum over its directed paths to Y : 0.8 directly plus 0.6×0.98 through X , which is 1.388. The coefficient in the regression misses the part that goes through X , because X is held fixed. W_3 has no parents and no back-door paths, so the empty set is an adjustment set for its effect: the simple regression of Y on W_3 estimates 1.388.

Exercise B3.

Suppose X is randomized, so it has no parents, and P is a pre-treatment cause of Y . Show that both $\emptyset$ and $\{P\}$ are adjustment sets and that $v(\{P\}) = (1 - \rho_{Y P \cdot X}^2) v(\emptyset)$, where $\rho_{Y P \cdot X}$ is the partial correlation of Y and P given X . Compare with [Proposition 18.1.2](#).

25.5 Bad controls: mediators and colliders

A regression that “controls for” many variables is not better for it. A control helps when it blocks a back-door path, costs at most precision when it lies on no path, and does harm when it lies on the causal path or when conditioning on it opens a closed path. Angrist and Pischke (2009) call the last two kinds **bad controls**. This section computes the damage in the linear models of [Figure 25.5.1](#) and describes the related bias from selecting the sample on a collider.

Figure 25.5.1. Three bad controls C (shaded). (a) C is a mediator. (b) C is a common effect of X and Y . (c) C is measured before X but is a collider on the back-door path through the unrecorded H_1 and H_2 .

25.5.1 Three computations

Theorem 25.5.1 — Bad controls in linear models

In each model below the disturbances U_X, U_Y, U_C (and, in (c), the unrecorded variables H_1, H_2) are independent with mean zero and variances $\sigma_X^2, \sigma_Y^2, \sigma_C^2 > 0$ (and 1). Let τ be the total effect of X on Y . In every case the slope of $L(Y | X)$ equals τ , so the simple regression is consistent, while the coefficient $\beta_{X|C}$ of X in $L(Y | X, C)$ is as follows.

- (a) **Mediator:** $X = U_X$, $C = \delta X + U_C$, $Y = \theta X + \gamma C + U_Y$. Here $\tau = \theta + \gamma\delta$ and $\beta_{X|C} = \theta$: adjustment removes the indirect effect $\gamma\delta$.
- (b) **Common effect:** $X = U_X$, $Y = \tau X + U_Y$, $C = aX + bY + U_C$. Then

$$\beta_{X|C} = \tau - \frac{(a + b\tau) b \sigma_Y^2}{b^2 \sigma_Y^2 + \sigma_C^2}. \quad (25.5.1)$$

- (c) **M-structure:** $X = aH_1 + U_X$, $C = c_1H_1 + c_2H_2 + U_C$, $Y = \tau X + bH_2 + U_Y$. Then

$$\beta_{X|C} = \tau - \frac{a b c_1 c_2}{D}, \quad (25.5.2)$$

$$D = (a^2 + \sigma_X^2)(c_1^2 + c_2^2 + \sigma_C^2) - a^2 c_1^2 > 0.$$

Proof.

- (a) $Y - \theta X - \gamma C = U_Y$ is uncorrelated with X and C , so $L(Y | X, C) = \theta X + \gamma C$. Without C , $Y = (\theta + \gamma\delta)X + (\gamma U_C + U_Y)$, and the bracket is uncorrelated with X , so the slope is τ .
- (b) Without C , U_Y is uncorrelated with X and the slope is τ . With C , write $E = C - (a + b\tau)X = bU_Y + U_C$, which is uncorrelated with X . The span of $1, X, C$ is the span of $1, X, E$, with E orthogonal to 1 and X , so $L(U_Y | X, C) = L(U_Y | X) + L(U_Y | E) = 0 + \lambda E$, where $\lambda = \text{Cov}(U_Y, E) / \text{Var}(E) = b\sigma_Y^2 / (b^2\sigma_Y^2 + \sigma_C^2)$. Hence $L(Y | X, C) = \tau X + \lambda C - \lambda(a + b\tau)X$, whose coefficient of X is Eq. 25.5.1.
- (c) Without C , $bH_2 + U_Y$ is uncorrelated with X and the slope is τ . With C , $L(Y | X, C) = \tau X + bL(H_2 | X, C)$, since U_Y is uncorrelated with X and C . The coefficients of $L(H_2 | X, C)$ solve the population equations of Theorem 6.11.1,

with covariance matrix of (X, C) equal to

$$\begin{pmatrix} a^2 + \sigma_X^2 & ac_1 \\ ac_1 & c_1^2 + c_2^2 + \sigma_C^2 \end{pmatrix}$$

and right-hand side $(\text{Cov}(X, H_2), \text{Cov}(C, H_2)) = (0, c_2)$. The determinant is D , positive since the matrix is a positive definite covariance matrix, and the first coefficient is $-ac_1c_2/D$. Multiply by b .

■

In (a) the adjusted coefficient is the **direct effect**, with the mediator held fixed by intervention. That may be of interest, but only if nothing confounds the mediator and the outcome ([Exercise \(B2\)](#)); a policy decision needs τ ([Section 18.1](#) gave the experimental version).

In (b) the bias exists even when $\tau = 0$: adjusting for a consequence of both variables produces an “effect” $-ab\sigma_Y^2/(b^2\sigma_Y^2 + \sigma_C^2)$ where there is none, negative when a and b have the same sign. This is the collider of [Proposition 25.3.3\(c\)](#).

In (c) the control is measured before X , so the advice to adjust only for pre-treatment variables does not exclude it, yet adjustment opens the back-door path $X \leftarrow H_1 \rightarrow C \leftarrow H_2 \rightarrow Y$. This **M-bias**, named after the graph’s shape, was pointed out by Greenland, Pearl and Robins (1999). It is a product of four path coefficients over D and tends to be small unless all four are large (Ding and Miratrix 2015). When the collider is also a confounder, with arrows $C \rightarrow X$ and $C \rightarrow Y$, neither choice removes the bias; Ding and Miratrix call this butterfly bias.

Example. (Three bad controls by simulation)

Take, with unit variances throughout:

- a mediator with $\theta = 0.5$, $\delta = 1.2$, $\gamma = 1$, so that $\tau = 1.7$ and $\beta_{X|C} = 0.5$;
- a common effect with $\tau = 1$, $a = 0.5$, $b = 1$, for which [Eq. 25.5.1](#) gives $\beta_{X|C} = 1 - (1.5)(1)/2 = 0.25$;
- an M-structure with $\tau = 1$ and $a = b = c_1 = c_2 = 1.5$, for which $D = \frac{13}{4} \cdot \frac{11}{2} - \frac{81}{16} = \frac{205}{16} = 12.8125$ and $\beta_{X|C} = 1 - \frac{81}{205} = 0.605$.

Over 4000 samples of $n = 400$, the least squares coefficients of X without and with C average 1.700 and 0.499 for the mediator, 1.000 and 0.251 for the common effect, and 0.999 and 0.605 for the M-structure ([Figure 25.5.2](#)). In the M-structure the adjusted estimate is also slightly *less* variable (standard deviation 0.046 against 0.050), a reminder that a smaller standard error says nothing about bias.

```
import numpy as np

rng = np.random.default_rng(2505)

def mediator(n):
    # X -> C -> Y and X -> Y; total effect 0.5 + 1.2 * 1.0 = 1.7
    x = rng.normal(size=n); c = 1.2 * x + rng.normal(size=n)
    return x, c, 0.5 * x + 1.0 * c + rng.normal(size=n)

def collider(n):
    # X -> Y, and X -> C <- Y; total effect 1
    x = rng.normal(size=n); y = 1.0 * x + rng.normal(size=n)
```

Figure 25.5.1: Sampling distributions of the least squares coefficient of X without (blue) and with (brown) adjustment for C , in the three models of [Example \(Three bad controls by simulation\)](#); 4000 samples of size 400. The dashed line is the total effect τ .

```

return x, 0.5 * x + 1.0 * y + rng.normal(size=n), y

def m_bias(n):
    # X <- H1 -> C <- H2 -> Y, and X -> Y; total effect 1
    h1, h2 = rng.normal(size=(2, n))
    x = 1.5 * h1 + rng.normal(size=n)
    c = 1.5 * h1 + 1.5 * h2 + rng.normal(size=n)
    return x, c, 1.0 * x + 1.5 * h2 + rng.normal(size=n)

def slopes(x, c, y):
    """Coefficient of x without and with adjustment for c."""
    one = np.ones(len(x))
    b_short = np.linalg.lstsq(np.column_stack([one, x]), y, rcond=None)[0][1]
    b_long = np.linalg.lstsq(np.column_stack([one, x, c]), y, rcond=None)[0][1]
    return b_short, b_long

```

```

n, reps = 400, 500
for name, model in [("mediator", mediator), ("collider", collider), ("M-bias",
    m_bias)]:
    est = np.array([slopes(*model(n)) for _ in range(reps)])
    print(f"{name:9s} mean without C {est[:, 0].mean():.3f}    mean with C {est[:,
    1].mean():.3f}")

```

25.5.2 Post-treatment variables in general

A variable affected by X removes part of the effect if it lies on a directed path to Y , and opens a path if Y or a cause of Y also affects it; its descendants act partially ([Exercise \(B1\)](#)). A descendant of X with no other connection to Y costs only precision ([Exercise \(B1\)](#)). “Adjust only for pre-treatment variables” is sound in randomized experiments ([Section 25.6](#)); in observational data it is neither sufficient, by the M-structure, nor necessary, since a later measurement can proxy an unrecorded confounder. The graph, not the timing, decides. Adjusting for a pure cause of X can even *increase* the bias from an unrecorded confounder ([Exercise \(B3\)](#)); Pearl (2010) calls such variables bias amplifiers.

25.5.3 Selection on a collider

A sample selected on a common effect of X and Y is conditioned on a collider without any adjustment. Berkson (1946) saw two diseases, independent in the population, associated among hospital patients, since either brings a patient to hospital; Elwert and Winship (2014) survey this *endogenous selection bias*. In the common-effect model of [Example \(Three bad controls by simulation\)](#), observing only the units with $C > 1$ (about 0.31 of them) moves the slope of Y on X from 1.002 to 0.584.

```
x, c, y = collider(200_000)
keep = c > 1                                # only units with a large C
                                         are observed
slope_all = np.polyfit(x, y, 1)[0]
slope_sel = np.polyfit(x[keep], y[keep], 1)[0]
print(f"slope of Y on X: all units {slope_all:.3f}, units with C > 1 {slope_sel:.3f}")
```

Warning. A variable belongs in a causal regression because of its position in the graph, not because it improves R^2 or is “significant”; predictive model selection ([Chapter 29](#)) readily selects mediators and colliders.

25.5.4 Exercises

25.5.4.1 A. Check your understanding

Exercise A1.

A study of the effect of a training programme (X) on earnings two years later (Y) considers adjusting for: (i) education before the programme; (ii) the job obtained six months after the programme; (iii) whether the person was still living in the region at the end of the study, which depends on both training and earnings; (iv) the day of the week on which the person applied. Classify each as a confounder, mediator, collider or irrelevant, under a plausible graph, and say which should be adjusted for.

25.5.4.2 B. Practice

Exercise B1.

Let $X = U_X$, $Y = \tau X + U_Y$ and $D = dX + U_D$, where D is affected by X but has no connection with Y . Show that the coefficient of X in $L(Y | X, D)$ is τ , and that the asymptotic variance of the least squares coefficient is larger with D than without it by the factor $(d^2\sigma_X^2 + \sigma_D^2)/\sigma_D^2$.

Exercise B2.

In the mediator model add an unrecorded U , with variance σ_U^2 , that affects both the

mediator and the outcome: $C = \delta X + gU + U_C$, $Y = \theta X + \gamma C + hU + U_Y$. Show that

$$\beta_{X|C} = \theta - \frac{\delta g h \sigma_U^2}{g^2 \sigma_U^2 + \sigma_C^2},$$

so that adjusting for the mediator does not even recover the direct effect θ .

Solution. $Y = \theta X + \gamma C + hU + U_Y$ and U_Y is uncorrelated with (X, C) , so $\beta_{X|C} = \theta + h\kappa$, where κ is the coefficient of X in $L(U | X, C)$. Put $E = C - \delta X = gU + U_C$, uncorrelated with X . As in the proof of [Theorem 25.5.1\(b\)](#), $L(U | X, C) = L(U | E) = \lambda(C - \delta X)$ with $\lambda = g\sigma_U^2/(g^2\sigma_U^2 + \sigma_C^2)$, so $\kappa = -\lambda\delta$. The mediator is a collider on the path $X \rightarrow C \leftarrow U \rightarrow Y$, which adjustment opens.

Exercise B3.

Let U be unrecorded, $X = \pi I + gU + U_X$ and $Y = \tau X + hU + U_Y$, with I, U, U_X, U_Y independent, $\text{Var } I = \text{Var } U = 1$ and $\text{Var } U_X = \sigma^2$. Show that the slope of $L(Y | X)$ is $\tau + gh/(\pi^2 + g^2 + \sigma^2)$, and that the coefficient of X in $L(Y | X, I)$ is $\tau + gh/(g^2 + \sigma^2)$. Adjusting for the instrument I enlarges the bias.

Solution. $\text{Cov}(X, Y) = \tau \text{Var } X + gh$ and $\text{Var } X = \pi^2 + g^2 + \sigma^2$, which gives the first slope. For the second, by [Proposition 14.5.2](#) the coefficient is $\sigma_{YX \cdot I}/\sigma_{XX \cdot I}$. Removing the linear effect of I leaves $X - \pi I = gU + U_X$, with variance $g^2 + \sigma^2$, and $Y - L(Y | I) = \tau(gU + U_X) + hU + U_Y$, so $\sigma_{YX \cdot I} = \tau(g^2 + \sigma^2) + gh$. Divide. The confounded covariance gh is the same in both, but adjustment divides it by a smaller variance.

25.6 Regression adjustment in randomized experiments

In an experiment covariates are not needed to remove bias ([Theorem 25.2.3](#)); they are used to reduce variance, which analysis of covariance does under a normal linear model with a common slope ([Proposition 18.1.2](#)). Freedman (2008a) analysed adjustment in Neyman's framework of [Section 25.2](#), with no model, and found that the adjusted estimator is biased in finite samples, that its usual standard error can be wrong, and that it can be *less* precise than the difference in means. Lin (2013) showed that interacting the covariates with the treatment repairs the precision problem. This section proves both halves.

25.6.1 The setting

A completely randomized experiment assigns n_1 of n units to treatment and $n_0 = n - n_1$ to control. Each unit has potential outcomes $y_i(1), y_i(0)$ and a vector $\mathbf{x}_i \in \mathbb{R}^q$ of covariates measured before randomization, hence fixed numbers unaffected by treatment, which we centre:

$\sum_i \mathbf{x}_i = \mathbf{0}$. Write

$$\mathbf{S}_{xx} = \frac{1}{n-1} \sum_i \mathbf{x}_i \mathbf{x}_i^\top, \quad \mathbf{s}_t = \frac{1}{n-1} \sum_i \mathbf{x}_i (y_i(t) - \bar{y}(t)),$$

$$\boldsymbol{\beta}_t = \mathbf{S}_{xx}^{-1} \mathbf{s}_t \quad (t = 0, 1),$$

assuming $\mathbf{S}_{xx}$ positive definite. The vector $\boldsymbol{\beta}_t$ is the least squares slope of the potential outcomes $y_i(t)$ on $\mathbf{x}_i$ over *all* n units, a finite-population projection coefficient in the sense of [Section 6.11](#). No linear model is assumed.

With $\bar{Y}_t$ and $\bar{\mathbf{x}}_t$ the arm means, three estimators are in use: the **difference in means** $\hat{\tau}_D = \bar{Y}_1 - \bar{Y}_0$; **Fisher's** $\hat{\tau}_F$, the coefficient of T in the least squares regression of Y on $1, T, \mathbf{x}$ (the analysis of covariance of [Section 18.1](#)); and **Lin's** $\hat{\tau}_L$, the coefficient of T in the regression on $1, T, \mathbf{x}, T\mathbf{x}$. All three belong to one family. For fixed vectors $\mathbf{b}_1, \mathbf{b}_0 \in \mathbb{R}^q$ put

$$\hat{\tau}(\mathbf{b}_1, \mathbf{b}_0) = (\bar{Y}_1 - \mathbf{b}_1^\top \bar{\mathbf{x}}_1) - (\bar{Y}_0 - \mathbf{b}_0^\top \bar{\mathbf{x}}_0). \quad (25.6.1)$$

Each arm mean is corrected for the chance imbalance of its covariate mean. Then $\hat{\tau}_D = \hat{\tau}(\mathbf{0}, \mathbf{0})$. By [Theorem 18.1.1](#)(b,c), the analysis of covariance estimates the slope by the pooled within-arm slope $\hat{\boldsymbol{\beta}}_p$ and the treatment effect by the difference of the arm means adjusted with it, so $\hat{\tau}_F = \hat{\tau}(\hat{\boldsymbol{\beta}}_p, \hat{\boldsymbol{\beta}}_p)$. The regression with the interaction fits a separate line in each arm, so by [Exercise \(C1\)](#) (whose argument is unchanged for a vector covariate) $\hat{\tau}_L = \hat{\tau}(\hat{\boldsymbol{\beta}}_1, \hat{\boldsymbol{\beta}}_0)$, with $\hat{\boldsymbol{\beta}}_t$ the least squares slope within arm t .

25.6.2 Fixed coefficients: an exact result

If the coefficients in [Eq. 25.6.1](#) are fixed in advance, everything is exact.

Lemma 25.6.1 — Adjustment with fixed coefficients

For fixed $\mathbf{b}_1, \mathbf{b}_0$, put $\mathbf{c} = (n_0 \mathbf{b}_1 + n_1 \mathbf{b}_0)/n$ and $\mathbf{c}^* = (n_0 \boldsymbol{\beta}_1 + n_1 \boldsymbol{\beta}_0)/n$. Then:

- (a) $E \hat{\tau}(\mathbf{b}_1, \mathbf{b}_0) = \tau$;
- (b) the variance is

$$\text{Var } \hat{\tau}(\mathbf{b}_1, \mathbf{b}_0) = \text{Var } \hat{\tau}_D + \frac{n}{n_0 n_1} \left[(\mathbf{c} - \mathbf{c}^*)^\top \mathbf{S}_{xx} (\mathbf{c} - \mathbf{c}^*) - \mathbf{c}^{*\top} \mathbf{S}_{xx} \mathbf{c}^* \right].$$

In particular the variance depends on $(\mathbf{b}_1, \mathbf{b}_0)$ only through $\mathbf{c}$, and it is smallest, over all fixed coefficients, exactly when $\mathbf{c} = \mathbf{c}^*$, for example when $(\mathbf{b}_1, \mathbf{b}_0) = (\boldsymbol{\beta}_1, \boldsymbol{\beta}_0)$.

Proof. Define adjusted potential outcomes $\tilde{y}_i(t) = y_i(t) - \mathbf{b}_t^\top \mathbf{x}_i$. Because the treated units are exactly those whose $\tilde{y}_i(1)$ is observed, $\hat{\tau}(\mathbf{b}_1, \mathbf{b}_0)$ is the difference in means for the $\tilde{y}$'s, and their average effect is $\tau - (\mathbf{b}_1 - \mathbf{b}_0)^\top \bar{\mathbf{x}} = \tau$ since the covariates are centred. Part (a) is [Theorem 25.2.3](#)(a). By [Eq. 25.2.4](#) and [Lemma 25.2.2](#), the variance is $\{n_0/(nn_1)\} S_{\tilde{u}}^2$, where

$$\tilde{u}_i = \tilde{y}_i(1) + \frac{n_1}{n_0} \tilde{y}_i(0) = u_i - \frac{n}{n_0} \mathbf{c}^\top \mathbf{x}_i, \quad u_i = y_i(1) + \frac{n_1}{n_0} y_i(0).$$

Expanding,

$$S_u^2 = S_u^2 - 2(n/n_0)\mathbf{c}^\top \mathbf{s}_{xu} + (n/n_0)^2 \mathbf{c}^\top \mathbf{S}_{xx} \mathbf{c},$$

with

$$\mathbf{s}_{xu} = \mathbf{s}_1 + (n_1/n_0)\mathbf{s}_0 = \mathbf{S}_{xx}(\boldsymbol{\beta}_1 + (n_1/n_0)\boldsymbol{\beta}_0) = (n/n_0)\mathbf{S}_{xx}\mathbf{c}^*.$$

Completing the square,

$$S_u^2 = S_u^2 + \frac{n^2}{n_0^2} \left[(\mathbf{c} - \mathbf{c}^*)^\top \mathbf{S}_{xx} (\mathbf{c} - \mathbf{c}^*) - \mathbf{c}^{*\top} \mathbf{S}_{xx} \mathbf{c}^* \right].$$

Multiplying by $n_0/(nn_1)$, and noting that $\{n_0/(nn_1)\}S_u^2 = \text{Var } \hat{\tau}_D$, gives (b). The bracket is smallest iff $\mathbf{c} = \mathbf{c}^*$, because $\mathbf{S}_{xx}$ is positive definite. ■

The optimal $\mathbf{c}^*$ weights the treated slope by the *control* fraction and the control slope by the *treated* fraction: by Eq. 25.2.4, $\mathbf{c}^*$ is, up to the factor n_0/n , the slope of $u_i = y_i(1) + (n_1/n_0)y_i(0)$ on $\mathbf{x}_i$.

25.6.3 Estimated coefficients: Freedman's critique and Lin's repair

Estimated coefficients cost exact unbiasedness but, in large experiments, nothing else. Consider a sequence of finite populations and experiments indexed by n , with covariates centred in each, and assume:

- (A1) $n_1/n \rightarrow p \in (0, 1)$;
- (A2) the mean and the covariance matrix, over the n units, of $\mathbf{w}_i = (\mathbf{x}_i^\top, y_i(1), y_i(0))^\top$ converge to finite limits, and the limit of $\mathbf{S}_{xx}$ is positive definite;
- (A3) $n^{-1} \sum_i \|\mathbf{w}_i - \bar{\mathbf{w}}\|^4$ is bounded.

A sequence of random vectors $\mathbf{g}_n$ is **bounded in probability** if for every $\epsilon > 0$ there is an M with $\Pr(\|\mathbf{g}_n\| > M) < \epsilon$ for all n . If $\mathbf{g}_n$ is bounded in probability and $\mathbf{h}_n \rightarrow \mathbf{0}$ in probability, then $\mathbf{h}_n^\top \mathbf{g}_n \rightarrow 0$ in probability.

Theorem 25.6.2 — Regression adjustment in a completely randomized experiment

Under (A1)–(A3), let $\mathbf{b}_n = (n_1\boldsymbol{\beta}_1 + n_0\boldsymbol{\beta}_0)/n$.

- (a) $\hat{\boldsymbol{\beta}}_t - \boldsymbol{\beta}_t \rightarrow \mathbf{0}$ for $t = 0, 1$, and $\hat{\boldsymbol{\beta}}_p - \mathbf{b}_n \rightarrow \mathbf{0}$, in probability.
- (b) $\sqrt{n} \{\hat{\tau}_L - \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0)\} \rightarrow 0$ and $\sqrt{n} \{\hat{\tau}_F - \hat{\tau}(\mathbf{b}_n, \mathbf{b}_n)\} \rightarrow 0$ in probability. So, to order $n^{-1/2}$, Lin's estimator behaves like the optimal fixed-coefficient estimator and Fisher's like the fixed-coefficient estimator with the common coefficient $\mathbf{b}_n$.
- (c) The variances of these approximating estimators satisfy

$$\text{Var } \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0) \leq \text{Var } \hat{\tau}(\mathbf{b}, \mathbf{b}) \quad \text{for every } \mathbf{b},$$

in particular $\text{Var } \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0) \leq \text{Var } \hat{\tau}_D$; and

$$\text{Var } \hat{\tau}(\mathbf{b}_n, \mathbf{b}_n) - \text{Var } \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0) = \frac{(n_1 - n_0)^2}{nn_0n_1} (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)^\top \mathbf{S}_{xx} (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0), \quad (25.6.2)$$

which is zero iff $n_1 = n_0$ or $\boldsymbol{\beta}_1 = \boldsymbol{\beta}_0$. Fisher's approximating estimator has *larger* variance than the difference in means iff $\mathbf{b}_n^\top \mathbf{S}_{xx} \mathbf{b}_n > 2 \mathbf{b}_n^\top \mathbf{S}_{xx} \mathbf{c}^*$.

Proof.

- (a) Fix components j, l of $\mathbf{w}$, and let z_i be $w_{ij} - \bar{w}_j$ or $(w_{ij} - \bar{w}_j)(w_{il} - \bar{w}_l)$. The treated units are a simple random sample of size n_1 , so by Lemma 25.2.2 the mean of the z_i over the treated arm has mean equal to their mean over all units and variance at most S_z^2/n_1 , where $S_z^2 \leq (n-1)^{-1} \sum_i z_i^2 \leq (n-1)^{-1} \sum_i (1 + \|\mathbf{w}_i - \bar{\mathbf{w}}\|^4)$, which is bounded by (A3). By (A1) and Chebyshev's inequality, every such arm mean differs from the corresponding mean over all units by a quantity tending to zero in probability. The within-arm covariance matrix of $\mathbf{w}$ is $n_1/(n_1 - 1)$ times the arm mean of the products minus the product of the arm means, so it differs from the covariance matrix over all units by a quantity tending to zero in probability. In particular the arm's $\mathbf{x}$ -covariance matrix and its covariance vector of $\mathbf{x}$ with $y(1)$ are close to $\mathbf{S}_{xx}$ and $\mathbf{s}_1$. Since the limit of $\mathbf{S}_{xx}$ is positive definite and matrix inversion is continuous there, and $\boldsymbol{\beta}_1$ converges by (A2), $\hat{\boldsymbol{\beta}}_1 - \boldsymbol{\beta}_1 \rightarrow \mathbf{0}$ in probability. The control arm is the same. The pooled slope is

$$\begin{aligned} \hat{\boldsymbol{\beta}}_p &= [(n_1 - 1)\hat{\mathbf{S}}_{xx,1} + (n_0 - 1)\hat{\mathbf{S}}_{xx,0}]^{-1} \\ &\quad \times [(n_1 - 1)\hat{\mathbf{s}}_1 + (n_0 - 1)\hat{\mathbf{s}}_0] \end{aligned}$$

in terms of the arm moments, which by the same argument is close to $[(n - 2)\mathbf{S}_{xx}]^{-1} \mathbf{S}_{xx} [(n_1 - 1)\boldsymbol{\beta}_1 + (n_0 - 1)\boldsymbol{\beta}_0]$, and this differs from $\mathbf{b}_n$ by $O(1/n)$.

- (b) By Eq. 25.6.1,

$$\hat{\tau}_L - \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0) = -(\hat{\boldsymbol{\beta}}_1 - \boldsymbol{\beta}_1)^\top \bar{\mathbf{x}}_1 + (\hat{\boldsymbol{\beta}}_0 - \boldsymbol{\beta}_0)^\top \bar{\mathbf{x}}_0.$$

By Lemma 25.2.2, $E \bar{\mathbf{x}}_1 = \mathbf{0}$ and $E \|\bar{\mathbf{x}}_1\|^2 = (1/n_1 - 1/n) \text{tr } \mathbf{S}_{xx}$, so $n E \|\bar{\mathbf{x}}_1\|^2$ is bounded, and $\sqrt{n} \bar{\mathbf{x}}_1$ is bounded in probability by Markov's inequality; likewise $\sqrt{n} \bar{\mathbf{x}}_0$. With (a), both products tend to zero in probability. The argument for $\hat{\tau}_F$ is identical, with $\hat{\boldsymbol{\beta}}_p - \mathbf{b}_n$ in both places.

- (c) Apply Lemma 25.6.1. The pair $(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0)$ has $\mathbf{c} = \mathbf{c}^*$, the minimum, and $(\mathbf{b}, \mathbf{b})$ has $\mathbf{c} = \mathbf{b}$. For $\mathbf{b} = \mathbf{b}_n$, $\mathbf{b}_n - \mathbf{c}^* = \{(n_1 - n_0)/n\}(\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)$, which gives Eq. 25.6.2. Comparing with $\mathbf{b} = \mathbf{0}$, the variance is larger iff

$$(\mathbf{b}_n - \mathbf{c}^*)^\top \mathbf{S}_{xx} (\mathbf{b}_n - \mathbf{c}^*) > \mathbf{c}^{*\top} \mathbf{S}_{xx} \mathbf{c}^*,$$

which simplifies to the stated condition. ■

Part (b) concerns the leading term only. Because the slopes and $\bar{\mathbf{x}}_t$ come from the same assignment, $\hat{\tau}_L$ and $\hat{\tau}_F$ have a bias of order $1/n$ under moment conditions, negligible beside a standard error of order $n^{-1/2}$ (Freedman 2008a; Lin 2013). With a finite-population central limit theorem (Li and Ding 2017), part (b) makes both estimators asymptotically normal with the variances

Figure 25.6.1: n times the variance of the three estimators in [Example \(When adjustment hurts\)](#) as a function of the fraction treated. Curves: exact variances of the fixed-coefficient estimators that the estimators approach ([Theorem 25.6.2](#)). Points: simulation over 20000 randomizations. The vertical line is $p = 2/3$, beyond which the analysis of covariance loses to the difference in means.

of part (c).

Freedman’s critique is part (c) for Fisher’s estimator: its common slope converges to $\mathbf{b}_n$, which weights each arm’s slope by the arm’s *own* size, while the optimal $\mathbf{c}^*$ uses the *other* arm’s size. With an unbalanced design and an effect that varies with the covariate, the analysis of covariance can lose to no adjustment at all. **Lin’s repair** is part (c) for the interacted regression, which converges to the optimal coefficients and is asymptotically at least as precise as both alternatives *whether or not the linear model is true*. When $n_1 = n_0$ the two adjusted estimators agree to first order.

Example. (When adjustment hurts)

A synthetic population of $n = 400$ units has one standardized covariate, on which the response depends under treatment ($\beta_1 = 2.007$) but not under control ($\beta_0 = -0.009$); $\tau = 1.003$. With $\beta_0 \approx 0$ and $S_{xx} = 1$, the condition of part (c) reads $p\beta_1(p\beta_1 - 2(1-p)\beta_1) > 0$, that is $p > 2/3$. [Figure 25.6.1](#) compares n times the variance of each estimator over 20000 randomizations with the exact variances of the approximating fixed-coefficient estimators:

fraction treated	difference in means	Fisher (ANCOVA)	Lin (interacted)
0.2	20.88 (20.81)	14.03 (13.87)	4.80 (4.73)
0.5	6.01 (6.02)	2.04 (2.03)	2.03 (2.03)
0.8	5.20 (5.20)	13.50 (13.37)	4.26 (4.23)

(simulated; values from [Lemma 25.6.1](#) in brackets). At $p = 0.8$ the analysis of covariance has more than twice the variance of the unadjusted estimate while Lin’s estimator still gains; at $p = 0.5$ both cut it by two thirds.

```

25.6.4 Standard errors

Freedman (2008a) showed that the classical standard error of the analysis of covariance can be inconsistent in either direction. Lin (2013) showed that the sandwich standard errors of [Chapter 21 \(Theorem 21.4.2\)](#) for the interacted regression are consistent or asymptotically conservative, for the reason seen in [Exercise \(B2\)](#): the residuals estimate the variances of [Exercise \(B1\)](#) arm by arm, and the one term that cannot be estimated enters with a negative sign.

In [Example \(When adjustment hurts\)](#) at $p = 0.8$, over 10000 randomizations, nominal 95% intervals covered τ with frequency 0.997 for the difference in means with Neyman's standard error, 0.921 for the analysis of covariance with its classical standard error, and 0.984 for Lin's estimator with the HC2 standard error. The first and last are conservative because the effect varies across units.

Idea. In a randomized experiment, adjust only for covariates measured before randomization; include their interactions with the treatment (with the covariates centred at their overall mean); and use sandwich standard errors. Then adjustment cannot hurt in

large samples, whatever the true relation between covariates and responses, and it helps as much as a linear adjustment can.

Freedman (2008b) extends the critique to several treatments; the interacted regression, with one set of slopes per arm, extends Lin's repair. With many covariates relative to n the $O(1/n)$ terms are no longer negligible.

25.6.5 Exercises

25.6.5.1 A. Check your understanding

Exercise A1.

With one covariate and a fixed common coefficient b , show from [Lemma 25.6.1](#) that $\hat{\tau}(b, b)$ has smaller variance than the difference in means iff b lies strictly between 0 and $2c^*$. What does this say about guessing a slope from a previous study?

Solution. With $\mathbf{c} = b$ and $S_{xx} > 0$, the variance difference is $\{n/(n_0n_1)\}S_{xx}[(b - c^*)^2 - c^{*2}] = \{n/(n_0n_1)\}S_{xx}b(b - 2c^*)$, which is negative iff b is strictly between 0 and $2c^*$. A slope guessed from earlier data, fixed before randomization, keeps the estimator exactly unbiased, and it reduces the variance as long as it has the right sign and is less than twice the optimal value: a crude guess is enough.

25.6.5.2 B. Practice

Exercise B1.

Let $e_i(t) = y_i(t) - \bar{y}(t) - \boldsymbol{\beta}_t^\top \mathbf{x}_i$ be the residuals of the finite-population regressions. Show that

$$\text{Var } \hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0) = \frac{S_{e(1)}^2}{n_1} + \frac{S_{e(0)}^2}{n_0} - \frac{S_{e(1)-e(0)}^2}{n},$$

Neyman's formula with the potential outcomes replaced by their residuals. Deduce that the proportional gain over the difference in means is large when the covariates explain much of both potential outcomes.

Solution. As in the proof of [Lemma 25.6.1](#), $\hat{\tau}(\boldsymbol{\beta}_1, \boldsymbol{\beta}_0)$ is the difference in means for the adjusted outcomes $y_i(t) - \boldsymbol{\beta}_t^\top \mathbf{x}_i = \bar{y}(t) + e_i(t)$. Adding constants changes nothing in [Eq. 25.2.3](#), so its variance is Neyman's formula for the $e_i(t)$, whose unit effects are $e_i(1) - e_i(0)$ up to a constant. The first two terms are $(1 - R_t^2)$ times those of the unadjusted formula, where R_t^2 is the finite-population R^2 of $y(t)$ on $\mathbf{x}$.

Exercise B2.

In the setting of [Example \(When adjustment hurts\)](#), let $\beta_0 = 0$, $\beta_1 = \beta \neq 0$ and $S_{xx} = 1$, and write $p = n_1/n$. Show that the excess [Eq. 25.6.2](#), multiplied by n , is $(2p - 1)^2\beta^2/\{p(1 - p)\}$, and that the analysis of covariance loses to the difference in means iff $p > 2/3$. What happens if instead $\beta_1 = 0$ and $\beta_0 = \beta$?

25.6.5.3 C. Going deeper

Exercise C1.

Show that Lin's estimator is the average over *all* n units of the difference between the two arms' fitted regression lines: if $\hat{\alpha}_t + \hat{\beta}_t^\top \mathbf{x}$ is the least squares fit in arm t , then

$$\hat{\tau}_L = n^{-1} \sum_i \{(\hat{\alpha}_1 + \hat{\beta}_1^\top \mathbf{x}_i) - (\hat{\alpha}_0 + \hat{\beta}_0^\top \mathbf{x}_i)\}.$$

Relate each arm's term to the regression estimator of a population mean in survey sampling.

25.7 Summary and Notes

25.7.1 Summary

Idea.

1. $E(Y \mid \text{do}(X = x))$, defined by a structural causal model (Definition 25.1.1), differs from $E(Y \mid X = x)$ under confounding, at every sample size (Proposition 25.1.1).
2. Potential outcomes (Definition 25.2.1): the naive comparison is the effect on the treated plus a selection bias (Proposition 25.2.1).
3. Under complete randomization the difference in means is unbiased, with Neyman's variance; the estimate $s_1^2/n_1 + s_0^2/n_0$ is conservative and equals the HC2 sandwich (Theorem 25.2.3).
4. An intervention deletes one factor of the Markov factorization (Proposition 25.3.1); linear effects are sums over paths (Proposition 25.3.2); d-separation reads conditional independence off the graph (Proposition 25.3.3, Theorem 25.3.4).
5. Confounding is an open back-door path, and in linear models its bias is a sum over common ancestors (Proposition 25.3.5).
6. An adjustment set identifies the effect; in linear models the coefficient of X is then the total effect (Theorem 25.4.1). Causes of Y improve precision, pure causes of X worsen it (Proposition 25.4.2).
7. Mediators, common effects and pre-treatment colliders are bad controls (Theorem 25.5.1).
8. In experiments, analysis of covariance can lose to no adjustment, and the interacted regression is asymptotically optimal (Lemma 25.6.1, Theorem 25.6.2).

25.7.2 Notes and sources

Structural models and graphs. Wright (1921, 1934) introduced path analysis (Proposition 25.3.2), and Haavelmo (1943) read structural equations as autonomous mechanisms that interventions change one at a time. The intervention as an explicit operation and the truncated factorization (Proposition 25.3.1) are from Pearl (1995), and in parallel the manipulation theo-

rem of Spirtes, Glymour and Scheines (2000; first edition 1993); Pearl (2009) is the systematic account. d-separation is due to Pearl (1988), with proofs by Geiger, Verma and Pearl (1990) and Lauritzen, Dawid, Larsen and Leimer (1990); Spirtes, Glymour and Scheines (2000) develop faithfulness.

Potential outcomes. [Definition 25.2.1](#) and [Eq. 25.2.3](#) are Neyman’s (1923), in a paper on field trials translated in 1990. Rubin (1974) extended the framework to observational studies, Holland (1986) named the fundamental problem of causal inference, and Imbens and Rubin (2015) set out the finite-population view. Finite-population central limit theorems go back to Hájek (1960); Li and Ding (2017) give forms suited to causal inference. Samii and Aronow (2012) show that Neyman’s estimate is the HC2 sandwich ([Exercise \(B2\)](#)).

Adjustment and bad controls. The back-door and front-door criteria are from Pearl (1995); Rosenbaum and Rubin (1983) introduced strong ignorability and the propensity score; Shpitser, VanderWeele and Robins (2010) give a necessary and sufficient adjustment criterion; and Henckel, Perković and Maathuis (2022) find the most efficient adjustment set in linear models. [Exercise \(B1\)](#) is Angrist (1998)’s observation, and the “Table 2 fallacy” is named by Westreich and Greenland (2013). Angrist and Pischke (2009) popularized the term bad control. Berkson (1946) described selection on a common effect, Greenland, Pearl and Robins (1999) showed that pre-treatment colliders can bias adjustment, Ding and Miratrix (2015) quantify M-bias and butterfly bias, Elwert and Winship (2014) survey collider bias, and Pearl (2010) analyses bias amplification.

Adjustment in experiments. Covariance adjustment of experiments is Fisher’s (1935). The design-based critique is Freedman (2008a, 2008b), and the interacted estimator and its sandwich standard errors are Lin (2013). The route through the exact variance of fixed-coefficient estimators ([Lemma 25.6.1](#)), which reduces the comparison to completing a square, is this book’s.

Chapter 26

Collinearity: Diagnosis and Consequences

Part VI gives up unbiasedness in exchange for smaller variance, and collinearity is the situation that first made that trade attractive. When the columns of the model matrix are nearly linearly dependent, the data answer some questions well and others barely at all, and the badly answered ones are often those the analyst asked: the separate effects of regressors that moved together. This chapter says exactly which linear functions lose precision, builds the standard diagnostics (variance inflation factors and their generalization to groups of columns, condition indices and the Belsley–Kuh–Welsch variance decomposition), shows why predictions that follow the pattern of the data survive intact, and ends with the remedies, the last of which, biased estimation, is where [Chapter 27](#) begins.

What you need. [Chapter 1](#) (the spectral theorem and Rayleigh quotients, [Theorem 1.7.2](#) and [Theorem 1.7.7](#); the singular value decomposition and the condition number, [Theorem 1.8.1](#) and [Definition 1.8.1](#)), [Chapter 6](#) (the Frisch–Waugh–Lovell theorem and the variance identity [Eq. 6.6.2](#); leverage, [Proposition 6.8.1](#)), [Chapter 8](#) (estimability), [Chapter 10](#) (conditioning and column scaling, [Theorem 10.5.1](#) and [Proposition 10.5.2](#)) and [Chapter 12](#) (confidence ellipsoids and prediction at a new point). [Section 19.6](#) previewed the subject ([Proposition 19.6.1](#)); this chapter builds on that preview rather than repeating it.

26.0.1 Roadmap

- [What collinearity does to variance](#)
- [Variance inflation factors](#)
- [Condition indices and variance decomposition](#)
- [Collinearity and prediction](#)
- [What to do about collinearity](#)
- [Summary and notes](#)

26.1 What collinearity does to variance

The columns of a model matrix are **collinear** when a nontrivial linear combination of them is zero, and **nearly collinear** when a combination with coefficients of reasonable size is a short vector. The exact case is rank deficiency, settled in [Chapter 8](#). Here $\mathbf{X}$ has full column rank and every linear function of $\boldsymbol{\beta}$ is estimable, yet some are estimated so poorly that in practice they have not been estimated at all; “collinearity” below means this near case.

[Section 19.6](#) wrote the variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ as a sum over the eigenvectors of $\mathbf{X}^\top \mathbf{X}$ ([Proposition 19.6.1](#)). This section says which functions collinearity damages, links them to estimability, and separates the statistical problem from the numerical one of [Chapter 10](#).

26.1.1 Canonical coordinates

Throughout the section $\mathbf{X}$ is $n \times p$ of rank p , $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$. Write the spectral decomposition ([Theorem 1.7.2](#)) as

$$\mathbf{X}^\top \mathbf{X} = \sum_{\ell=1}^p \lambda_\ell \mathbf{v}_\ell \mathbf{v}_\ell^\top, \quad \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_p > 0,$$

with orthonormal eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_p$, and put $\gamma_\ell = \mathbf{v}_\ell^\top \boldsymbol{\beta}$. The numbers γ_ℓ are the coordinates of $\boldsymbol{\beta}$ in the eigenvector basis, the **canonical coordinates** of the regression. Since $\mathbf{X}\mathbf{v}_\ell$ has squared length λ_ℓ , the mean vector is

$$\mathbf{X}\boldsymbol{\beta} = \sum_{\ell=1}^p \gamma_\ell \mathbf{X}\mathbf{v}_\ell = \sum_{\ell=1}^p \sqrt{\lambda_\ell} \gamma_\ell \mathbf{u}_\ell, \quad \mathbf{u}_\ell = \mathbf{X}\mathbf{v}_\ell / \sqrt{\lambda_\ell}, \quad (26.1.1)$$

and the vectors $\mathbf{u}_\ell$ are the left singular vectors of $\mathbf{X}$ ([Theorem 1.8.1](#)). A small λ_ℓ means that a unit change in γ_ℓ moves the mean vector only by $\sqrt{\lambda_\ell}$. The data then carry little information about γ_ℓ , and the following theorem makes this precise.

Theorem 26.1.1 — Variances in canonical coordinates

Under the assumptions above, let $\hat{\gamma}_\ell = \mathbf{v}_\ell^\top \hat{\boldsymbol{\beta}}$.

- (a) $\hat{\gamma}_\ell = \mathbf{u}_\ell^\top \mathbf{Y} / \sqrt{\lambda_\ell}$, and $\hat{\boldsymbol{\beta}} = \sum_{\ell} \hat{\gamma}_\ell \mathbf{v}_\ell$. The $\hat{\gamma}_\ell$ are uncorrelated, with $\text{Var}(\hat{\gamma}_\ell) = \sigma^2 / \lambda_\ell$.
- (b) For every nonzero $\mathbf{a} \in \mathbb{R}^p$,

$$\frac{\sigma^2 \|\mathbf{a}\|^2}{\lambda_1} \leq \text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) \leq \frac{\sigma^2 \|\mathbf{a}\|^2}{\lambda_p},$$

with equality on the left at $\mathbf{a} = \mathbf{v}_1$ and on the right at $\mathbf{a} = \mathbf{v}_p$. The ratio of the largest to the smallest variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ over unit vectors $\mathbf{a}$ is $\kappa(\mathbf{X})^2$.

- (c) If $\mathbf{a} \in \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$, then $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) \leq \sigma^2 \|\mathbf{a}\|^2 / \lambda_k$: the eigenvalues $\lambda_{k+1}, \dots, \lambda_p$ do not enter. For every $\mathbf{a}$, $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) \geq \sigma^2 (\mathbf{a}^\top \mathbf{v}_p)^2 / \lambda_p$.
- (d) $E\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 = \sigma^2 \sum_{\ell} 1/\lambda_\ell \geq \sigma^2 / \lambda_p$, while, by [Proposition 19.6.1\(b\)](#), $E\|\mathbf{X}\hat{\boldsymbol{\beta}} - \mathbf{X}\boldsymbol{\beta}\|^2 = \sigma^2 p$ whatever the eigenvalues.

- (e) For each column, $\|(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j\|^2 \geq \lambda_p$, where $\mathbf{M}_{(j)}$ projects onto the span of the other columns. Hence $\text{Var}(\hat{\beta}_j) \leq \sigma^2/\lambda_p$.

Proof.

- (a) By [Theorem 5.5.1](#), $\hat{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}$ with covariance $\sigma^2(\mathbf{X}^\top \mathbf{X})^{-1} = \sigma^2 \sum_{\ell} \lambda_{\ell}^{-1} \mathbf{v}_{\ell} \mathbf{v}_{\ell}^\top$. Hence $\mathbf{v}_{\ell}^\top \hat{\boldsymbol{\beta}} = \lambda_{\ell}^{-1} (\mathbf{X} \mathbf{v}_{\ell})^\top \mathbf{Y} = \mathbf{u}_{\ell}^\top \mathbf{Y} / \sqrt{\lambda_{\ell}}$, and $\text{Cov}(\mathbf{v}_{\ell}^\top \hat{\boldsymbol{\beta}}, \mathbf{v}_m^\top \hat{\boldsymbol{\beta}}) = \sigma^2 \mathbf{v}_{\ell}^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{v}_m$, which is σ^2/λ_{ℓ} if $\ell = m$ and zero otherwise. The expansion of $\hat{\boldsymbol{\beta}}$ holds because the $\mathbf{v}_{\ell}$ form an orthonormal basis.
- (b) Write $c_{\ell} = \mathbf{a}^\top \mathbf{v}_{\ell}$, so that $\sum_{\ell} c_{\ell}^2 = \|\mathbf{a}\|^2$. By [Proposition 19.6.1\(a\)](#), $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}) = \sigma^2 \sum_{\ell} c_{\ell}^2 / \lambda_{\ell}$, which lies between $\sigma^2 \|\mathbf{a}\|^2 / \lambda_1$ and $\sigma^2 \|\mathbf{a}\|^2 / \lambda_p$, with the stated equality cases. The singular values of $\mathbf{X}$ are $\sqrt{\lambda_{\ell}}$ ([Theorem 1.8.1](#)), so the ratio of the extremes is $\lambda_1/\lambda_p = \kappa(\mathbf{X})^2$ by [Definition 1.8.1](#).
- (c) If $\mathbf{a} \in \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_k\}$, then $c_{\ell} = 0$ for $\ell > k$ and $\sum_{\ell \leq k} c_{\ell}^2 / \lambda_{\ell} \leq \|\mathbf{a}\|^2 / \lambda_k$. The lower bound keeps only the term $\ell = p$.
- (d) $E\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 = \text{tr Cov}(\hat{\boldsymbol{\beta}}) = \sigma^2 \text{tr}(\mathbf{X}^\top \mathbf{X})^{-1}$, and the eigenvalues of $(\mathbf{X}^\top \mathbf{X})^{-1}$ are the $1/\lambda_{\ell}$. The statement about fitted values is [Proposition 19.6.1\(b\)](#) multiplied by n .
- (e) $(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j = \mathbf{x}_j - \mathbf{X}_{(j)}\mathbf{c}$ for some $\mathbf{c}$, which is $\mathbf{X}\mathbf{b}$ for a vector $\mathbf{b}$ with $b_j = 1$. By [Theorem 1.7.7](#), $\|\mathbf{X}\mathbf{b}\|^2 \geq \lambda_p \|\mathbf{b}\|^2 \geq \lambda_p$. The variance bound follows from [Proposition 7.2.4](#). ■

Part (b) is the precise sense in which $\kappa(\mathbf{X})^2$ measures collinearity: it is the ratio of the worst to the best precision among linear functions of the same length. Part (e) is the Frisch–Waugh–Lovell picture of [Theorem 6.6.2](#): a coefficient is imprecise when its column's part orthogonal to the others is short, and no such part is shorter than $\sqrt{\lambda_p}$.

Idea. Collinearity does not make least squares imprecise in general. It makes it imprecise in a few directions of coefficient space, those of the eigenvectors with small eigenvalues, and precise in the others. Whether it matters depends on whether the question asked points along a weak direction.

Example. (Two regressors that move together)

Draw $n = 30$ values x_{i1} from a standard normal distribution and set $x_{i2} = x_{i1} + 0.15z_i$ with independent standard normal z_i . The sample correlation is 0.9951. Centre both regressors and fit $E(Y) = \beta_0 + \beta_1 x_1 + \beta_2 x_2$, so that the intercept is orthogonal to the slopes and the slope block of $\mathbf{X}^\top \mathbf{X}$ carries all the collinearity. Its eigenvalues are 70.05 and 0.1718. The weak eigenvector is close to $(1, -1)^\top / \sqrt{2}$ (its first coordinate is 0.718 in absolute value), so the weak canonical coordinate is essentially the difference $\beta_1 - \beta_2$. In units of σ , the standard deviations are

Function	Standard deviation
$\hat{\beta}_1$	1.734
$\hat{\beta}_2$	1.682
$\hat{\beta}_1 + \hat{\beta}_2$	0.177
$\hat{\beta}_1 - \hat{\beta}_2$	3.412

Figure 26.1.1: (a) The design of [Example \(Two regressors that move together\)](#). (b) Estimates $(\hat{\beta}_1, \hat{\beta}_2)$ from 2000 replicate responses, true value marked: long in the weak direction $(1, -1)$, thin along $(1, 1)$; dashed, $\beta_1 + \beta_2 = 2$.

Had x_1 been orthogonal to x_2 with the same spread, the first entry would have been 0.171, smaller by the factor $10.1 = \sqrt{102.4}$, the root of the variance inflation factor of Section 26.2. The sum of the slopes is estimated about as well as a slope in an orthogonal design, the difference worst of all. The ratio of the largest to the smallest variance over unit vectors is 407.8, the squared condition number of the centred slope columns ([Theorem 26.1.1\(b\)](#)).

[Figure 26.1.1](#) shows what this means for a single data set. With the design fixed and true slopes $\beta_1 = \beta_2 = 1$, the estimates from 2000 replicate responses lie along the line $\beta_1 + \beta_2 = 2$. The estimate of β_2 ranges from -4.535 to 7.359 and is negative in 26.1 per cent of the replicates, while $\hat{\beta}_1 + \hat{\beta}_2$ stays between 1.440 and 2.639. Every data set says clearly that the two regressors together matter, yet a quarter of them give β_2 the wrong sign, and 54.1 per cent give at least one of the two slopes the wrong sign.

    3))
```

26.1.2 The symptoms

The classical symptoms all follow from [Theorem 26.1.1](#): large standard errors for single coefficients alongside small ones for some combinations; coefficients of implausible size or sign; instability under deletion of a few cases; and a significant F test for a group in which no single t test is significant, because the group statistic is governed by the best combination of its members ([Proposition 11.6.2](#)). None of them means the model is wrong.

26.1.3 Near-estimability

When the near-dependence is a small perturbation of an exact one, the functions that stay precise are exactly those estimable in the limiting, rank-deficient design.

Proposition 26.1.2 — Near-estimability

Let $\mathbf{X}_1$ be $n \times (p-1)$ of full column rank, $\mathbf{c} \in \mathbb{R}^{p-1}$, and $\mathbf{z}$ a unit vector orthogonal to $\mathcal{C}(\mathbf{X}_1)$. For $\delta > 0$ let $\mathbf{X}_\delta = [\mathbf{X}_1, \mathbf{X}_1\mathbf{c} + \delta\mathbf{z}]$, with least squares estimate $\hat{\boldsymbol{\beta}}_\delta = (\hat{\boldsymbol{\beta}}_1^\top, \hat{\beta}_2)^\top$, and let $\mathbf{X}_0 = [\mathbf{X}_1, \mathbf{X}_1\mathbf{c}]$, which has rank $p-1$. Write $\mathbf{a} = (\mathbf{a}_1^\top, a_2)^\top$.

- (a) $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}_\delta) = \sigma^2 \mathbf{a}_1^\top (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{a}_1 + \sigma^2 (a_2 - \mathbf{c}^\top \mathbf{a}_1)^2 / \delta^2$.
- (b) $\mathbf{a}^\top \boldsymbol{\beta}$ is estimable in the model with matrix $\mathbf{X}_0$ iff $a_2 = \mathbf{c}^\top \mathbf{a}_1$. For such $\mathbf{a}$, $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}_\delta)$ does not depend on δ and equals the variance of the least squares estimator of $\mathbf{a}^\top \boldsymbol{\beta}$ in the limiting model. For every other $\mathbf{a}$ it grows like δ^{-2} as $\delta \rightarrow 0$.

Proof.

- (a) Apply [Theorem 6.6.2](#) with $\mathbf{X}_2 = \mathbf{X}_1$ and the last column in the role of $\mathbf{X}_1$ there. The last column residualized on $\mathcal{C}(\mathbf{X}_1)$ is $(\mathbf{I} - \mathbf{M}_1)(\mathbf{X}_1\mathbf{c} + \delta\mathbf{z}) = \delta\mathbf{z}$, so $\hat{\beta}_2 = \mathbf{z}^\top \mathbf{Y} / \delta$.

By part (c) of the same theorem and $\mathbf{X}_1^\top \mathbf{z} = \mathbf{0}$,

$$\hat{\boldsymbol{\beta}}_1 = (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top (\mathbf{Y} - (\mathbf{X}_1 \mathbf{c} + \delta \mathbf{z}) \hat{\beta}_2) = \hat{\boldsymbol{\beta}}_1^S - \mathbf{c} \hat{\beta}_2, \quad \hat{\boldsymbol{\beta}}_1^S = (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top \mathbf{Y}.$$

Hence $\mathbf{a}^\top \hat{\boldsymbol{\beta}}_\delta = \mathbf{a}_1^\top \hat{\boldsymbol{\beta}}_1^S + (a_2 - \mathbf{c}^\top \mathbf{a}_1) \hat{\beta}_2$. The two terms are uncorrelated, because $\text{Cov}(\hat{\boldsymbol{\beta}}_1^S, \hat{\beta}_2) = \sigma^2 (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{X}_1^\top \mathbf{z} / \delta = \mathbf{0}$, and $\text{Var}(\hat{\beta}_2) = \sigma^2 / \delta^2$.

- (b) By [Theorem 8.3.1](#), $\mathbf{a}^\top \boldsymbol{\beta}$ is estimable under $\mathbf{X}_0$ iff $\mathbf{a} \in \mathcal{C}(\mathbf{X}_0^\top)$. Since $\mathbf{X}_1$ has full column rank, $\mathcal{C}(\mathbf{X}_1^\top) = \mathbb{R}^{p-1}$, so $\mathcal{C}(\mathbf{X}_0^\top) = \{(\mathbf{a}_1^\top, \mathbf{c}^\top \mathbf{a}_1)^\top : \mathbf{a}_1 \in \mathbb{R}^{p-1}\}$. For such $\mathbf{a}$ the second term in (a) vanishes. In the limiting model $\mathbf{X}_0 \boldsymbol{\beta} = \mathbf{X}_1(\boldsymbol{\beta}_1 + \mathbf{c} \beta_2)$, so $\mathbf{a}^\top \boldsymbol{\beta} = \mathbf{a}_1^\top (\boldsymbol{\beta}_1 + \mathbf{c} \beta_2)$ is estimated by $\mathbf{a}_1^\top \hat{\boldsymbol{\beta}}_1^S$, with variance $\sigma^2 \mathbf{a}_1^\top (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{a}_1$. If $a_2 \neq \mathbf{c}^\top \mathbf{a}_1$, the second term is a positive multiple of δ^{-2} .

■

The orthogonality of $\mathbf{z}$ to $\mathcal{C}(\mathbf{X}_1)$ matters only for the size of the bounded term. A general perturbation $\mathbf{w}$ splits as $\mathbf{M}_1 \mathbf{w} + (\mathbf{I} - \mathbf{M}_1) \mathbf{w}$, and the first part, being $\mathbf{X}_1 \mathbf{d}$ for some $\mathbf{d}$, can be absorbed into $\mathbf{c}$. The dichotomy survives: a function estimable in the limit keeps a variance that does not depend on δ , and every other function's variance grows like δ^{-2} . But the bounded value can exceed the limiting-model variance ([Exercise \(B2\)](#)). [Figure 8.3.1](#) showed the δ^{-2} growth numerically; the proposition identifies the rate and the exact set of functions that escape it.

26.1.4 Statistical, not numerical

[Chapter 10](#) met ill-conditioning as a numerical problem: a large $\kappa(\mathbf{X})$ amplifies rounding errors ([Theorem 10.5.1](#)). The statistical cost is different. It is σ^2 / λ_ℓ along each weak direction, so it involves the error variance and the absolute size of the eigenvalues, not only their ratio. Rescaling a column changes $\kappa(\mathbf{X})$ ([Exercise \(B2\)](#)) but no estimand's variance, so diagnostics must be computed for a stated scaling ([Section 26.3](#)) or be scale-free ([Section 26.2](#)). And the eigenvalues grow with n : if the rows are drawn independently from a distribution with nonsingular second-moment matrix $\boldsymbol{\Sigma}$, then $\lambda_p / n \rightarrow \lambda_{\min}(\boldsymbol{\Sigma})$ by the strong law of large numbers and [Proposition 10.4.2](#), so collinearity in the population is paid for by a larger n . Longley's regression shows how far apart the two problems can be: QR computes its coefficients to about eleven digits ([Example \(Longley's data, exactly\)](#)), yet its variance inflation factors reach 1788.5 ([Example \(Longley's regression\)](#)).

Measurement error in the regressors sits between the two. It perturbs $\mathbf{X}$ as rounding does, by an amount that more digits cannot reduce, and a perturbation comparable to $\sqrt{\lambda_p}$ can turn the weak eigenvector and change which combinations appear well estimated ([Theorem 10.5.1](#), with $\kappa(\mathbf{X})$ as the amplifier). The directions that collinearity leaves ill-determined are thus the least robust to errors in $\mathbf{X}$; [Chapter 24](#) treats the resulting bias ([Theorem 24.1.1](#)).

26.1.5 Exercises

26.1.5.1 A. Check your understanding

Exercise A1.

In [Example \(Two regressors that move together\)](#), the difference $\beta_1 - \beta_2$ corresponds to $\mathbf{a} = (0, 1, -1)^\top$, of squared length 2. Check that the variance quoted for $\hat{\beta}_1 - \hat{\beta}_2$ lies between the two bounds of [Theorem 26.1.1\(b\)](#), applied to the slope block, and explain why it is close to the upper one.

Solution. Computed without rounding, the variance is $11.640\sigma^2$, and the bounds are $2\sigma^2/70.05 = 0.0286\sigma^2$ and $2\sigma^2/\lambda_2 = 11.643\sigma^2$. (The check needs more digits than the table gives: 3.412^2 and $2/0.1718$ agree to four figures.) The variance is $\sigma^2 \sum_\ell (\mathbf{a}^\top \mathbf{v}_\ell)^2 / \lambda_\ell$, and $(\mathbf{a}^\top \mathbf{v}_2)^2 = 1.9995$ of the total $\|\mathbf{a}\|^2 = 2$, because $\mathbf{a}$ points almost exactly along the weak eigenvector. Nearly all of its weight sits on the term with the small eigenvalue.

Exercise A2.

Under normal errors, $\hat{\beta}_2 \sim N(\beta_2, \text{Var}(\hat{\beta}_2))$. With $\beta_2 = 1$ and the standard deviation of [Example \(Two regressors that move together\)](#), compute $\Pr(\hat{\beta}_2 < 0)$ and compare it with the share of replicates in which $\hat{\beta}_2$ was negative.

Exercise A3.

Let $\mathbf{X} = [\mathbf{x}_1, \mathbf{x}_2]$ have orthogonal columns with $\|\mathbf{x}_1\| = 1$ and $\|\mathbf{x}_2\| = 10$. Find the canonical coordinates and the weak direction. Now measure the second regressor in units ten times larger, so that the column becomes $\mathbf{x}_2/10$. What happens to the weak direction and to $\kappa(\mathbf{X})$? Which variances of estimable quantities have changed?

26.1.5.2 B. Practice**Exercise B1.**

Show that $\max_j \text{Var}(\hat{\beta}_j) \geq \sigma^2 / (p\lambda_p)$, so that a small λ_p always hurts at least one coefficient. Give an example with $p = 3$ in which λ_p is tiny but only one coefficient has a large variance.

Solution. By [Theorem 26.1.1\(d\)](#), $\sum_j \text{Var}(\hat{\beta}_j) = \sigma^2 \sum_\ell 1/\lambda_\ell \geq \sigma^2/\lambda_p$, and the largest of p numbers is at least their average. For the example take $\mathbf{X}$ with orthonormal columns and multiply the third column by ϵ . Then $\mathbf{X}^\top \mathbf{X} = \text{diag}(1, 1, \epsilon^2)$, $\lambda_p = \epsilon^2$, and only $\text{Var}(\hat{\beta}_3) = \sigma^2/\epsilon^2$ is large: a short column, not a near-dependence, which is why [Section 26.3](#) scales the columns.

Exercise B2.

In [Proposition 26.1.2](#), replace $\mathbf{z}$ by an arbitrary vector $\mathbf{w} \notin \mathcal{C}(\mathbf{X}_1)$. Write $\mathbf{w} = \mathbf{X}_1 \mathbf{d} + \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\| \mathbf{z}$ with $\mathbf{z}$ a unit vector orthogonal to $\mathcal{C}(\mathbf{X}_1)$, and show that

$$\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}_\delta) = \sigma^2 \mathbf{a}_1^\top (\mathbf{X}_1^\top \mathbf{X}_1)^{-1} \mathbf{a}_1 + \sigma^2 \frac{(a_2 - (\mathbf{c} + \delta \mathbf{d})^\top \mathbf{a}_1)^2}{\delta^2 \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\|^2}.$$

Deduce that if $a_2 = \mathbf{c}^\top \mathbf{a}_1$ the variance does not depend on δ and equals the limiting-model variance plus $\sigma^2(\mathbf{d}^\top \mathbf{a}_1)^2 / \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\|^2$, which vanishes iff $\mathbf{d}^\top \mathbf{a}_1 = 0$, and that for every other $\mathbf{a}$ it still grows like δ^{-2} .

Solution. $\mathbf{X}_1 \mathbf{c} + \delta \mathbf{w} = \mathbf{X}_1(\mathbf{c} + \delta \mathbf{d}) + \delta \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\| \mathbf{z}$, which is the setting of the proposition with $\mathbf{c}$ replaced by $\mathbf{c} + \delta \mathbf{d}$ and δ by $\delta \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\|$. Part (a) gives the formula. If $a_2 = \mathbf{c}^\top \mathbf{a}_1$, the numerator of the second term is $\delta^2(\mathbf{d}^\top \mathbf{a}_1)^2$, the δ^2 cancels, and the second term is the constant $\sigma^2(\mathbf{d}^\top \mathbf{a}_1)^2 / \|(\mathbf{I} - \mathbf{M}_1)\mathbf{w}\|^2$; the first is the limiting-model variance, by part (b) of the proposition. Otherwise the numerator tends to $(a_2 - \mathbf{c}^\top \mathbf{a}_1)^2 > 0$ and the term grows like δ^{-2} .

Exercise B3.

Section 8.3 used twelve equally spaced t_i on $[-1, 1]$, $\mathbf{X}_1 = [\mathbf{1}, \mathbf{t}]$, $\mathbf{c} = (0, 1)^\top$ and $\mathbf{w} = (\cos \pi t_i)$, and reported $\text{Var}(\hat{\beta}_1 + \hat{\beta}_2) = 0.212 \sigma^2$ whatever δ . Use Exercise (B2) to explain the number: show that $\mathbf{d} = (d_1, 0)^\top$ because $\mathbf{w}$ is even and $\mathbf{t}$ is odd, and that the variance equals $\sigma^2 / \sum_i t_i^2$.

Solution. Here $\mathbf{a} = (0, 1, 1)^\top$, so $\mathbf{a}_1 = (0, 1)^\top$ and $a_2 = \mathbf{c}^\top \mathbf{a}_1 = 1$: the function is estimable in the limit. The coefficients $\mathbf{d}$ of the projection of $\mathbf{w}$ on $\mathcal{C}(\mathbf{1}, \mathbf{t})$ are $d_1 = \bar{w}$ and $d_2 = \mathbf{t}^\top \mathbf{w} / \mathbf{t}^\top \mathbf{t} = 0$, because the t_i are symmetric about zero and $\cos$ is even. So $\mathbf{d}^\top \mathbf{a}_1 = d_2 = 0$ and the second term vanishes. The first is $\sigma^2[(\mathbf{X}_1^\top \mathbf{X}_1)^{-1}]_{22} = \sigma^2 / \sum_i t_i^2$, since $\mathbf{1} \perp \mathbf{t}$. With $t_i = -1 + 2i/11$, $i = 0, \dots, 11$, $\sum_i t_i^2 = (4/121) \sum_{i=0}^{11} (i - 5.5)^2 = (4/121) \cdot 143 = 4.727$, and $1/4.727 = 0.2115$, which rounds to 0.212.

26.2 Variance inflation factors

Analysts usually want something coarser than the eigenvalues: one number per coefficient saying how much its precision has suffered. Chapter 6 supplied that number as a by-product of the Frisch–Waugh–Lovell theorem. This section states what it measures and what it does not, and extends it to a group of columns such as the indicators of a factor.

26.2.1 Definition and meaning

Throughout, the model contains an intercept, $\mathbf{x}_j$ is one of the other columns, and $\mathbf{X}_{(j)}$ is $\mathbf{X}$ with $\mathbf{x}_j$ removed, with projection $\mathbf{M}_{(j)}$. Write $S_{jj} = \|\mathbf{x}_j - \bar{x}_j \mathbf{1}\|^2$ for the centred sum of squares of $\mathbf{x}_j$.

Definition 26.2.1 — Variance inflation factor

Let R_j^2 be the coefficient of determination of the least squares regression of $\mathbf{x}_j$ on the columns of $\mathbf{X}_{(j)}$, which include $\mathbf{1}$, and suppose $R_j^2 < 1$. The **variance inflation factor** of $\mathbf{x}_j$ is

$$\text{VIF}_j = \frac{1}{1 - R_j^2},$$

and $\text{TOL}_j = 1 - R_j^2 = 1/\text{VIF}_j$ is its **tolerance**.

The identity Eq. 6.6.2, proved with the Frisch–Waugh–Lovell theorem, reads $\text{Var}(\hat{\beta}_j) = \sigma^2 \text{VIF}_j / S_{jj}$. The next proposition collects what follows from it.

Proposition 26.2.1 — What a variance inflation factor measures

- (a) $\|(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j\|^2 = S_{jj}/\text{VIF}_j$, and VIF_j is the ratio of $\text{Var}(\hat{\beta}_j)$ to σ^2/S_{jj} , the variance $\hat{\beta}_j$ would have if the centred $\mathbf{x}_j$ were orthogonal to every other centred column. By Exercise (A2), $\text{VIF}_j \geq 1$.
- (b) VIF_j depends on $\mathbf{X}$ only through $\mathbf{x}_j$ and $\mathcal{C}(\mathbf{X}_{(j)})$. It is unchanged when $\mathbf{x}_j$ is replaced by $a\mathbf{x}_j + b\mathbf{1}$ with $a \neq 0$, and when $\mathbf{X}_{(j)}$ is replaced by any matrix with the same column space.
- (c) If $\mathbf{R}$ is the correlation matrix of the non-intercept columns, then $\text{VIF}_j = [\mathbf{R}^{-1}]_{jj}$.
- (d) The t interval for β_j at any level is $\sqrt{\text{VIF}_j}$ times as long, on average, as in the orthogonal design of (a), and the noncentrality of the F test of $\beta_j = 0$ (the square of the t statistic's) is divided by VIF_j :

$$\frac{\beta_j^2}{\text{Var}(\hat{\beta}_j)} = \frac{\beta_j^2 S_{jj}}{\sigma^2} \cdot \frac{1}{\text{VIF}_j}.$$

Proof.

- (a) Since $\mathbf{1} \in \mathcal{C}(\mathbf{X}_{(j)})$, the vector $(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j$ is the residual of the regression of $\mathbf{x}_j$ on $\mathbf{X}_{(j)}$, and its squared length is $S_{jj}(1 - R_j^2)$ by the definition of R_j^2 (Exercise (B1)). The variance ratio is Eq. 6.6.2 divided by σ^2/S_{jj} , which is the variance in the orthogonal case by Proposition 7.2.4 applied to the model with centred columns.
- (b) By (a), $1/\text{VIF}_j = \|(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j\|^2/S_{jj}$, and $\mathbf{M}_{(j)}$ depends only on $\mathcal{C}(\mathbf{X}_{(j)})$. Replacing $\mathbf{x}_j$ by $a\mathbf{x}_j + b\mathbf{1}$ multiplies the numerator by a^2 , because $(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{1} = \mathbf{0}$, and multiplies S_{jj} by a^2 .
- (c) This is Exercise (A1).
- (d) The t interval has half-length $t_{\alpha/2}(n-p) s \sqrt{\text{VIF}_j/S_{jj}}$, and s has the same distribution in both designs. The noncentrality is $\beta_j^2/\text{Var}(\hat{\beta}_j)$ with the variance from (a) (Theorem 11.6.1).

■

By (b) the factor is scale-free: a property of the angle between the centred $\mathbf{x}_j$ and the space of the other centred columns, whose squared cosine is R_j^2 (Theorem 6.7.2). By (a), with the spread per observation fixed, $\hat{\beta}_j$ is as precise as in an orthogonal design with n/VIF_j observations.

Idea. A variance inflation factor of 10 costs $\hat{\beta}_j$ as much precision as discarding nine observations in ten from an orthogonal design with the same spread.

26.2.2 Reading variance inflation factors

Rules of thumb flag a regressor when VIF_j exceeds 10, or 5, or 4. The thresholds are arbitrary, and they measure the wrong thing. The factor compares the design with a hypothetical orthogonal design of the same size; it says nothing about whether the actual standard error is small enough for the purpose, which depends also on σ^2 and on S_{jj} , hence on n . As n grows with the regressors drawn from a fixed population, VIF_j settles to a population value while S_{jj} grows like n , so a factor that is ruinous at $n = 20$ can be irrelevant at $n = 20,000$. O'Brien (2007) makes this case in detail. A large factor is a reason to look at the interval, never a verdict by itself.

Example. (Large factors, precise estimate)

The quarterly US macroeconomic series of [Example \(A macroeconomic design\)](#) run from 1959 to 2009, $n = 203$. Regress real personal consumption on real disposable income, population, the consumer price index, the money stock M1, the three-month Treasury bill rate and the unemployment rate, with an intercept. The variance inflation factors are

Regressor	income	population	CPI	M1	T-bill	unemployment
VIF_j	154.5	183.7	140.4	97.0	2.9	1.3

By every rule of thumb, four regressors are badly collinear. Yet the coefficient of income is 1.0659 with standard error 0.0210, a t statistic of 50.9: the standard error is $\sqrt{154.5} \approx 12.4$ times what an orthogonal design would give, and still small, because income varies widely and consumption tracks it closely. (The errors are autocorrelated, so all the standard errors are too small, [Chapter 21](#); the factors depend on $\mathbf{X}$ alone.)

```
import numpy as np
import statsmodels.api as sm

def vifs(Z):
    """VIFs of the columns of Z (an intercept is always included): diagonal of R
    ~{-1}."""
    return np.diag(np.linalg.inv(np.corrcoef(Z, rowvar=False)))

macro = sm.datasets.macrodta.load_pandas().data
names = ["realdpi", "pop", "cpi", "m1", "tbilrate", "unemp"]
Z = macro[names].to_numpy()
fit = sm.OLS(macro["realcons"].to_numpy(), sm.add_constant(Z)).fit()
for name, v, b, se in zip(names, vifs(Z), fit.params[1:], fit.bse[1:]):
    print(f"{name:9s} VIF {v:7.1f} estimate {b:9.4f} se {se:7.4f} t {b / se:6.1f}")
```

26.2.3 Collinearity that a reparameterization removes

Some large factors are produced by the parameterization, not by the data. Polynomial and interaction terms built from regressors whose origin lies far from the data are the standard case.

Such collinearity is sometimes called *nonessential*.

Example. (A quadratic far from the origin)

Take $n = 21$ equally spaced values $x_i = 10, 10.5, \dots, 20$ and the quadratic model $E(Y) = \beta_0 + \beta_1 x + \beta_2 x^2$. Over this range x and x^2 are almost perfectly correlated: $R^2 = 0.9920$, and both have $\text{VIF} = 124.6$. Rewrite the model in the centred regressors $x - 15$ and $(x - 15)^2$. The fitted values are identical, and both variance inflation factors are now exactly 1, because the design is symmetric about 15 and an odd function of $x - 15$ is orthogonal to an even one once both are centred.

What changed is the question. In the raw coding β_1 is the slope of the mean function at $x = 0$, ten units below the data, with standard deviation 0.804σ . In the centred coding the coefficient of $x - 15$ is the slope at $x = 15$, with standard deviation 0.0721σ , and the raw coding estimates the same slope, $\beta_1 + 30\beta_2$, with exactly the same standard deviation. The large factors described the difficulty of a question, the slope at the origin, that the analyst probably did not mean to ask ([Exercise \(B2\)](#) derives 124.6 by hand).

```
x = np.linspace(10, 20, 21)                                # a regressor far from its
                                                           origin

raw = np.column_stack([x, x**2])
cen = np.column_stack([x - x.mean(), (x - x.mean()) ** 2])
print("VIFs, raw      :", np.round(vifs(raw), 1))
print("VIFs, centred :", np.round(vifs(cen), 3))

X_raw = np.column_stack([np.ones_like(x), raw])
X_cen = np.column_stack([np.ones_like(x), cen])
G_raw, G_cen = np.linalg.inv(X_raw.T @ X_raw), np.linalg.inv(X_cen.T @ X_cen)
a_mean = np.array([0, 1, 2 * x.mean()])                    # slope at x = 15 in the raw
                                                           coefficients
print("sd of the slope at 0 (raw b1)      :", round(np.sqrt(G_raw[1, 1]), 3))
print("sd of the slope at 15, raw coding  :", round(np.sqrt(a_mean @ G_raw @ a_mean
), 4))
print("sd of the slope at 15, centred (b1) :", round(np.sqrt(G_cen[1, 1]), 4))
```

26.2.4 Groups of columns

A factor enters the model through several indicator columns, a polynomial through several powers. The individual coefficients of such a block depend on the coding ([Definition 8.5.1](#)), and so do their variance inflation factors. What is intrinsic is the joint precision of the block, which the next definition, due to Fox and Monette (1992), measures.

For the rest of the section, split the non-intercept columns of $\mathbf{X}$ into $\mathbf{Z}_1$ ($n \times q$) and $\mathbf{Z}_2$ ($n \times (k - q)$), let $\tilde{\mathbf{Z}}_1$ and $\tilde{\mathbf{Z}}_2$ be the centred versions, and let $\tilde{\mathbf{M}}_2$ project onto $\mathcal{C}(\tilde{\mathbf{Z}}_2)$. Assume $\mathbf{X} = [\mathbf{1}, \mathbf{Z}_1, \mathbf{Z}_2]$ has full column rank.

Definition 26.2.2 — Generalized variance inflation factor

The **generalized variance inflation factor** of the block $\mathbf{Z}_1$ is

$$\text{GVIF}_1 = \frac{\det(\tilde{\mathbf{Z}}_1^\top \tilde{\mathbf{Z}}_1)}{\det(\tilde{\mathbf{Z}}_1^\top (\mathbf{I} - \tilde{\mathbf{M}}_2) \tilde{\mathbf{Z}}_1)}.$$

The **canonical correlations** between the two blocks are defined through orthonormal bases $\mathbf{Q}_1$ of $\mathcal{C}(\tilde{\mathbf{Z}}_1)$ and $\mathbf{Q}_2$ of $\mathcal{C}(\tilde{\mathbf{Z}}_2)$: they are the singular values $\rho_1 \geq \rho_2 \geq \dots \geq \rho_m$, $m = \min(q, k - q)$, of the $q \times (k - q)$ matrix $\mathbf{Q}_1^\top \mathbf{Q}_2$. The largest, ρ_1 , is the largest correlation between a linear combination of the centred columns of $\mathbf{Z}_1$ and a linear combination of the centred columns of $\mathbf{Z}_2$ ([Exercise \(C1\)](#)).

Proposition 26.2.2 — Properties of the generalized factor

Let $\boldsymbol{\beta}_1$ be the coefficients of $\mathbf{Z}_1$.

- (a) $\det \text{Cov}(\hat{\boldsymbol{\beta}}_1) = \text{GVIF}_1 \cdot \det \text{Cov}_\perp$, where $\text{Cov}_\perp = \sigma^2(\tilde{\mathbf{Z}}_1^\top \tilde{\mathbf{Z}}_1)^{-1}$ is the covariance $\hat{\boldsymbol{\beta}}_1$ would have if $\mathcal{C}(\tilde{\mathbf{Z}}_1)$ were orthogonal to $\mathcal{C}(\tilde{\mathbf{Z}}_2)$. So GVIF_1 is the squared ratio of the volumes of the joint confidence ellipsoids for $\boldsymbol{\beta}_1$ in the two designs.
- (b) $\text{GVIF}_1 = \prod_{i=1}^m 1/(1 - \rho_i^2)$.
- (c) GVIF_1 is unchanged when $\mathbf{Z}_1$ is replaced by $\mathbf{Z}_1 \mathbf{A} + \mathbf{1} \mathbf{f}^\top$ and $\mathbf{Z}_2$ by $\mathbf{Z}_2 \mathbf{B} + \mathbf{1} \mathbf{g}^\top$, for nonsingular $\mathbf{A}$ and $\mathbf{B}$ and any vectors $\mathbf{f}$ and $\mathbf{g}$. In particular it does not depend on the coding of a factor. It is symmetric: $\text{GVIF}_1 = \text{GVIF}_2$.
- (d) If $q = 1$, GVIF_1 is the variance inflation factor of [Definition 26.2.1](#). In general, with $\mathbf{R}$ the correlation matrix of $[\mathbf{Z}_1, \mathbf{Z}_2]$ partitioned conformably, $\text{GVIF}_1 = \det \mathbf{R}_{11} \det \mathbf{R}_{22} / \det \mathbf{R}$.

Proof.

- (a) Since $\mathcal{C}(\mathbf{1}, \mathbf{Z}_2) = \mathcal{C}(\mathbf{1}) \oplus \mathcal{C}(\tilde{\mathbf{Z}}_2)$ with orthogonal summands, the projection onto $\mathcal{C}(\mathbf{1}, \mathbf{Z}_2)$ is $n^{-1} \mathbf{1} \mathbf{1}^\top + \tilde{\mathbf{M}}_2$ ([Theorem 6.3.7](#)), and the residual of $\mathbf{Z}_1$ after it is $(\mathbf{I} - \tilde{\mathbf{M}}_2) \tilde{\mathbf{Z}}_1$. By [Theorem 6.6.2](#) and [Eq. 6.6.1](#), $\text{Cov}(\hat{\boldsymbol{\beta}}_1) = \sigma^2(\tilde{\mathbf{Z}}_1^\top (\mathbf{I} - \tilde{\mathbf{M}}_2) \tilde{\mathbf{Z}}_1)^{-1}$. If $\mathcal{C}(\tilde{\mathbf{Z}}_1) \perp \mathcal{C}(\tilde{\mathbf{Z}}_2)$, then $\tilde{\mathbf{M}}_2 \tilde{\mathbf{Z}}_1 = \mathbf{0}$ and the covariance is $\text{Cov}_\perp$. Take the ratio of determinants. By [Theorem 12.2.1\(b\)](#), the volume of the confidence ellipsoid is proportional to $(\det \boldsymbol{\Sigma})^{1/2}$, where $\boldsymbol{\Sigma}$ is the covariance matrix, with the same constant in both designs.
- (b) Centring annihilates $\mathbf{1} \mathbf{f}^\top$ and commutes with multiplication on the right, so replacing $\mathbf{Z}_1$ by $\mathbf{Z}_1 \mathbf{A} + \mathbf{1} \mathbf{f}^\top$ replaces $\tilde{\mathbf{Z}}_1$ by $\tilde{\mathbf{Z}}_1 \mathbf{A}$, and both determinants in [Definition 26.2.2](#) are multiplied by $\det(\mathbf{A})^2$. For the same reason $\mathbf{Z}_2 \mapsto \mathbf{Z}_2 \mathbf{B} + \mathbf{1} \mathbf{g}^\top$ replaces $\tilde{\mathbf{Z}}_2$ by $\tilde{\mathbf{Z}}_2 \mathbf{B}$, which leaves $\mathcal{C}(\tilde{\mathbf{Z}}_2)$, and so $\tilde{\mathbf{M}}_2$, unchanged. We may therefore take $\tilde{\mathbf{Z}}_1 = \mathbf{Q}_1$. Then $\tilde{\mathbf{M}}_2 = \mathbf{Q}_2 \mathbf{Q}_2^\top$, and with $\mathbf{C} = \mathbf{Q}_1^\top \mathbf{Q}_2$,

$$\text{GVIF}_1 = \frac{\det(\mathbf{Q}_1^\top \mathbf{Q}_1)}{\det(\mathbf{Q}_1^\top \mathbf{Q}_1 - \mathbf{C} \mathbf{C}^\top)} = \frac{1}{\det(\mathbf{I}_q - \mathbf{C} \mathbf{C}^\top)}.$$

The eigenvalues of $\mathbf{C} \mathbf{C}^\top$ are $\rho_1^2, \dots, \rho_m^2$ and $q - m$ zeros, so the determinant is $\prod_i (1 - \rho_i^2)$.

- (c) The invariance was shown in the proof of (b). Symmetry follows from (b), because $\mathbf{Q}_1^\top \mathbf{Q}_2$ and $\mathbf{Q}_2^\top \mathbf{Q}_1$ have the same singular values.
- (d) For $q = 1$ the ratio is $S_{jj} / \|(\mathbf{I} - \mathbf{M}_{(j)}) \mathbf{x}_j\|^2 = \text{VIF}_j$ by [Proposition 26.2.1\(a\)](#). For the

determinant form, let $\mathbf{D}$ be the diagonal matrix with $\mathbf{R} = \mathbf{D}[\tilde{\mathbf{Z}}_1, \tilde{\mathbf{Z}}_2]^\top [\tilde{\mathbf{Z}}_1, \tilde{\mathbf{Z}}_2] \mathbf{D}$, with diagonal blocks $\mathbf{D}_1, \mathbf{D}_2$. By [Theorem 1.6.3](#), $\det \mathbf{R} = \det \mathbf{R}_{22} \det(\mathbf{R}_{11} - \mathbf{R}_{12} \mathbf{R}_{22}^{-1} \mathbf{R}_{21})$, and the Schur complement is $\mathbf{D}_1 \tilde{\mathbf{Z}}_1^\top (\mathbf{I} - \tilde{\mathbf{M}}_2) \tilde{\mathbf{Z}}_1 \mathbf{D}_1$. Since $\mathbf{R}_{11} = \mathbf{D}_1 \tilde{\mathbf{Z}}_1^\top \tilde{\mathbf{Z}}_1 \mathbf{D}_1$, the factors $\det(\mathbf{D}_1)^2$ cancel in $\det \mathbf{R}_{11} \det \mathbf{R}_{22} / \det \mathbf{R}$, which leaves GVIF_1 . ■

A generalized factor inflates a q -dimensional volume, so for comparison with single columns Fox and Monette suggest $\text{GVIF}_1^{1/(2q)}$, the geometric mean of the factors by which the axes of the confidence ellipsoid lengthen; for $q = 1$ it is $\sqrt{\text{VIF}_j}$.

Example. (A factor that explains a regressor)

Grunfeld's panel ([Example \(Grunfeld's investment data\)](#)) has 220 firm-years of gross investment, market value and capital stock for 11 firms. Regress investment on value, capital and the firm, entered as 10 indicator columns with the first firm as reference. The generalized factors are

Term	columns q	GVIF	$\text{GVIF}^{1/(2q)}$
value	1	18.32	4.280
capital	1	2.04	
firm	10	23.61	1.171

The canonical correlations between the firm block and the pair (value, capital) are 0.9694 and 0.5459, and $1/((1 - 0.9694^2)(1 - 0.5459^2)) \approx 23.6$ as [Proposition 26.2.2\(b\)](#) requires. Market value is largely a characteristic of the firm. With the firm indicators in the model, the coefficient of value is identified by movements within firms (the within estimator of [Section 6.6](#)), and the part of value that neither firm nor capital explains is $1/18.32$, about 5.5 per cent, of its variation.

The ordinary factors of the ten indicator columns range from 1.8 to 16.8; with the last firm as reference the largest is 12.7. The generalized factors are the same under every coding, including sum-to-zero coding ([Proposition 26.2.2\(c\)](#)).

```
import pandas as pd
grun = sm.datasets.grunfeld.load_pandas().data
D = pd.get_dummies(grun["firm"], drop_first=True).to_numpy(dtype=float)  # 10
    indicator columns
Zg = np.column_stack([grun["value"], grun["capital"], D])

def gvif(Z, block):
    """det(R_11) det(R_22) / det(R) for the columns in block against the rest."""
    R = np.corrcoef(Z, rowvar=False)
    rest = [k for k in range(Z.shape[1]) if k not in block]
    return (np.linalg.det(R[np.ix_(block, block)]) * np.linalg.det(R[np.ix_(rest,
    rest)]))
        / np.linalg.det(R))

firm = list(range(2, Zg.shape[1]))
print("GVIF value  :", round(gvif(Zg, [0]), 2))
```

```
print("GVIF capital:", round(gvif(Zg, [1]), 2))
print("GVIF firm   :", round(gvif(Zg, firm), 2), " per dimension:", round(gvif(Zg,
    firm) ** (1 / 20), 3))
print("VIFs of the firm indicators:", np.round(vifs(Zg)[2:], 1))
```

26.2.5 Exercises

26.2.5.1 A. Check your understanding

Exercise A1.

Which values of R_j^2 correspond to variance inflation factors of 4, 5 and 10? By what factor does each multiply the length of a confidence interval for β_j , relative to the orthogonal design of [Proposition 26.2.1\(a\)](#)?

Exercise A2.

For a model with an intercept and two regressors with sample correlation r , show that $\text{VIF}_1 = \text{VIF}_2 = 1/(1 - r^2)$. What does [Proposition 26.2.1\(a\)](#) say about the design of [Example \(Two regressors that move together\)](#)?

26.2.5.2 B. Practice

Exercise B1.

Show that appending a column $\mathbf{w} \notin \mathcal{C}(\mathbf{X})$ to $\mathbf{X}$ cannot decrease the variance inflation factor of any column already in the model, and that it leaves VIF_j unchanged iff the residual of $\mathbf{w}$ on $\mathbf{X}_{(j)}$ is orthogonal to the residual of $\mathbf{x}_j$ on $\mathbf{X}_{(j)}$. Is $\text{Var}(\hat{\beta}_j)$ also nondecreasing?

Solution. Appending a column enlarges $\mathcal{C}(\mathbf{X}_{(j)})$, so $\|(\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j\|^2$ cannot increase, and by [Proposition 26.2.1\(a\)](#) VIF_j cannot decrease. Let $\tilde{\mathbf{w}} \neq \mathbf{0}$ be the residual of $\mathbf{w}$ on $\mathbf{X}_{(j)}$. The enlarged space is $\mathcal{C}(\mathbf{X}_{(j)}) \oplus \mathcal{C}(\tilde{\mathbf{w}})$ with orthogonal summands, so the squared residual of $\mathbf{x}_j$ drops by $(\tilde{\mathbf{w}}^\top \mathbf{x}_j)^2 / \|\tilde{\mathbf{w}}\|^2$, and $\tilde{\mathbf{w}}^\top \mathbf{x}_j = \tilde{\mathbf{w}}^\top (\mathbf{I} - \mathbf{M}_{(j)})\mathbf{x}_j$. So VIF_j is unchanged iff the two residuals are orthogonal. Since S_{jj} does not change, $\text{Var}(\hat{\beta}_j) = \sigma^2 \text{VIF}_j / S_{jj}$ is nondecreasing too. This is the variance half of [Theorem 19.1.3](#).

Exercise B2.

Let $x_i = m + u_i$, where the u_i are symmetric about zero. Write v for the mean of the u_i^2 and w for the variance of the u_i^2 (both with divisor n). Show that the variance inflation factor of x and of x^2 in the quadratic model is

$$\text{VIF} = 1 + \frac{4m^2v}{w}.$$

Check the value in [Example \(A quadratic far from the origin\)](#).

Solution. With one other regressor, $\text{VIF} = 1/(1 - r^2)$, where r is the correlation of x and x^2 (Exercise A2). Since $x^2 = m^2 + 2mu + u^2$, the covariance of x and x^2 is that of u and $2mu + u^2$, which is $2mv$ because the third moment of u vanishes. The variance of x^2 is $4m^2v + w$, since u and u^2 are uncorrelated. So $r^2 = 4m^2v^2/(v(4m^2v + w)) = 4m^2v/(4m^2v + w)$ and $1/(1 - r^2) = 1 + 4m^2v/w$. In the example, $m = 15$ and u runs over $-5, -4.5, \dots, 5$: $v = 192.5/21 \approx 9.167$, the mean of u^4 is $3166.6/21 \approx 150.79$, so $w \approx 150.79 - 84.03 = 66.76$ and $\text{VIF} \approx 1 + 900 \cdot 9.167/66.76 \approx 124.6$.

Exercise B3.

Let $\mathbf{x}_j$ be a column of the block $\mathbf{Z}_1$. Show that $\text{GVIF}_1 \geq 1/(1 - R_{j|2}^2)$, where $R_{j|2}^2$ is the coefficient of determination of $\mathbf{x}_j$ regressed on $\mathbf{1}$ and $\mathbf{Z}_2$ alone. Why is there no such inequality between GVIF_1 and the ordinary VIF_j computed in the full model?

Solution. $R_{j|2}$ is the correlation between the centred $\mathbf{x}_j$ and its projection on $\mathcal{C}(\tilde{\mathbf{Z}}_2)$, which is a correlation between a vector $\mathbf{Q}_1\mathbf{s}$ of $\mathcal{C}(\tilde{\mathbf{Z}}_1)$ and a vector $\mathbf{Q}_2\mathbf{t}$ of $\mathcal{C}(\tilde{\mathbf{Z}}_2)$, with $\mathbf{s}$ and $\mathbf{t}$ unit vectors. That correlation is $\mathbf{s}^\top \mathbf{Q}_1^\top \mathbf{Q}_2 \mathbf{t} \leq \rho_1$ (Proposition 1.8.2; this is the first part of Exercise C1). Hence $\text{GVIF}_1 \geq 1/(1 - \rho_1^2) \geq 1/(1 - R_{j|2}^2)$ by Proposition 26.2.2(b). The ordinary VIF_j regresses $\mathbf{x}_j$ also on the other columns of its own block, which can explain it well even when $\mathbf{Z}_2$ cannot. The indicators of a factor with a small reference level are an example: each is nearly determined by the others.

26.2.5.3 C. Going deeper

Exercise C1.

Show that $\rho_1 = \max\{\cos \angle(\mathbf{u}, \mathbf{v}) : \mathbf{u} \in \mathcal{C}(\tilde{\mathbf{Z}}_1), \mathbf{v} \in \mathcal{C}(\tilde{\mathbf{Z}}_2), \mathbf{u}, \mathbf{v} \neq \mathbf{0}\}$. More generally, show that the generalized eigenvalues of $\text{Cov}(\hat{\boldsymbol{\beta}}_1)$ relative to $\text{Cov}_\perp$, the roots θ of $\det(\text{Cov}(\hat{\boldsymbol{\beta}}_1) - \theta \text{Cov}_\perp) = 0$, are $1/(1 - \rho_i^2)$, $i \leq m$, together with $q - m$ ones. Deduce that for every $\mathbf{a} \neq \mathbf{0}$ the ratio $\text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}}_1)/\mathbf{a}^\top \text{Cov}_\perp \mathbf{a}$ lies between 1 and $1/(1 - \rho_1^2)$.

Solution. Write $\mathbf{u} = \mathbf{Q}_1\mathbf{s}$ and $\mathbf{v} = \mathbf{Q}_2\mathbf{t}$ with unit $\mathbf{s}, \mathbf{t}$. Then $\cos \angle(\mathbf{u}, \mathbf{v}) = \mathbf{s}^\top \mathbf{Q}_1^\top \mathbf{Q}_2 \mathbf{t}$, whose maximum over unit vectors is the largest singular value of $\mathbf{Q}_1^\top \mathbf{Q}_2$ (Proposition 1.8.2). For the second part, take $\tilde{\mathbf{Z}}_1 = \mathbf{Q}_1$ by Proposition 26.2.2(c), which changes both matrices by the same congruence and so leaves the generalized eigenvalues unchanged. Then $\text{Cov}_\perp = \sigma^2 \mathbf{I}$ and $\text{Cov}(\hat{\boldsymbol{\beta}}_1) = \sigma^2(\mathbf{I} - \mathbf{C}\mathbf{C}^\top)^{-1}$, whose eigenvalues are the stated ones. The ratio in the last part is a ratio of quadratic forms, bounded by Corollary 1.7.8, so it lies between the smallest and the largest generalized eigenvalue.

26.3 Condition indices and variance decomposition

A variance inflation factor says how much one coefficient has suffered, but not which other regressors are responsible, how many near-dependencies there are, or whether the intercept is involved. The eigenvalue analysis of Section 26.1 answers those questions but depends on

the units of the columns. This section fixes a scaling and derives the variance-decomposition proportions of Belsley, Kuh and Welsch (1980).

26.3.1 Scaling the columns

The canonical directions of $\mathbf{X}^\top \mathbf{X}$ change when a column is rescaled (Exercise (A3)), and a merely short column produces a small eigenvalue without any near-dependence (Exercise (B1)). The diagnostics are therefore computed for the design with every column, including $\mathbf{1}$, scaled to unit length:

$$\tilde{\mathbf{X}} = \mathbf{X}\mathbf{D}_0, \quad \mathbf{D}_0 = \text{diag}(1/\|\mathbf{x}_1\|, \dots, 1/\|\mathbf{x}_p\|).$$

By Proposition 10.5.2 this is within a factor $\sqrt{p}$ of the best diagonal scaling for the condition number. The coefficients of $\tilde{\mathbf{X}}$ are $\tilde{\beta}_j = \|\mathbf{x}_j\|\beta_j$.

Definition 26.3.1 — Condition indices

Let $\tilde{\mathbf{X}}$ have singular values $\mu_1 \geq \mu_2 \geq \dots \geq \mu_p > 0$. The **condition indices** of $\mathbf{X}$ are

$$\eta_k = \frac{\mu_1}{\mu_k}, \quad k = 1, \dots, p.$$

The largest, $\eta_p = \kappa(\tilde{\mathbf{X}})$, is the **scaled condition number**.

Whether to centre before scaling is a real choice. Let $\mathbf{R}$ be the correlation matrix of the non-intercept columns, the cross-product matrix of the centred and scaled design, and write $s_j^2 = S_{jj}/n$ and $\text{CV}_j = s_j/|\bar{x}_j|$ for the **coefficient of variation** of a column with nonzero mean.

Proposition 26.3.1 — Scaled condition numbers

Let $\mathbf{X}$ contain the column $\mathbf{1}$ and have full column rank, and let $\mathbf{R}$ be nonsingular.

- (a) $\sum_k \mu_k^2 = p$, so $1 \leq \mu_1^2 \leq p$. Every diagonal entry of $(\tilde{\mathbf{X}}^\top \tilde{\mathbf{X}})^{-1}$ is at most $1/\mu_p^2 \leq \eta_p^2$.
- (b) $\lambda_{\min}(\mathbf{R}) \geq \mu_p^2$. Hence $\eta_p^2 \geq 1/\lambda_{\min}(\mathbf{R}) \geq \max_j \text{VIF}_j$: every near-dependency among the centred regressors is at least as severe in the uncentred scaled design.
- (c) If a non-intercept column $\mathbf{x}_j$ has $\bar{x}_j \neq 0$, then $\mu_p^2 \leq \text{CV}_j^2/(\text{CV}_j^2 + 2)$, so that $\eta_p \geq \sqrt{(\text{CV}_j^2 + 2)/\text{CV}_j^2} > \sqrt{2}/\text{CV}_j$.

Proof.

- (a) $\sum_k \mu_k^2 = \|\tilde{\mathbf{X}}\|_F^2 = p$ (Proposition 1.8.2), since each column has unit length. The largest of p numbers with sum p is between 1 and p . The j th diagonal entry of $(\tilde{\mathbf{X}}^\top \tilde{\mathbf{X}})^{-1}$ is a Rayleigh quotient of a matrix whose largest eigenvalue is $1/\mu_p^2$ (Theorem 1.7.7), and $1/\mu_p^2 = \eta_p^2/\mu_1^2 \leq \eta_p^2$.
- (b) Number the columns so that $\mathbf{x}_0 = \mathbf{1}$ and $\mathbf{x}_1, \dots, \mathbf{x}_k$ are the others. The centred and scaled columns are $\mathbf{z}_j = (\mathbf{x}_j - \bar{x}_j \mathbf{1})/(\sqrt{n} s_j)$, so that $\mathbf{R} = \mathbf{Z}^\top \mathbf{Z}$ with $\mathbf{Z} = [\mathbf{z}_1, \dots, \mathbf{z}_k]$.

Since $\mathbf{1} = \sqrt{n} \tilde{\mathbf{x}}_0$ and $\mathbf{x}_j = \|\mathbf{x}_j\| \tilde{\mathbf{x}}_j$, where $\tilde{\mathbf{x}}_j$ are the columns of $\tilde{\mathbf{X}}$,

$$\mathbf{Zc} = \sum_{j=1}^k c_j \frac{\|\mathbf{x}_j\| \tilde{\mathbf{x}}_j - \sqrt{n} \bar{x}_j \tilde{\mathbf{x}}_0}{\sqrt{n} s_j} = \tilde{\mathbf{X}} \mathbf{b},$$

where

$$b_j = \frac{c_j \|\mathbf{x}_j\|}{\sqrt{n} s_j} \quad (j \geq 1), \quad b_0 = -\sum_{j=1}^k \frac{c_j \bar{x}_j}{s_j}.$$

Because $\|\mathbf{x}_j\|^2 = n(s_j^2 + \bar{x}_j^2) \geq ns_j^2$, $|b_j| \geq |c_j|$, so $\|\mathbf{b}\| \geq \|\mathbf{c}\|$. For a unit vector $\mathbf{c}$, $\mathbf{c}^\top \mathbf{R} \mathbf{c} = \|\tilde{\mathbf{X}} \mathbf{b}\|^2 \geq \mu_p^2 \|\mathbf{b}\|^2 \geq \mu_p^2$ by [Theorem 1.7.7](#); minimizing over $\mathbf{c}$ gives $\lambda_{\min}(\mathbf{R}) \geq \mu_p^2$. Then $\eta_p^2 \geq 1/\mu_p^2 \geq 1/\lambda_{\min}(\mathbf{R})$ by (a), and $1/\lambda_{\min}(\mathbf{R}) \geq \text{VIF}_j$ by [Proposition 19.6.1\(c\)](#).

- (c) Take $\mathbf{b}$ with $b_j = \|\mathbf{x}_j\|$, $b_0 = -\sqrt{n} \bar{x}_j$ and all other entries zero. Then $\tilde{\mathbf{X}} \mathbf{b} = \mathbf{x}_j - \bar{x}_j \mathbf{1}$, with squared length ns_j^2 , while $\|\mathbf{b}\|^2 = n(s_j^2 + \bar{x}_j^2) + n\bar{x}_j^2$. So $\mu_p^2 \leq ns_j^2/(n(s_j^2 + 2\bar{x}_j^2)) = \text{CV}_j^2/(\text{CV}_j^2 + 2)$, and $\eta_p \geq 1/\mu_p$ by (a). ■

Part (b) is the formal content of the argument of Belsley (1984) for not centring: centring can only hide near-dependencies, never create them. Part (c) shows what it hides. A regressor that varies little relative to its mean is nearly a multiple of the column of ones, and that near-dependency with the intercept is invisible in $\mathbf{R}$ and in every variance inflation factor. The design of [Example \(A macroeconomic design\)](#) shows the size of the effect: scaled to unit length, its condition number is 383; centred and scaled, 124.

Whether the hidden dependency matters depends on the question, as in [Example \(A quadratic far from the origin\)](#). It inflates the variance of the intercept, the mean response at the origin, and of the coefficients whose columns take part in it. If the origin is far from the data, it concerns a question nobody asked; if the origin is meaningful, the uncentred diagnostic is the honest one. This chapter uses the uncentred scaled design, as Belsley, Kuh and Welsch do, and reports the centred condition number alongside.

26.3.2 The variance-decomposition proportions

Let the singular value decomposition of the scaled design be

$$\tilde{\mathbf{X}} = \sum_{k=1}^p \mu_k \mathbf{u}_k \mathbf{t}_k^\top,$$

with orthonormal right singular vectors $\mathbf{t}_k = (t_{1k}, \dots, t_{pk})^\top$. The $p \times p$ matrix with columns $\mathbf{t}_k$ is orthogonal, so its rows also have unit length: $\sum_k t_{jk}^2 = 1$ for every j .

Theorem 26.3.2 — Variance-decomposition proportions

Let $\mathbf{X}$ have rank p , $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, and let $\phi_{jk} = t_{jk}^2 / \mu_k^2$.

(a) $\text{Var}(\hat{\beta}_j) = \frac{\sigma^2}{\|\mathbf{x}_j\|^2} \sum_{k=1}^p \phi_{jk}$. The **variance-decomposition proportions**

$$\pi_{kj} = \frac{\phi_{jk}}{\sum_{l=1}^p \phi_{jl}}$$

satisfy $\sum_k \pi_{kj} = 1$, do not depend on σ^2 , and vanish iff $t_{jk} = 0$. The term π_{kj} is the share of $\text{Var}(\hat{\beta}_j)$ contributed by the canonical coordinate with condition index η_k .

- (b) For each k , $\|\sum_j t_{jk} \tilde{\mathbf{x}}_j\| = \mu_k$ while $\|\mathbf{t}_k\| = 1$: the vector $\mathbf{t}_k$ holds the coefficients of a near-dependency among the scaled columns, of strength μ_k .
- (c) Let S be a nonempty proper subset of $\{1, \dots, p\}$ such that $\mu_k \leq \mu_S$ for $k \in S$ and $\mu_k \geq \mu_L$ for $k \notin S$, with $\mu_S < \mu_L$. Let $w_j = \sum_{k \in S} t_{jk}^2$ measure the participation of column j in the near-dependencies indexed by S . Then

$$\sum_{k \in S} \pi_{kj} \geq \frac{w_j}{w_j + (1 - w_j) \mu_S^2 / \mu_L^2}, \quad \text{Var}(\hat{\beta}_j) \geq \frac{\sigma^2 w_j}{\|\mathbf{x}_j\|^2 \mu_S^2}.$$

Proof.

- (a) Since $\mathbf{X}\boldsymbol{\beta} = \tilde{\mathbf{X}}\mathbf{D}_0^{-1}\boldsymbol{\beta}$, the least squares coefficients of $\tilde{\mathbf{X}}$ are $\hat{\tilde{\beta}}_j = \|\mathbf{x}_j\| \hat{\beta}_j$, and by [Theorem 26.1.1\(a\)](#) applied to $\tilde{\mathbf{X}}$, whose cross-product matrix has eigenvalues μ_k^2 and eigenvectors $\mathbf{t}_k$, $\text{Cov}(\hat{\tilde{\beta}}) = \sigma^2 \sum_k \mathbf{t}_k \mathbf{t}_k^\top / \mu_k^2$. Its j th diagonal entry is $\sigma^2 \sum_k \phi_{jk}$. The statements about the proportions follow from the definition, since $\mu_k > 0$.
- (b) $\sum_j t_{jk} \tilde{\mathbf{x}}_j = \tilde{\mathbf{X}} \mathbf{t}_k = \mu_k \mathbf{u}_k$.
- (c) Put $A = \sum_{k \in S} \phi_{jk}$ and $B = \sum_{k \notin S} \phi_{jk}$. Then $A \geq w_j / \mu_S^2$ and, since $\sum_{k \notin S} t_{jk}^2 = 1 - w_j$, $B \leq (1 - w_j) / \mu_L^2$. The sum of the proportions over S is $A / (A + B)$, which increases with A and decreases with B , so it is at least $(w_j / \mu_S^2) / (w_j / \mu_S^2 + (1 - w_j) / \mu_L^2)$, which is the stated bound. The variance bound is $\text{Var}(\hat{\beta}_j) \geq \sigma^2 A / \|\mathbf{x}_j\|^2$ together with $A \geq w_j / \mu_S^2$. ■

Part (c) is why the proportions locate near-dependencies. If the condition indices in S are at least ten times those outside it, $\mu_S^2 / \mu_L^2 \leq 0.01$, then any column with even a tenth of its unit row inside S , $w_j \geq 0.1$, has at least $0.1 / (0.1 + 0.9 \times 0.01) \approx 0.92$ of its variance attributed to S , and its variance is inflated accordingly. A column that does not take part has proportions near zero there. When several small singular values are close together, the individual $\mathbf{t}_k$ are poorly determined, and a column's proportions can be split between their rows in unpredictable ratios. Part (c) bounds the *sum* over the group, which is stable, and that is what should be read ([Exercise \(C1\)](#)).

Idea. Belsley, Kuh and Welsch's reading of the table: scale the columns to unit length; flag condition indices of about 30 or more (indices near 10 signal weak dependencies); in each flagged row, or group of rows with similar indices, look for two or more coefficients with large proportions, conventionally above 0.5. Those columns form a near-dependency. Confirm it by regressing one of them on the others.

Example. (A consumption function)

Return to the regression of [Example \(Large factors, precise estimate\)](#), with an intercept and six regressors. The scaled design has condition indices and proportions

Index	const.	income	pop.	CPI	M1	T-bill	unemp.
1.0	0.000	0.000	0.000	0.000	0.000	0.001	0.001
3.4	0.000	0.000	0.000	0.000	0.001	0.053	0.007
7.7	0.000	0.000	0.000	0.001	0.001	0.347	0.090
13.4	0.002	0.001	0.000	0.001	0.002	0.001	0.688
38.9	0.005	0.149	0.000	0.001	0.290	0.049	0.036
74.3	0.007	0.130	0.000	0.995	0.569	0.241	0.116
270.9	0.985	0.720	0.999	0.001	0.138	0.307	0.060

[Figure 26.3.1](#) shows the table graphically. Three indices exceed 30, and the table separates them.

- *Index 270.9: intercept, income and population* (proportions 0.985, 0.720, 0.999). The singular vector has entries -0.522 , -0.236 and 0.817 on these columns and small ones elsewhere: population, which grew steadily with income, is nearly an affine function of it ($R^2 = 0.9885$). Its small coefficient of variation, 0.156, alone forces an index of at least 9.1 by [Proposition 26.3.1\(c\)](#); the shared trend does the rest.
- *Index 74.3: the price level and money*. CPI has proportion 0.995 and M1 0.569. Regressing CPI on income and M1 gives $R^2 = 0.9868$.
- *Index 38.9: a weaker dependency involving M1 and income*. Taken with the previous row, M1 has $0.290 + 0.569 = 0.859$ of its variance in the two rows, and income has $0.149 + 0.130 + 0.720 = 0.999$ in the three rows above 30. Income takes part in all three near-dependencies.

A proportion is a share, not a size: the 0.307 of the T-bill rate at index 270.9 is a share of a variance that collinearity has barely inflated (its variance inflation factor is 2.9). Centred and scaled, the design has condition number 37.9 against 270.9 uncentred: centring removes the intercept from the largest near-dependency, and what is left is the relation between income and population that the variance inflation factors 154.5 and 183.7 already showed.

```
import numpy as np
import statsmodels.api as sm
macro = sm.datasets.macrodatab.load_pandas().data
names = ["const", "realdpi", "pop", "cpi", "m1", "tbilrate", "unemp"]
X = sm.add_constant(macro[names[1:]].to_numpy())
X_s = X / np.linalg.norm(X, axis=0)                                # unit-length columns, not
    centred

U, mu, Vt = np.linalg.svd(X_s, full_matrices=False)              # X_s = U diag(mu) V'
eta = mu[0] / mu                                                  # condition indices
phi = Vt.T ** 2 / mu**2                                           # phi[j, k] = v_jk^2 / mu_k^2
prop = (phi / phi.sum(axis=1, keepdims=True)).T                  # row k: proportions for index
    eta_k
```

Figure 26.3.1: Variance-decomposition proportions of [Example \(A consumption function\)](#): rows are condition indices, columns coefficients, dot area proportional to π_{kj} . Highlighted: $\pi_{kj} \geq 0.5$ with index at least 30.

```
print("index   " + " ".join(f"{nm[:7]:>7s}" for nm in names))
for k in range(len(mu)):
    print(f"{eta[k]:7.1f} " + " ".join(f"{p:7.3f}" for p in prop[k]))
```

```
Z = X[:, 1:] - X[:, 1:].mean(axis=0)
Z_s = Z / np.linalg.norm(Z, axis=0) # centred, then unit length
mu_c = np.linalg.svd(Z_s, compute_uv=False)
print("scaled condition number, not centred:", round(eta[-1], 1))
print("scaled condition number, centred   :", round(mu_c[0] / mu_c[-1], 1))
cv = X[:, 1:].std(axis=0) / X[:, 1:].mean(axis=0)
print("coefficients of variation:", dict(zip(names[1:], np.round(cv, 3))))
```

```
def r_squared(target, others):
    fit = sm.OLS(macro[target], sm.add_constant(macro[others])).fit()
    return fit.rsquared

print("pop on realdpi      : R^2 =", round(r_squared("pop", ["realdpi"]), 4))
print("cpi on realdpi, m1 : R^2 =", round(r_squared("cpi", ["realdpi", "m1"]), 4))
```

The script behind the example checks the bound of [Theorem 26.3.2\(c\)](#) for the groups formed by the last one, two and three indices, and the inequalities of [Proposition 26.3.1](#).

26.3.3 Single cases

Collinearity diagnostics can be dominated by a few cases: one far out along a near-dependency can create it, one lying across it can hide it. The deletion formulas of [Chapter 20](#) show that only cases of high leverage can have much effect.

Proposition 26.3.3 — Deleting a case

Let $\mathbf{X}$ have rank p , let $\mathbf{x}_{(i)}$ be its i th row with leverage $h_{ii} < 1$, let $\mathbf{X}_{[i]}$ be $\mathbf{X}$ without that row ([Theorem 20.3.1](#) writes $\mathbf{X}_{(i)}$; square brackets here avoid a clash with $\mathbf{X}_{(j)}$), the matrix without column j), and write $\mathbf{G} = (\mathbf{X}^\top \mathbf{X})^{-1}$, $\mathbf{G}_{[i]} = (\mathbf{X}_{[i]}^\top \mathbf{X}_{[i]})^{-1}$.

- (a) $\mathbf{a}^\top \mathbf{G}_{[i]} \mathbf{a} = \mathbf{a}^\top \mathbf{G} \mathbf{a} + (\mathbf{a}^\top \mathbf{G} \mathbf{x}_{(i)})^2 / (1 - h_{ii})$ for every $\mathbf{a}$.
- (b) $\mathbf{a}^\top \mathbf{G} \mathbf{a} \leq \mathbf{a}^\top \mathbf{G}_{[i]} \mathbf{a} \leq \mathbf{a}^\top \mathbf{G} \mathbf{a} / (1 - h_{ii})$: deleting case i multiplies the variance of every linear function of $\hat{\boldsymbol{\beta}}$ by a factor between 1 and $1/(1 - h_{ii})$.
- (c) $(1 - h_{ii}) \lambda_{\min}(\mathbf{X}^\top \mathbf{X}) \leq \lambda_{\min}(\mathbf{X}_{[i]}^\top \mathbf{X}_{[i]}) \leq \lambda_{\min}(\mathbf{X}^\top \mathbf{X})$.

Proof.

- (a) This is the rank-one deletion formula $\mathbf{G}_{[i]} = \mathbf{G} + \mathbf{G} \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top \mathbf{G} / (1 - h_{ii})$ of [Example \(Deleting an observation\)](#), on which [Theorem 20.3.1](#) rests, sandwiched between $\mathbf{a}^\top$ and $\mathbf{a}$.
- (b) The lower bound is clear from (a). For the upper, apply the Cauchy–Schwarz inequality to the inner product $\langle \mathbf{a}, \mathbf{b} \rangle = \mathbf{a}^\top \mathbf{G} \mathbf{b}$, which is legitimate because $\mathbf{G}$ is positive definite: $(\mathbf{a}^\top \mathbf{G} \mathbf{x}_{(i)})^2 \leq (\mathbf{a}^\top \mathbf{G} \mathbf{a}) h_{ii}$. Then $\mathbf{a}^\top \mathbf{G}_{[i]} \mathbf{a} \leq \mathbf{a}^\top \mathbf{G} \mathbf{a} (1 + h_{ii} / (1 - h_{ii}))$.
- (c) For a positive definite matrix, $1/\lambda_{\min}$ is the largest eigenvalue of the inverse, which is $\max_{\|\mathbf{a}\|=1} \mathbf{a}^\top (\cdot)^{-1} \mathbf{a}$ ([Theorem 1.7.7](#)). Taking the maximum in (b) over unit vectors gives the two inequalities. ■

So removing a case of small leverage changes the smallest eigenvalue by at most the factor $1 - h_{ii}$, and no variance by more than $1/(1 - h_{ii})$. In the consumption regression the largest leverage is 0.161, at 2009Q3, so by (c) no single quarter can reduce the smallest eigenvalue of the scaled cross-product matrix by more than the factor 1.192, with the column scaling of the full data held fixed. The largest reduction actually achieved by deleting one of the 203 quarters is by the factor 1.055. The near-dependencies of this design are carried by the whole sample, not by a few quarters.

Adding a case never increases a variance, by (b) read the other way round, but it can increase every variance inflation factor and the condition number ([Exercise \(B2\)](#)).

26.3.4 Exercises

26.3.4.1 A. Check your understanding

Exercise A1.

In the table of [Example \(A consumption function\)](#), why is the intercept's variance almost entirely attributed to the largest index, although the intercept is not an economic variable? Which coefficients would you expect to change most if a few more years of data were added in which population grew faster than income?

26.3.4.2 B. Practice

Exercise B1.

Let $\mathbf{X} = [\mathbf{1}, \mathbf{x}]$ with $\bar{x} \neq 0$. Show that the scaled design has $\mu_{1,2}^2 = 1 \pm \cos \theta$, where $\cos \theta = 1/\sqrt{1 + \text{CV}^2}$ is the cosine of the angle between $\mathbf{1}$ and $\mathbf{x}$, and hence $\eta_2^2 = (1 + \cos \theta)/(1 - \cos \theta)$. Compare with the bound of Proposition 26.3.1(c). What is the variance inflation factor of $\mathbf{x}$?

Solution. The scaled columns are unit vectors at angle θ , so $\tilde{\mathbf{X}}^\top \tilde{\mathbf{X}} = \begin{pmatrix} 1 & c \\ c & 1 \end{pmatrix}$ with $c = \cos \theta$, whose eigenvalues are $1 \pm c$ (Exercise (B1)). Now $c = \mathbf{1}^\top \mathbf{x} / (\sqrt{n} \|\mathbf{x}\|) = n\bar{x} / \sqrt{n \cdot n(s^2 + \bar{x}^2)} = 1/\sqrt{1 + \text{CV}^2}$ (taking $\bar{x} > 0$). So $\eta_2^2 = (1 + c)/(1 - c)$. The bound of the proposition gives $\mu_2^2 \leq \text{CV}^2/(\text{CV}^2 + 2)$. For small CV, $1 - c \approx \text{CV}^2/2$, so $\mu_2^2 = 1 - c \approx \text{CV}^2/2$, and the bound is attained to first order. With a single regressor $R_j^2 = 0$ and $\text{VIF} = 1$: the variance inflation factor cannot see this near-dependency at all.

Exercise B2.

Take $n = 20$ cases with (x_1, x_2) at the points of a 4×5 grid in $[-1, 1]^2$, so that the regressors are uncorrelated, and add a twenty-first case at (t, t) . Show that the correlation of the two regressors tends to one as $t \rightarrow \infty$, so that both variance inflation factors grow without bound, while no variance of any linear function of $\hat{\beta}$ increases. Reconcile the two statements.

Solution. By Proposition 26.3.3(b) read backwards, adding a case can only decrease $\mathbf{a}^\top \mathbf{G} \mathbf{a}$ for every $\mathbf{a}$. The sample covariance of x_1, x_2 in the enlarged data is $t^2(1 - 1/21)/21$ (the grid contributes nothing, being centred and uncorrelated), and the sample variance of x_j is $(S_j + t^2(1 - 1/21))/21$, where S_j is the grid's sum of squares for x_j . As $t \rightarrow \infty$ the correlation tends to one and $\text{VIF}_j = 1/(1 - r^2) \rightarrow \infty$. But $\text{Var}(\hat{\beta}_j) = \sigma^2 \text{VIF}_j / S_{jj}$, and S_{jj} grows like t^2 as fast as VIF_j does, so the variances converge to finite limits no larger than before. The variance inflation factor compares with an orthogonal design with the *new* spread, which the added point has made enormous; the point added information along $(1, 1)$ and none across it.

26.3.4.3 C. Going deeper

Exercise C1.

Suppose $\mu_k = \mu$ for all $k \in S$. Show that the singular vectors $\mathbf{t}_k$, $k \in S$, are determined only up to an orthogonal transformation of their span, that the individual proportions π_{kj} , $k \in S$, depend on the choice, and that $\sum_{k \in S} \pi_{kj}$ does not.

Solution. If $\mathbf{T}_S$ has columns $\mathbf{t}_k$, $k \in S$, and $\mathbf{O}$ is orthogonal, then $\tilde{\mathbf{X}}^\top \tilde{\mathbf{X}} \mathbf{T}_S \mathbf{O} = \mu^2 \mathbf{T}_S \mathbf{O}$, so the columns of $\mathbf{T}_S \mathbf{O}$ are equally valid singular vectors, and the individual t_{jk}^2 change with $\mathbf{O}$. But $\sum_{k \in S} \phi_{jk} = \mu^{-2} \sum_{k \in S} t_{jk}^2 = \mu^{-2} \mathbf{e}_j^\top \mathbf{T}_S \mathbf{T}_S^\top \mathbf{e}_j$, and $\mathbf{T}_S \mathbf{T}_S^\top$ is the projection onto the span, which does not depend on $\mathbf{O}$. The denominator $\sum_l \phi_{jl}$ is a diagonal entry of $(\tilde{\mathbf{X}}^\top \tilde{\mathbf{X}})^{-1}$ and does not depend on the choice either.

26.4 Collinearity and prediction

By [Theorem 26.1.1\(d\)](#), collinearity leaves the total variance of the fitted values, the predictions at the design points, untouched. At a new point $\mathbf{x}_0$, collinearity damages a prediction exactly to the extent that the point asks for information along a weak direction. [Example \(Predicting along and across the pattern\)](#) showed this contrast on simulated data; this section proves it in general and measures it on real data.

26.4.1 The variance of a prediction

Keep the notation of [Section 26.1](#): $\mathbf{X}^\top \mathbf{X} = \sum_{\ell} \lambda_{\ell} \mathbf{v}_{\ell} \mathbf{v}_{\ell}^\top$, and let

$$m_{\ell} = \frac{\lambda_{\ell}}{n} = \frac{1}{n} \sum_{i=1}^n (\mathbf{x}_{(i)}^\top \mathbf{v}_{\ell})^2$$

be the mean square of the design rows along the direction $\mathbf{v}_{\ell}$. A small m_{ℓ} means that the rows hardly vary along $\mathbf{v}_{\ell}$: the data cloud is thin in that direction. The estimate of the mean response at $\mathbf{x}_0$ is $\hat{Y}_0 = \mathbf{x}_0^\top \hat{\boldsymbol{\beta}}$.

Proposition 26.4.1 — Prediction under collinearity

Let $\mathbf{X}$ have rank p and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$.

- (a) $\text{Var}(\hat{Y}_0) = \frac{\sigma^2}{n} \sum_{\ell=1}^p \frac{(\mathbf{x}_0^\top \mathbf{v}_{\ell})^2}{m_{\ell}}$.
- (b) If $\mathbf{x}_0 = \mathbf{X}^\top \mathbf{w}$ for some $\mathbf{w} \in \mathbb{R}^n$, then $\text{Var}(\hat{Y}_0) = \sigma^2 \|\mathbf{M}\mathbf{w}\|^2 \leq \sigma^2 \|\mathbf{w}\|^2$. If $\mathbf{x}_0$ is a convex combination of the rows of $\mathbf{X}$, then $\text{Var}(\hat{Y}_0) \leq \sigma^2 \max_i h_{ii} \leq \sigma^2$. Neither bound involves the eigenvalues.
- (c) Let $\mathbf{x}_0$ be random, independent of $\mathbf{Y}$, with $\text{E}(\mathbf{x}_0 \mathbf{x}_0^\top) = \boldsymbol{\Sigma}_0$. Then

$$\text{E}\{\text{Var}(\hat{Y}_0 \mid \mathbf{x}_0)\} = \frac{\sigma^2}{n} \sum_{\ell=1}^p \frac{\mathbf{v}_{\ell}^\top \boldsymbol{\Sigma}_0 \mathbf{v}_{\ell}}{m_{\ell}}.$$

If $\mathbf{x}_0$ is drawn uniformly from the rows of $\mathbf{X}$, this equals $\sigma^2 p/n$, whatever the eigenvalues. For every $\boldsymbol{\Sigma}_0$ it is at least $(\sigma^2/n) \mathbf{v}_p^\top \boldsymbol{\Sigma}_0 \mathbf{v}_p / m_p$.

Proof.

- (a) This is [Proposition 19.6.1\(a\)](#) with $\mathbf{a} = \mathbf{x}_0$ and $\lambda_{\ell} = nm_{\ell}$. The second expression for m_{ℓ} is $\|\mathbf{X}\mathbf{v}_{\ell}\|^2/n$.
- (b) By [Theorem 6.3.6](#),

$$\text{Var}(\hat{Y}_0) = \sigma^2 \mathbf{w}^\top \mathbf{X}(\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{w} = \sigma^2 \mathbf{w}^\top \mathbf{M}\mathbf{w} = \sigma^2 \|\mathbf{M}\mathbf{w}\|^2,$$

and $\|\mathbf{M}\mathbf{w}\| \leq \|\mathbf{w}\|$ ([Proposition 6.3.4](#)). If $\mathbf{x}_0 = \sum_i w_i \mathbf{x}_{(i)}$ with $w_i \geq 0$ and $\sum_i w_i =$

1, then $\mathbf{x}_0 = \mathbf{X}^\top \mathbf{w}$, and by the triangle inequality and [Proposition 6.8.1\(a\)](#),

$$\|\mathbf{M}\mathbf{w}\| \leq \sum_i w_i \|\mathbf{M}\mathbf{e}_i\| = \sum_i w_i \sqrt{h_{ii}} \leq \max_i \sqrt{h_{ii}},$$

and $h_{ii} \leq 1$.

- (c) Conditionally on $\mathbf{x}_0$, (a) holds. Taking expectations, $E(\mathbf{x}_0^\top (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{x}_0) = \text{tr}((\mathbf{X}^\top \mathbf{X})^{-1} \boldsymbol{\Sigma}_0) = \sum_\ell \mathbf{v}_\ell^\top \boldsymbol{\Sigma}_0 \mathbf{v}_\ell / \lambda_\ell$. If $\mathbf{x}_0$ is uniform on the rows, $\boldsymbol{\Sigma}_0 = \mathbf{X}^\top \mathbf{X} / n$, and the trace is $\text{tr}(\mathbf{I}_p) / n = p / n$. The lower bound keeps the term $\ell = p$, since all terms are non-negative.

■

Part (b) answers the first question of [Exercise \(C1\)](#): inside the convex hull of the data, a prediction is never worse than the worst fitted value, however collinear the regressors. Part (a) says what “the pattern of the data” means: a point outside the hull is still predicted well if its coordinates along the weak directions are small compared with $\sqrt{m_\ell}$, and a point inside the range of every regressor separately can be far off the pattern ([Example \(Hidden extrapolation\)](#)). By part (c), if future regressors are generated the way the design was, the average prediction variance is $\sigma^2 p / n$; if a relation between the regressors breaks down, the term $\mathbf{v}_p^\top \boldsymbol{\Sigma}_0 \mathbf{v}_p / m_p$ can be enormous.

Warning (Variance is not the whole risk). [Proposition 26.4.1](#) is about variance under a correct model. Off the pattern of the data the model itself has not been checked, so its bias there is unknown ([Section 12.3](#)). A small prediction variance is not a guarantee.

Example. (Predicting consumption along and across the pattern)

In the consumption regression of [Example \(Large factors, precise estimate\)](#), $s = 58.1$ (billions of 2005 dollars). At 1985Q1, a design point with population 237.9 million, the estimated mean has standard deviation 8.5, below the design average $s\sqrt{p/n} = 10.8$. Midway between the first quarters of 1969 and 1999 the standard deviation is 7.8, and by [Proposition 26.4.1\(b\)](#) no point in the convex hull of the data can exceed $s\sqrt{\max_i h_{ii}} = 23.3$.

Now keep every regressor at its 1985 value except population, which is lowered by ten per cent, to 214.1 million. Population did take that value, in 1974, and income took its 1985 value, but never together. The standard deviation of the estimated mean becomes 36.8, 4.3 times as large. Decomposing the variance over the canonical directions of the scaled design, as in the proof of [Theorem 26.3.2](#), the direction with condition index 270.9, the income–population near-dependency of [Example \(A consumption function\)](#), contributes 93.9 per cent of the variance at the new point and 0.2 per cent at the 1985 quarter itself.

[Figure 26.4.1](#) shows 2000 parametric replicates: responses generated from the fitted model with normal errors of standard deviation s , each refitted. The income and population coefficients are strongly negatively correlated: their exact correlation is -0.842 (-0.832 in the replicates). The prediction at 1985Q1 barely moves while the one off the pattern spreads widely.

```
import numpy as np
import statsmodels.api as sm
```

26.4.2 Coefficients against predictions

A coefficient β_j is the difference between the mean responses at two points that differ by one unit in x_j and agree in every other regressor; with collinear data at least one of them lies off the pattern. A regression built for forecasting, where the relations among the regressors are expected to persist, can ignore collinearity; one built to attribute effects to individual regressors cannot.

26.4.3 Exercises

26.4.3.1 A. Check your understanding

Exercise A1.

For the design of [Example \(Two regressors that move together\)](#), rank the following new points by the variance of the fitted mean, without computing: the centroid; $(x_1, x_2) = (3, 3)$; $(x_1, x_2) = (0.5, -0.5)$; the average of the two design points with the largest x_1 . Which bound of [Proposition 26.4.1](#) applies to each? Compare [Figure 19.6.1](#).

26.4.3.2 B. Practice

Exercise B1.

Show that the bound $\text{Var}(\hat{Y}_0) \leq \sigma^2 \|\mathbf{w}\|^2$ of [Proposition 26.4.1\(b\)](#) is attained iff $\mathbf{w} \in \mathcal{C}(\mathbf{X})$, and that $\min\{\|\mathbf{w}\|^2 : \mathbf{X}^\top \mathbf{w} = \mathbf{x}_0\}$ equals $\text{Var}(\hat{Y}_0)/\sigma^2$. Compare with [Proposition 12.3.2\(a\)](#).

Solution. $\|\mathbf{M}\mathbf{w}\|^2 = \|\mathbf{w}\|^2 - \|(\mathbf{I} - \mathbf{M})\mathbf{w}\|^2$, so equality holds iff $(\mathbf{I} - \mathbf{M})\mathbf{w} = \mathbf{0}$, that is, $\mathbf{w} \in \mathcal{C}(\mathbf{X})$. Every $\mathbf{w}$ with $\mathbf{X}^\top \mathbf{w} = \mathbf{x}_0$ has the same $\mathbf{M}\mathbf{w}$, because two such vectors differ by an element of $\mathcal{N}(\mathbf{X}^\top) = \mathcal{C}(\mathbf{X})^\perp$. The minimum norm is therefore attained at $\mathbf{w} = \mathbf{M}\mathbf{w}$ and equals $\|\mathbf{M}\mathbf{w}\|^2 = \text{Var}(\hat{Y}_0)/\sigma^2$. This is [Proposition 12.3.2\(a\)](#) with $h_0 = \text{Var}(\hat{Y}_0)/\sigma^2$: the leverage of a new point is the smallest squared norm of a set of weights that builds $\mathbf{x}_0$ from the rows of the design.

Exercise B2.

Let the model have an intercept and centred regressors, so that the rows of $\mathbf{X}$ are $(1, \mathbf{z}_{(i)}^\top)$ with $\sum_i \mathbf{z}_{(i)} = \mathbf{0}$. For a design row i and $t > 1$, let $\mathbf{x}_0 = (1, t\mathbf{z}_{(i)}^\top)^\top$, an extrapolation

from the centroid along the ray through a design point. Show that $\text{Var}(\hat{Y}_0) = \sigma^2(1/n + t^2(h_{ii} - 1/n))$. Why does collinearity not enter, although $\mathbf{x}_0$ is outside the convex hull of the data when t is large?

Solution. With centred regressors $\mathbf{X}^\top \mathbf{X} = \text{diag}(n, \mathbf{Z}^\top \mathbf{Z})$, where $\mathbf{Z}$ has rows $\mathbf{z}_{(i)}^\top$, so $\text{Var}(\hat{Y}_0) = \sigma^2(1/n + t^2 \mathbf{z}_{(i)}^\top (\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{z}_{(i)})$, and $h_{ii} = 1/n + \mathbf{z}_{(i)}^\top (\mathbf{Z}^\top \mathbf{Z})^{-1} \mathbf{z}_{(i)}$ by [Proposition 6.8.2](#). The slope part of $\mathbf{x}_0$ is t times that of a row, so its coordinate along every eigenvector is t times the row's, and in each term of [Proposition 26.4.1\(a\)](#) it is penalized relative to the data exactly as much as the row is, times t^2 . Collinearity could enter only through a component along a weak direction that is large compared with the spread of the data there, and the row itself has no such component.

26.4.3.3 C. Going deeper

Exercise C1.

In the design of [Example \(Two regressors that move together\)](#), suppose future regressor values satisfy $x_2 - x_1 = \tau\zeta$ with ζ independent of x_1 , $E\zeta = 0$, $\text{Var}\zeta = 1$, and x_1 distributed as in the sample. Using [Proposition 26.4.1\(c\)](#), show that the average prediction variance is approximately $(\sigma^2/n)(2 + \tau^2/(2m_2))$, where $m_2 = \lambda_2/n$ is the mean square of the design along the weak slope direction. Check that this is $\sigma^2 p/n$ when τ^2 equals the within-sample mean square of $x_2 - x_1$, and discuss what happens when τ is several times larger. What would a sensible forecaster do?

26.5 What to do about collinearity

Refitting the same data in another way cannot supply information the design lacks, and every genuine remedy does one of four things: it gets more information of the right kind, changes the question to one the data can answer, adds information from outside the data, or accepts bias in exchange for variance. Before choosing among them, decide whether anything needs to be done at all.

26.5.1 Does it matter?

By [Theorem 26.1.1\(c\)](#) and [Proposition 26.4.1](#), collinearity is harmless for quantities with no component along the weak directions: fitted values, predictions that follow the pattern of the data, and combinations such as the sum in [Example \(Two regressors that move together\)](#). If those are the targets, report them and stop.

26.5.2 Collect better data

The only remedy that keeps the question is more information along the weak directions. The next proposition shows how much a single well-placed observation can supply.

Proposition 26.5.1 — One new observation

Let $\mathbf{A} = \mathbf{X}^\top \mathbf{X}$ be positive definite with eigenvalues $\lambda_1 \geq \dots \geq \lambda_p$ and orthonormal eigenvectors $\mathbf{v}_1, \dots, \mathbf{v}_p$, $p \geq 2$, and let a case with regressor vector $\mathbf{x}$ be added, so that $\mathbf{A}$ becomes $\mathbf{A} + \mathbf{x}\mathbf{x}^\top$. Write $\mathbf{G} = \mathbf{A}^{-1}$.

- (a) For every $\mathbf{a}$, the variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ falls by $\sigma^2(\mathbf{a}^\top \mathbf{G}\mathbf{x})^2/(1 + \mathbf{x}^\top \mathbf{G}\mathbf{x})$; in particular it never increases.
- (b) If $\|\mathbf{x}\| \leq c$, then $\lambda_{\min}(\mathbf{A} + \mathbf{x}\mathbf{x}^\top) \leq \min(\lambda_p + c^2, \lambda_{p-1})$, with equality when $\mathbf{x} = c\mathbf{v}_p$.
- (c) Among all $\mathbf{x}$ with $\|\mathbf{x}\| = c$, the choice $\mathbf{x} = c\mathbf{v}_p$ minimizes the largest variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ over unit vectors $\mathbf{a}$.

Proof.

- (a) By Eq. 1.6.7, $(\mathbf{A} + \mathbf{x}\mathbf{x}^\top)^{-1} = \mathbf{G} - \mathbf{G}\mathbf{x}\mathbf{x}^\top \mathbf{G}/(1 + \mathbf{x}^\top \mathbf{G}\mathbf{x})$.
- (b) By Theorem 1.7.7, $\lambda_{\min}(\mathbf{A} + \mathbf{x}\mathbf{x}^\top) \leq \mathbf{v}_p^\top (\mathbf{A} + \mathbf{x}\mathbf{x}^\top) \mathbf{v}_p = \lambda_p + (\mathbf{x}^\top \mathbf{v}_p)^2 \leq \lambda_p + c^2$. For the second bound, the plane $\text{span}\{\mathbf{v}_{p-1}, \mathbf{v}_p\}$ contains a unit vector $\mathbf{b}$ orthogonal to $\mathbf{x}$, since the linear map $\mathbf{b} \mapsto \mathbf{x}^\top \mathbf{b}$ from the plane to $\mathbb{R}$ has a nontrivial null space. Then $\lambda_{\min}(\mathbf{A} + \mathbf{x}\mathbf{x}^\top) \leq \mathbf{b}^\top \mathbf{A} \mathbf{b} \leq \lambda_{p-1}$. If $\mathbf{x} = c\mathbf{v}_p$, then $\mathbf{A} + \mathbf{x}\mathbf{x}^\top$ has the same eigenvectors as $\mathbf{A}$ and eigenvalues $\lambda_1, \dots, \lambda_{p-1}, \lambda_p + c^2$, whose minimum is $\min(\lambda_p + c^2, \lambda_{p-1})$.
- (c) By Theorem 26.1.1(b), the largest variance over unit vectors is $\sigma^2/\lambda_{\min}$, and (b) says that $\mathbf{x} = c\mathbf{v}_p$ maximizes $\lambda_{\min}$.

■

The new case should lie along the weakest direction, where the existing data are thin. Such a point breaks the pattern of the regressors, and in observational data it may not exist; in an experiment, or when the sample can be chosen, the proposition says what to look for.

Example. (The value of one observation)

In the design of Example (Two regressors that move together), add one case at the centred values $(x_1, x_2) = (1.077, -1.044)$, the point at distance 1.5 from the centroid along the weak slope direction. Each coordinate is well inside the range of its regressor; only the combination is new. The slope estimates are governed by the slope block with the intercept partialled out (Theorem 6.6.2), and the new case, which has an intercept entry, changes that block from $\mathbf{S}$ to $\mathbf{S} + \frac{n}{n+1} \mathbf{x}\mathbf{x}^\top$, where $\mathbf{x}$ holds its two slope entries: the columns must be centred again about the new mean, and that costs the factor $n/(n+1)$. Applied to this block, Proposition 26.5.1(b) predicts that the smaller eigenvalue rises from 0.172 to $0.172 + 1.5^2 \cdot 30/31 = 2.349$, which is what the script finds. The standard deviation of $\hat{\beta}_1$ falls from 1.734σ to 0.476σ . To achieve the same reduction with more data of the old pattern, the whole sample would have to be repeated 13.3 times, about 370 further cases in place of one. The script also checks, on the centred block, that no other direction does better.

    [0], 3),
    round(np.linalg.eigvalsh(S_new)[0], 3))
# repeating the old pattern k times multiplies X'X by k: Var(b1) falls by the factor
    1/k
k_equiv = G[1, 1] / G_new[1, 1]
print("equivalent number of copies of the whole data set:", round(k_equiv, 1))

```

26.5.3 Change the question

A reparameterization $\mathbf{X}\boldsymbol{\beta} = (\mathbf{X}\mathbf{T})(\mathbf{T}^{-1}\boldsymbol{\beta})$ leaves the least squares estimate of every linear function of $\boldsymbol{\beta}$ unchanged ([Theorem 6.7.1](#)), so it cannot make $\beta_1 - \beta_2$ better determined. It can make the reported parameters the well-determined ones. Replacing x_1 and x_2 by their average and their difference gives a coefficient for the average that estimates $\beta_1 + \beta_2$ precisely, and leaves all the imprecision in the coefficient of the difference. Centring polynomial terms ([Example \(A quadratic far from the origin\)](#)) is the same move.

Two common changes of model are really linear restrictions on $\boldsymbol{\beta}$, and should be judged as such. *Dropping a regressor* imposes $\beta_2 = 0$. By [Theorem 19.1.2](#) the short slope estimates $\beta_1 + \pi\beta_2$, where π is the slope of x_2 on x_1 ; in [Example \(Two regressors that move together\)](#) $\pi = 1.0261$, and the short slope has standard deviation 0.171σ against 1.734σ . It is precise because it answers a different question, giving x_1 the credit for both regressors: with true slopes $(1, 1)$ it centres at about 2.03. [Theorem 19.1.5](#) gives the condition under which it has the smaller mean squared error. *Combining regressors into an index* imposes a restriction such as $\beta_1 = \beta_2$. It concerns the weak direction $\beta_1 - \beta_2$, whose estimate has standard deviation 3.412σ in the example, so an F test of it has almost no power: the restriction is cheap in variance and nearly untestable, for the same reason.

26.5.4 Add information from outside the data

An exact restriction known from theory is fitted by restricted least squares ([Proposition 11.3.3](#)). An approximate one can be written as extra observations $\mathbf{r} = \mathbf{L}\boldsymbol{\beta} + \mathbf{u}$ and combined with the data by generalized least squares, the mixed estimation of Theil and Goldberger (1961) ([Exercise \(B1\)](#)). The Bayesian version is a prior: with the conjugate prior of [Theorem 7.6.2](#), under which $\boldsymbol{\beta}$ given σ^2 has covariance $\sigma^2 \mathbf{V}_0$, the posterior mean solves equations with matrix $\mathbf{V}_0^{-1} + \mathbf{X}^\top \mathbf{X}$. A prior informative along the weak eigenvector raises the smallest eigenvalue as a new observation does, and the answer along that direction then comes mostly from the prior.

26.5.5 Accept bias

The last option gives up unbiasedness. Principal component regression drops the canonical coordinates with small eigenvalues, the truncated SVD estimator of [Proposition 10.4.3](#); ridge regression shrinks every canonical coordinate towards zero, the weak ones most. [Chapter 27](#) develops both ([Theorem 27.2.2](#) and [Definition 27.3.1](#)). Neither creates information: they trade variance along the weak directions for bias along the same directions.

26.5.6 What not to do

- Do not drop regressors because their variance inflation factors exceed a threshold; the fit may hardly change while the meaning of every remaining coefficient does.
- Do not expect centring or rescaling to cure collinearity that is not created by the parameterization.
- Do not let an automatic search choose among collinear regressors: noise decides which enters ([Chapter 29](#)).

26.5.7 Exercises

26.5.7.1 A. Check your understanding

Exercise A1.

Explain, using [Theorem 26.1.1](#), why no reparameterization of [Example \(Two regressors that move together\)](#) can estimate $\beta_1 - \beta_2$ with a standard deviation smaller than 3.412σ , although the coefficient of the new difference regressor may have any standard deviation you like.

Exercise A2.

In [Example \(Two regressors that move together\)](#), what does the short regression of y on x_1 alone estimate if the true slopes are $(2, 0)$? If they are $(0, 2)$? What does this say about using the short regression to decide which regressor matters?

26.5.7.2 B. Practice

Exercise B1.

Suppose that, besides $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $\text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}$, there is independent information $\mathbf{r} = \mathbf{L}\boldsymbol{\beta} + \mathbf{u}$ with $E(\mathbf{u}) = \mathbf{0}$ and $\text{Cov}(\mathbf{u}) = \sigma^2 \boldsymbol{\Omega}$, $\boldsymbol{\Omega}$ known and positive definite. Show that the generalized least squares estimator from the stacked data is

$$\tilde{\boldsymbol{\beta}} = (\mathbf{X}^\top \mathbf{X} + \mathbf{L}^\top \boldsymbol{\Omega}^{-1} \mathbf{L})^{-1} (\mathbf{X}^\top \mathbf{Y} + \mathbf{L}^\top \boldsymbol{\Omega}^{-1} \mathbf{r}),$$

that it is unbiased with covariance $\sigma^2 (\mathbf{X}^\top \mathbf{X} + \mathbf{L}^\top \boldsymbol{\Omega}^{-1} \mathbf{L})^{-1}$, and that it equals the posterior mean of [Theorem 7.6.2](#) for a suitable prior. With $\mathbf{L} = \mathbf{v}_p^\top$, how does the smallest eigenvalue change?

Solution. Stack $(\mathbf{Y}^\top, \mathbf{r}^\top)^\top = (\mathbf{X}^\top, \mathbf{L}^\top)^\top \boldsymbol{\beta} + (\boldsymbol{\varepsilon}^\top, \mathbf{u}^\top)^\top$, with error covariance $\sigma^2 \text{diag}(\mathbf{I}, \boldsymbol{\Omega})$. Generalized least squares ([Corollary 7.2.3](#)) gives the stated estimator, and it is unbiased with covariance σ^2 times the inverse of the weighted cross-product matrix. If $\mathbf{L}$ is square and nonsingular, the prior $\boldsymbol{\beta} \sim N(\mathbf{L}^{-1} \mathbf{r}, \sigma^2 \mathbf{L}^{-1} \boldsymbol{\Omega} (\mathbf{L}^{-1})^\top)$ has precision $\mathbf{L}^\top \boldsymbol{\Omega}^{-1} \mathbf{L} / \sigma^2$ and mean $\mathbf{L}^{-1} \mathbf{r}$, and the posterior mean of [Theorem 7.6.2](#) is the same expression. With $\mathbf{L} = \mathbf{v}_p^\top$ and $\boldsymbol{\Omega} = \omega^2$, the matrix becomes $\mathbf{X}^\top \mathbf{X} + \mathbf{v}_p \mathbf{v}_p^\top / \omega^2$, whose smallest eigenvalue is $\min(\lambda_p + 1/\omega^2, \lambda_{p-1})$: exactly the effect of a new observation of length $1/\omega$ along $\mathbf{v}_p$ ([Proposition 26.5.1\(b\)](#)).

Exercise B2.

Let x_1, x_2 be centred with $\|\mathbf{x}_1\|^2 = S_1$, $\|\mathbf{x}_2\|^2 = S_2$ and $\mathbf{x}_1^\top \mathbf{x}_2 = S_{12}$, and fit the intercept and the single composite $\mathbf{s} = \mathbf{x}_1 + \mathbf{x}_2$. Show that its coefficient has expectation $\beta_1 + (\beta_2 - \beta_1)(S_2 + S_{12})/(S_1 + S_2 + 2S_{12})$. When is this $(\beta_1 + \beta_2)/2$?

Solution. The coefficient is $\mathbf{s}^\top \mathbf{Y} / \mathbf{s}^\top \mathbf{s}$, because $\mathbf{s}$ is centred and so orthogonal to $\mathbf{1}$. Its expectation is $\mathbf{s}^\top (\mathbf{x}_1 \beta_1 + \mathbf{x}_2 \beta_2) / \mathbf{s}^\top \mathbf{s}$, with $\mathbf{s}^\top \mathbf{x}_1 = S_1 + S_{12}$, $\mathbf{s}^\top \mathbf{x}_2 = S_2 + S_{12}$ and $\mathbf{s}^\top \mathbf{s} = S_1 + S_2 + 2S_{12}$. Writing $\beta_1(S_1 + S_{12}) = \beta_1(\mathbf{s}^\top \mathbf{s}) - \beta_1(S_2 + S_{12})$ gives the formula. It is $(\beta_1 + \beta_2)/2$ for all $\boldsymbol{\beta}$ iff $S_2 + S_{12} = (S_1 + S_2 + 2S_{12})/2$, that is, iff $S_1 = S_2$: the composite estimates the average slope when the two regressors have equal spread, whatever their correlation.

Exercise B3.

For $p = 2$ and $\mathbf{A} = \text{diag}(\lambda_1, \lambda_2)$ with $\lambda_1 > \lambda_2$, let $\mathbf{x} = c(\cos \theta, \sin \theta)^\top$. Compute $\lambda_{\min}(\mathbf{A} + \mathbf{x}\mathbf{x}^\top)$ and show directly that it is maximized at $\theta = \pi/2$.

Solution. The trace is $T = \lambda_1 + \lambda_2 + c^2$, independent of θ , and the determinant is $D = (\lambda_1 + c^2 \cos^2 \theta)(\lambda_2 + c^2 \sin^2 \theta) - c^4 \cos^2 \theta \sin^2 \theta = \lambda_1 \lambda_2 + c^2(\lambda_1 \sin^2 \theta + \lambda_2 \cos^2 \theta)$. The smaller eigenvalue is $(T - \sqrt{T^2 - 4D})/2$, which increases with D for fixed T . Since $\lambda_1 > \lambda_2$, D is largest when $\sin^2 \theta = 1$.

26.6 Summary and Notes

26.6.1 Summary

Idea.

1. Collinearity breaks no assumption. It inflates the variance of $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ when $\mathbf{a}$ points along an eigenvector of $\mathbf{X}^\top \mathbf{X}$ with a small eigenvalue; the worst-to-best ratio is $\kappa(\mathbf{X})^2$, and fitted values keep total variance $\sigma^2 p$ (Theorem 26.1.1).
2. Near a rank-deficient design, the functions with bounded variance are those estimable in the limit (Proposition 26.1.2).
3. The variance inflation factor is the variance ratio to an orthogonal design of the same spread: scale-free, but a ratio, not a verdict (Definition 26.2.1, Proposition 26.2.1). Large factors that vanish under centring belong to questions about the origin (Example (A quadratic far from the origin)).
4. For a block of columns, the generalized factor $\prod_i 1/(1 - \rho_i^2)$ measures the inflation of the joint confidence ellipsoid and does not depend on coding (Definition 26.2.2, Proposition 26.2.2).
5. Condition indices of the unit-length scaled design and the variance-decomposition proportions locate near-dependencies (Definition 26.3.1, Theorem 26.3.2). Centring can only hide them, namely those involving the intercept (Proposition 26.3.1), and only high-leverage cases can mask them (Proposition 26.3.3).
6. Predictions inside the convex hull, or along the pattern of the regressors, are unharmed (Proposition 26.4.1).
7. Remedies: data along the weak direction (Proposition 26.5.1), a question the data can answer, outside information, or biased estimation (Chapter 27).

26.6.2 Notes and sources

The problem. Frisch introduced the word “multicollinearity” in the 1930s. The statistical treatment rests on the observation that the eigenvectors of $\mathbf{X}^\top \mathbf{X}$ sort linear functions of $\boldsymbol{\beta}$ into well and badly estimated ones; Silvey (1969) set this out, including the advice to take new observations along the weak eigenvectors behind Proposition 26.5.1. Goldberger (1991) insisted that collinearity is a shortage of data, not a disease of the model. Stewart (1987) gave a numerical analyst’s account.

Diagnostics. The name “variance inflation factor” is usually traced to Marquardt (1970). The generalized factor and its $1/(2q)$ power are due to Fox and Monette (1992); the canonical-correlation form of Proposition 26.2.2(b) is implicit there. O’Brien (2007) examined the rules of thumb. Condition indices and variance-decomposition proportions, with the working rule of indices above about 30 and two or more proportions above one half, are due to Belsley, Kuh and Welsch (1980, chapter 3); Belsley (1991) is a book-length development, and Belsley (1984), with its discussion, argues for scaling without centring. The bounds Theorem 26.3.2(c) and Proposition 26.3.3 are stated in the form this book needs and follow from standard eigenvalue inequalities. Among the textbooks used for coverage, Seber and Lee (2003, sections 9.7 and 10.7) treat variance inflation factors, eigenvalues, centring and influential cases; Christensen (2020, sections 13.1–13.2) develops collinearity through ill-defined directions and tolerances; and Sen

and Srivastava (1990, chapter 10) give detailed variance-decomposition examples.

Data and remedies. The US macroeconomic series and Grunfeld's panel are public-domain data distributed with statsmodels; Longley (1967) built his data to test regression programs. Mixed estimation is due to Theil and Goldberger (1961). Shrinkage is the subject of [Chapter 27](#), and selection among collinear regressors of [Chapter 29](#).

Chapter 27

Shrinkage: Ridge, Principal Components and the Lasso

Least squares is the best linear unbiased estimator, and under normal errors the best unbiased estimator of any kind. With nearly dependent columns it can still be very bad, because its variance along poorly determined directions swamps everything else. This chapter gives up unbiasedness on purpose, measures estimators by mean squared error, and studies three ways of buying a large cut in variance with a little bias. Ridge regression shrinks every direction of the coefficient space, the weakly determined ones most; principal component regression discards the weakly determined directions; the lasso shrinks coefficients with an absolute-value penalty and sets some exactly to zero. The chapter ends with Stein's paradox: in three or more dimensions a shrinkage estimator beats least squares for every value of the parameter, for an empirical Bayes reason that also explains the other methods.

27.1 The bias–variance trade-off

Chapter 26 showed where collinearity does its damage (Theorem 26.1.1). The least squares estimate remains unbiased, but along a direction $\mathbf{v}$ in which the regressors barely vary, the variance of $\mathbf{v}^\top \hat{\boldsymbol{\beta}}$ is σ^2 divided by a tiny eigenvalue; for a single coefficient the same damage appears as the factor $1/(1 - R_j^2)$ of Eq. 6.6.2, the variance inflation factor of Definition 26.2.1. No assumption of Parts II and III is violated. The Gauss–Markov theorem (Theorem 7.2.1) concerns the class of *linear unbiased* estimators, within which least squares cannot be improved, so improving on it means leaving the class. This section sets up the criterion that makes biased and unbiased estimators comparable.

27.1.1 The mean squared error matrix

Definition 27.1.1 — Mean squared error

Let $\tilde{\boldsymbol{\theta}}$ be an estimator of $\boldsymbol{\theta} \in \mathbb{R}^q$ with finite second moments. Its **mean squared error matrix** is

$$\text{MSE}(\tilde{\boldsymbol{\theta}}) = \mathbb{E}[(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})^\top],$$

its **bias** is $\boldsymbol{\delta} = \mathbb{E}(\tilde{\boldsymbol{\theta}}) - \boldsymbol{\theta}$, and its **total mean squared error** is $\text{tr MSE}(\tilde{\boldsymbol{\theta}}) = \mathbb{E}\|\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2$. For estimators $\tilde{\boldsymbol{\theta}}_1, \tilde{\boldsymbol{\theta}}_2$ we say that $\tilde{\boldsymbol{\theta}}_1$ is **at least as good in the matrix sense** if $\text{MSE}(\tilde{\boldsymbol{\theta}}_2) - \text{MSE}(\tilde{\boldsymbol{\theta}}_1)$ is nonnegative definite.

All three quantities depend on the unknown parameter, so one estimator may be better for some parameter values and worse for others. For unbiased estimators the mean squared error matrix is the covariance matrix, and the matrix sense is the ordering in which Gauss–Markov declares least squares the winner (Theorem 7.2.1(d)).

Theorem 27.1.1 — Bias–variance decomposition for linear estimators

- (a) For any estimator with finite second moments, $\text{MSE}(\tilde{\boldsymbol{\theta}}) = \text{Cov}(\tilde{\boldsymbol{\theta}}) + \boldsymbol{\delta}\boldsymbol{\delta}^\top$. For every $\mathbf{a} \in \mathbb{R}^q$, $\mathbb{E}(\mathbf{a}^\top \tilde{\boldsymbol{\theta}} - \mathbf{a}^\top \boldsymbol{\theta})^2 = \mathbf{a}^\top \text{MSE}(\tilde{\boldsymbol{\theta}}) \mathbf{a}$, and for every nonnegative definite $\mathbf{W}$, $\mathbb{E}[(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})^\top \mathbf{W}(\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta})] = \text{tr}(\mathbf{W} \text{MSE}(\tilde{\boldsymbol{\theta}}))$.
- (b) Suppose $\mathbb{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, and let $\tilde{\boldsymbol{\beta}} = \mathbf{A}\mathbf{Y}$ be a linear estimator of $\boldsymbol{\beta}$. Then $\boldsymbol{\delta} = (\mathbf{A}\mathbf{X} - \mathbf{I})\boldsymbol{\beta}$ and $\text{MSE}(\tilde{\boldsymbol{\beta}}) = \sigma^2 \mathbf{A}\mathbf{A}^\top + (\mathbf{A}\mathbf{X} - \mathbf{I})\boldsymbol{\beta}\boldsymbol{\beta}^\top (\mathbf{A}\mathbf{X} - \mathbf{I})^\top$.
- (c) In the setting of (b), let $\mathbf{X}$ have full column rank, let $\hat{\boldsymbol{\beta}}$ be least squares, and put $\boldsymbol{\Delta}_{\mathbf{A}} = \sigma^2(\mathbf{X}^\top \mathbf{X})^{-1} - \sigma^2 \mathbf{A}\mathbf{A}^\top$, the covariance that $\tilde{\boldsymbol{\beta}}$ saves. The following are equivalent:
 - (i) $\tilde{\boldsymbol{\beta}}$ is at least as good as $\hat{\boldsymbol{\beta}}$ in the matrix sense;
 - (ii) $\mathbb{E}(\mathbf{a}^\top \tilde{\boldsymbol{\beta}} - \mathbf{a}^\top \boldsymbol{\beta})^2 \leq \text{Var}(\mathbf{a}^\top \hat{\boldsymbol{\beta}})$ for every $\mathbf{a}$;
 - (iii) $\mathbb{E}[(\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta})^\top \mathbf{W}(\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta})] \leq \mathbb{E}[(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})^\top \mathbf{W}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})]$ for every nonnegative definite $\mathbf{W}$;
 - (iv) $\boldsymbol{\Delta}_{\mathbf{A}}$ is nonnegative definite, $\boldsymbol{\delta} \in \mathcal{C}(\boldsymbol{\Delta}_{\mathbf{A}})$ and $\boldsymbol{\delta}^\top \boldsymbol{\Delta}_{\mathbf{A}}^+ \boldsymbol{\delta} \leq 1$.
 When $\boldsymbol{\Delta}_{\mathbf{A}}$ is positive definite, (iv) reads $\boldsymbol{\delta}^\top \boldsymbol{\Delta}_{\mathbf{A}}^{-1} \boldsymbol{\delta} \leq 1$.

Proof.

- (a) Write $\tilde{\boldsymbol{\theta}} - \boldsymbol{\theta} = (\tilde{\boldsymbol{\theta}} - \mathbb{E}\tilde{\boldsymbol{\theta}}) + \boldsymbol{\delta}$. The cross terms have expectation zero, which gives the decomposition. The scalar identities follow from $\mathbb{E}(\mathbf{a}^\top \mathbf{w})^2 = \mathbf{a}^\top \mathbb{E}(\mathbf{w}\mathbf{w}^\top) \mathbf{a}$ and $\mathbf{w}^\top \mathbf{W} \mathbf{w} = \text{tr}(\mathbf{W} \mathbf{w} \mathbf{w}^\top)$ with $\mathbf{w} = \tilde{\boldsymbol{\theta}} - \boldsymbol{\theta}$.
- (b) $\mathbb{E}(\mathbf{A}\mathbf{Y}) = \mathbf{A}\mathbf{X}\boldsymbol{\beta}$ and $\text{Cov}(\mathbf{A}\mathbf{Y}) = \sigma^2 \mathbf{A}\mathbf{A}^\top$ (Theorem 2.2.1); apply (a).
- (c) By (a), $\text{MSE}(\hat{\boldsymbol{\beta}}) - \text{MSE}(\tilde{\boldsymbol{\beta}}) = \boldsymbol{\Delta}_\mathbf{A} - \boldsymbol{\delta}\boldsymbol{\delta}^\top$, and (i) says this matrix is nonnegative definite. By (a), (ii) says $\mathbf{a}^\top (\boldsymbol{\Delta}_\mathbf{A} - \boldsymbol{\delta}\boldsymbol{\delta}^\top) \mathbf{a} \geq 0$ for all $\mathbf{a}$, which is (i). Next, (i) implies (iii) because $\text{tr}(\mathbf{W}\mathbf{N}) \geq 0$ when $\mathbf{W}$ and $\mathbf{N}$ are both nonnegative definite: with $\mathbf{W} = \sum_k \omega_k \mathbf{q}_k \mathbf{q}_k^\top$ (Theorem 1.7.2), $\text{tr}(\mathbf{W}\mathbf{N}) = \sum_k \omega_k \mathbf{q}_k^\top \mathbf{N} \mathbf{q}_k \geq 0$. And (iii) with $\mathbf{W} = \mathbf{a}\mathbf{a}^\top$ is (ii). For (i) $\Leftrightarrow$ (iv), put $\mathbf{N} = \boldsymbol{\Delta}_\mathbf{A} - \boldsymbol{\delta}\boldsymbol{\delta}^\top$. If $\mathbf{N}$ is nonnegative definite, so is $\boldsymbol{\Delta}_\mathbf{A} = \mathbf{N} + \boldsymbol{\delta}\boldsymbol{\delta}^\top$. If $\boldsymbol{\delta} \notin \mathcal{C}(\boldsymbol{\Delta}_\mathbf{A})$, there is $\mathbf{w} \in \mathcal{N}(\boldsymbol{\Delta}_\mathbf{A})$ with $\mathbf{w}^\top \boldsymbol{\delta} \neq 0$ (Proposition 1.5.1), and then $\mathbf{w}^\top \mathbf{N} \mathbf{w} = -(\mathbf{w}^\top \boldsymbol{\delta})^2 < 0$. So (i) forces $\boldsymbol{\delta} = \boldsymbol{\Delta}_\mathbf{A} \mathbf{c}$ for some $\mathbf{c}$, and $\mathbf{c}^\top \mathbf{N} \mathbf{c} = \mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c} (1 - \mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c}) \geq 0$ gives $\boldsymbol{\delta}^\top \boldsymbol{\Delta}_\mathbf{A}^+ \boldsymbol{\delta} = \mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c} \leq 1$ (when $\mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c} = 0$ there is nothing to prove). Here $\boldsymbol{\delta}^\top \boldsymbol{\Delta}_\mathbf{A}^+ \boldsymbol{\delta} = \mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \boldsymbol{\Delta}_\mathbf{A}^+ \boldsymbol{\Delta}_\mathbf{A} \mathbf{c} = \mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c}$ by the first Penrose condition. Conversely, under (iv) the Cauchy–Schwarz inequality for the semi-inner product $(\mathbf{w}, \mathbf{z}) \mapsto \mathbf{w}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{z}$ gives, for every $\mathbf{w}$,

$$(\mathbf{w}^\top \boldsymbol{\delta})^2 = (\mathbf{w}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c})^2 \leq (\mathbf{w}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{w})(\mathbf{c}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{c}) \leq \mathbf{w}^\top \boldsymbol{\Delta}_\mathbf{A} \mathbf{w},$$

so $\mathbf{w}^\top \mathbf{N} \mathbf{w} \geq 0$. When $\boldsymbol{\Delta}_\mathbf{A}$ is invertible, $\boldsymbol{\Delta}_\mathbf{A}^+ = \boldsymbol{\Delta}_\mathbf{A}^{-1}$; this case is also Lemma 19.1.4. ■

Part (c) makes the trade-off precise: a biased linear estimator is better in every direction and under every quadratic loss exactly when its squared bias, measured in the metric of the covariance it saves, is at most one. Since $\boldsymbol{\delta} = (\mathbf{A}\mathbf{X} - \mathbf{I})\boldsymbol{\beta}$, condition (iv) holds when $\boldsymbol{\beta}$ is close to what the estimator shrinks towards, and fails far from it. No linear estimator with $\mathbf{A}\mathbf{X} \neq \mathbf{I}$ wins everywhere (Exercise (B1)). Theorem 19.1.5 was the first instance: the short regression is a biased linear estimator, and its winning region $\gamma \leq 1$ is condition (iv) for that choice of $\mathbf{A}$.

27.1.2 What unbiasedness buys, and what it costs

Unbiasedness concerns an estimator's centre, not its accuracy, and it does not survive transformation: $\|\hat{\boldsymbol{\beta}}\|^2$ overestimates $\|\boldsymbol{\beta}\|^2$ by $\sigma^2 \text{tr}(\mathbf{X}^\top \mathbf{X})^{-1}$ on average (Exercise (B3)), which under collinearity is enormous. Least squares estimates are systematically *too long*, and shrinking them is a correction, not a distortion. When many parameters are estimated at once, small biases spread over many coordinates can buy a large cut in total variance; Section 27.5 turns this into a theorem. The cost is in inference: the bias depends on the unknown $\boldsymbol{\beta}$, so an interval “estimate $\pm$ multiple of standard error” centred on a shrinkage estimate has no guaranteed coverage. Chapter 28 and Chapter 29 return to inference after shrinkage and selection.

27.1.3 Shrinkage in canonical coordinates

The collinearity problem has a natural coordinate system. Let $\mathbf{X}$ have full column rank and let $\mathbf{X} = \mathbf{U}\mathbf{D}\mathbf{V}^\top$ be its thin singular value decomposition (Theorem 1.8.1), with $\mathbf{U} = [\mathbf{u}_1, \dots, \mathbf{u}_p]$ and $\mathbf{V} = [\mathbf{v}_1, \dots, \mathbf{v}_p]$ having orthonormal columns and $\mathbf{D} = \text{diag}(d_1, \dots, d_p)$, $d_1 \geq \dots \geq d_p > 0$. We write d_j instead of the σ_j of Chapter 1 because σ is the error standard deviation. Put

$$\boldsymbol{\alpha} = \mathbf{V}^\top \boldsymbol{\beta}, \quad \hat{\boldsymbol{\alpha}} = \mathbf{V}^\top \hat{\boldsymbol{\beta}} = \mathbf{D}^{-1} \mathbf{U}^\top \mathbf{Y}, \quad c_j = \mathbf{u}_j^\top \mathbf{Y} = d_j \hat{\alpha}_j. \quad (27.1.1)$$

The α_j are the **canonical coefficients**: the coordinates of $\boldsymbol{\beta}$ along the eigenvectors $\mathbf{v}_j$ of $\mathbf{X}^\top \mathbf{X}$, whose eigenvalues are d_j^2 . By [Theorem 10.4.1\(d\)](#), the $\hat{\alpha}_j$ are uncorrelated with $E(\hat{\alpha}_j) = \alpha_j$ and $\text{Var}(\hat{\alpha}_j) = \sigma^2/d_j^2$. A small d_j is a direction $\mathbf{v}_j$ along which the regressors hardly move, and along which the data therefore say little ([Proposition 19.6.1](#)).

Many shrinkage estimators act on the canonical coordinates one at a time. For numbers $f_1, \dots, f_p$, called **shrinkage factors** or filter factors, define

$$\tilde{\boldsymbol{\beta}}_{\mathbf{f}} = \sum_{j=1}^p f_j \hat{\alpha}_j \mathbf{v}_j = \mathbf{V} \mathbf{F} \hat{\boldsymbol{\alpha}}, \quad \mathbf{F} = \text{diag}(f_1, \dots, f_p).$$

Least squares has every $f_j = 1$. Principal component regression ([Section 27.3](#)) has $f_j \in \{0, 1\}$, and ridge regression ([Section 27.2](#)) has $f_j = d_j^2/(d_j^2 + \lambda)$. The signal-to-noise ratio of direction j is

$$\tau_j^2 = \frac{\alpha_j^2}{\text{Var}(\hat{\alpha}_j)} = \frac{d_j^2 \alpha_j^2}{\sigma^2},$$

the squared mean of the standardized coordinate $\hat{\alpha}_j/\sqrt{\text{Var}(\hat{\alpha}_j)}$. Under normal errors it is the noncentrality of $c_j^2/\sigma^2 \sim \chi^2(1, \tau_j^2)$.

Proposition 27.1.2 — Shrinking along the principal directions

Let $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$ and $\text{rank}(\mathbf{X}) = p$. For fixed factors f_j :

- (a) $E\|\tilde{\boldsymbol{\beta}}_{\mathbf{f}} - \boldsymbol{\beta}\|^2 = \sum_j \{f_j^2 \sigma^2/d_j^2 + (1-f_j)^2 \alpha_j^2\}$;
- (b) $E\|\mathbf{X}\tilde{\boldsymbol{\beta}}_{\mathbf{f}} - \mathbf{X}\boldsymbol{\beta}\|^2 = \sum_j \{f_j^2 \sigma^2 + (1-f_j)^2 d_j^2 \alpha_j^2\}$;
- (c) both are minimized by the same factors $f_j^* = \tau_j^2/(1+\tau_j^2)$, and the minima are $\sum_j (\sigma^2/d_j^2) \tau_j^2/(1+\tau_j^2)$ and $\sigma^2 \sum_j \tau_j^2/(1+\tau_j^2)$;
- (d) replacing $f_j = 1$ by some $f_j \in [0, 1]$, with the other factors fixed, lowers both quantities iff $\tau_j^2 < (1+f_j)/(1-f_j)$. In particular dropping direction j ($f_j = 0$) helps iff $\tau_j^2 < 1$.

Proof. $\tilde{\boldsymbol{\beta}}_{\mathbf{f}} - \boldsymbol{\beta} = \mathbf{V}(\mathbf{F}\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha})$ and $\mathbf{V}$ is orthogonal, so $\|\tilde{\boldsymbol{\beta}}_{\mathbf{f}} - \boldsymbol{\beta}\|^2 = \sum_j (f_j \hat{\alpha}_j - \alpha_j)^2$. Each term has expectation $\text{Var}(f_j \hat{\alpha}_j) + (f_j \alpha_j - \alpha_j)^2 = f_j^2 \sigma^2/d_j^2 + (1-f_j)^2 \alpha_j^2$, which is (a). For (b), $\mathbf{X}(\tilde{\boldsymbol{\beta}}_{\mathbf{f}} - \boldsymbol{\beta}) = \mathbf{U}\mathbf{D}(\mathbf{F}\hat{\boldsymbol{\alpha}} - \boldsymbol{\alpha})$ and $\mathbf{U}$ has orthonormal columns, so each term of (a) is multiplied by d_j^2 . (c) Each term of (a) is a convex quadratic in f_j with derivative $2f_j \sigma^2/d_j^2 - 2(1-f_j)\alpha_j^2$, which vanishes at $f_j = \alpha_j^2/(\alpha_j^2 + \sigma^2/d_j^2) = \tau_j^2/(1+\tau_j^2)$. Terms of (b) are those of (a) times d_j^2 , so they have the same minimizer; substituting gives the minima. (d) The j th term of (a) falls below its value σ^2/d_j^2 at $f_j = 1$ iff $(1-f_j)^2 \alpha_j^2 < (1-f_j^2) \sigma^2/d_j^2$. Dividing by $(1-f_j)\sigma^2/d_j^2 > 0$ gives $(1-f_j)\tau_j^2 < 1+f_j$. The same holds for (b). ■

The ideal shrinkage depends on τ_j^2 , which combines the spread of the regressors in direction j and the size of the coefficient there, so a direction with tiny d_j but large α_j should be kept. The

ideal factors are the same for estimating β and $\mathbf{X}\beta$. The oracle factors depend on β and σ^2 ; each method of this chapter chooses factors from the data instead, ridge by one tuning constant, principal components by a cut-off, and James–Stein by an unbiased estimate of the risk. Part (d) with $f_j = 0$ is the criterion of [Proposition 10.4.3](#).

Example. (Two nearly collinear regressors)

Take $n = 50$ observations of two centred regressors, scaled so that $\mathbf{X}^\top \mathbf{X} = n\mathbf{R}$ where $\mathbf{R}$ is a correlation matrix with off-diagonal entry 0.95. Let $\sigma = 1$ and $\beta = (1, 0.5)^\top$. The eigenvalues of $\mathbf{X}^\top \mathbf{X}$ are $d_1^2 = n(1 + 0.95) = 97.5$ and $d_2^2 = n(1 - 0.95) = 2.5$, with eigenvectors $(1, 1)^\top/\sqrt{2}$ and $(1, -1)^\top/\sqrt{2}$. The canonical coefficients have sizes $|\alpha_1| = 1.0607$ and $|\alpha_2| = 0.3536$, and the signal-to-noise ratios are $\tau_1^2 = 109.7$ and $\tau_2^2 = 0.3125$. The first direction, the sum of the two regressors, is estimated precisely. The second, their difference, is not.

Estimator	Factors (f_1, f_2)	Total MSE
least squares	(1, 1)	0.4103
drop the second direction	(1, 0)	0.1353
halve the second direction	(1, 0.5)	0.1415
oracle f_j^*	(0.991, 0.238)	0.1054

Dropping the difference direction cuts the total mean squared error by two thirds, because $\tau_2^2 < 1$, and wins in the matrix sense too. Here $\Delta_{\mathbf{A}} = \sigma^2 \mathbf{v}_2 \mathbf{v}_2^\top / d_2^2$ is singular, the bias is $\delta = -\alpha_2 \mathbf{v}_2 \in \mathcal{C}(\Delta_{\mathbf{A}})$, and $\delta^\top \Delta_{\mathbf{A}}^+ \delta = \alpha_2^2 d_2^2 / \sigma^2 = \tau_2^2 = 0.3125 \leq 1$. So by [Theorem 27.1.1\(c\)](#), every linear combination $\mathbf{a}^\top \beta$ is estimated at least as accurately. Had the truth been $\beta = (1, -0.5)^\top$, with the same length but pointing along the difference, then $\tau_2^2 = 2.5 \times 1.125 = 2.81$ and dropping would have increased the total error.

```
import numpy as np
n, rho, sigma = 50, 0.95, 1.0
XtX = n * np.array([[1.0, rho], [rho, 1.0]])
beta = np.array([1.0, 0.5])

evals, V = np.linalg.eigh(XtX)
order = np.argsort(evals)[::-1]
d2, V = evals[order], V[:, order]          # d_1^2 >= d_2^2, eigenvectors v_1, v_2
alpha = V.T @ beta                         # canonical coefficients
tau2 = d2 * alpha ** 2 / sigma ** 2        # squared signal-to-noise ratio of each
direction

def mse(f):
    """Total MSE of the estimator that multiplies alpha_hat_j by f_j."""
    f = np.asarray(f, dtype=float)
    return np.sum(f ** 2 * sigma ** 2 / d2 + (1 - f) ** 2 * alpha ** 2)

f_oracle = tau2 / (1 + tau2)
for label, f in [("least squares", [1, 1]), ("drop v_2", [1, 0]),
                ("halve v_2", [1, 0.5]), ("oracle", f_oracle)]:
    print(f"{label:14s} f = {np.round(f, 3)}    MSE = {mse(f):.4f}")
print("tau^2 =", np.round(tau2, 3))
```

27.1.4 Exercises

27.1.4.1 A. Check your understanding

Exercise A1.

Let $\bar{Y}$ be the mean of n independent observations with mean μ and variance σ^2 . For a constant c , find the mean squared error of $c\bar{Y}$ as an estimator of μ . Show that it is minimized at $c^* = \mu^2/(\mu^2 + \sigma^2/n)$ and that $c\bar{Y}$ beats $\bar{Y}$ iff $(1 - c)\mu^2 < (1 + c)\sigma^2/n$. Why is c^* not an estimator?

Exercise A2.

In [Example \(Two nearly collinear regressors\)](#), verify the least squares total mean squared error $\sigma^2(1/d_1^2 + 1/d_2^2) = 0.4103$ by hand, and check the entry for “drop the second direction” using [Proposition 27.1.2\(a\)](#).

27.1.4.2 B. Practice

Exercise B1.

Let $\mathbf{X}$ have full column rank and let $\tilde{\boldsymbol{\beta}} = \mathbf{A}\mathbf{Y}$ with $\mathbf{A}\mathbf{X} \neq \mathbf{I}$. Show that there is a $\boldsymbol{\beta}$ for which $\mathbb{E}\|\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 > \mathbb{E}\|\hat{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2$. So no biased linear estimator dominates least squares.

Solution. By [Theorem 27.1.1\(b\)](#), $\mathbb{E}\|\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}\|^2 = \sigma^2 \text{tr}(\mathbf{A}\mathbf{A}^\top) + \|(\mathbf{A}\mathbf{X} - \mathbf{I})\boldsymbol{\beta}\|^2$. The first term does not depend on $\boldsymbol{\beta}$. Since $\mathbf{A}\mathbf{X} - \mathbf{I} \neq \mathbf{0}$ there is a unit vector $\mathbf{v}$ with $(\mathbf{A}\mathbf{X} - \mathbf{I})\mathbf{v} \neq \mathbf{0}$. Along $\boldsymbol{\beta} = t\mathbf{v}$ the second term is $t^2\|(\mathbf{A}\mathbf{X} - \mathbf{I})\mathbf{v}\|^2$, which exceeds the constant $\sigma^2 \text{tr}(\mathbf{X}^\top \mathbf{X})^{-1}$ for large t .

Exercise B2.

A **linear smoother** estimates the mean vector $\boldsymbol{\mu} = \mathbb{E}(\mathbf{Y})$ by $\mathbf{S}\mathbf{Y}$ for a fixed $n \times n$ matrix $\mathbf{S}$. Show that $\mathbb{E}\|\mathbf{S}\mathbf{Y} - \boldsymbol{\mu}\|^2 = \sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top) + \|(\mathbf{I} - \mathbf{S})\boldsymbol{\mu}\|^2$ when $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}$. For the projection $\mathbf{S} = \mathbf{M}$ and $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X})$, recover $\sigma^2 r$ with $r = \text{rank}(\mathbf{X})$.

Solution. $\mathbf{S}\mathbf{Y} - \boldsymbol{\mu} = \mathbf{S}(\mathbf{Y} - \boldsymbol{\mu}) - (\mathbf{I} - \mathbf{S})\boldsymbol{\mu}$. The first term has mean zero and covariance $\sigma^2\mathbf{S}\mathbf{S}^\top$, so its expected squared length is $\sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top)$ ([Theorem 2.3.1](#)). The second term is constant, and the cross term has mean zero. For $\mathbf{S} = \mathbf{M}$, $\text{tr}(\mathbf{M}\mathbf{M}^\top) = \text{tr} \mathbf{M} = r$ and $(\mathbf{I} - \mathbf{M})\boldsymbol{\mu} = \mathbf{0}$.

Exercise B3.

Show that $\mathbb{E}\|\hat{\boldsymbol{\beta}}\|^2 = \|\boldsymbol{\beta}\|^2 + \sigma^2 \sum_j d_j^{-2}$. For which c does $c\hat{\boldsymbol{\beta}}$ have smaller total mean squared error than $\hat{\boldsymbol{\beta}}$? Express the answer through $\|\boldsymbol{\beta}\|^2$ and $\sigma^2 \text{tr}(\mathbf{X}^\top \mathbf{X})^{-1}$.

27.1.4.3 C. Going deeper

Exercise C1.

Least squares is equivariant under rescaling: replacing $\mathbf{X}$ by $\mathbf{X}\mathbf{G}^{-1}$, with $\mathbf{G}$ diagonal and positive, turns the estimate into $\mathbf{G}\hat{\boldsymbol{\beta}}$. By rescaling one column in [Example \(Two nearly collinear regressors\)](#) by 10, show that $\hat{\boldsymbol{\beta}}_{\mathbf{f}}$ with $f_1 = 1$, $f_2 = 0$ is not equivariant. Why are shrinkage estimators usually applied to standardized regressors?

27.2 Ridge regression

The oldest remedy for collinearity is also the simplest: when $\mathbf{X}^\top \mathbf{X}$ has eigenvalues close to zero, add a positive constant to its diagonal before inverting. Hoerl and Kennard (1970) proposed this in statistics; numerical analysts knew it as Tikhonov regularization. The constant bounds the variance at the price of bias towards the origin. [Exercise \(B1\)](#) and [Exercise \(C1\)](#) met the estimator briefly.

27.2.1 Centring, scaling and the intercept

A penalty should not touch the intercept, or shifting the response by a constant would change the fitted slopes. Leaving the intercept unpenalized is equivalent to centring, for every penalty.

Proposition 27.2.1 — An unpenalized intercept

Let $\mathbf{X}_0$ be an $n \times p$ matrix of regressors with column means $\bar{\mathbf{x}}_0$, let $\mathbf{X} = \mathbf{X}_0 - \mathbf{1}\bar{\mathbf{x}}_0^\top$ and $\tilde{\mathbf{y}} = \mathbf{y} - \bar{y}\mathbf{1}$ be the centred regressors and response, and let $P : \mathbb{R}^p \rightarrow [0, \infty]$ be any function. Then $(\beta_0, \mathbf{b})$ minimizes

$$\|\mathbf{y} - \beta_0\mathbf{1} - \mathbf{X}_0\mathbf{b}\|^2 + P(\mathbf{b})$$

iff $\mathbf{b}$ minimizes $\|\tilde{\mathbf{y}} - \mathbf{X}\mathbf{b}\|^2 + P(\mathbf{b})$ and $\beta_0 = \bar{y} - \bar{\mathbf{x}}_0^\top \mathbf{b}$.

Proof. For fixed $\mathbf{b}$, the first term is the residual sum of squares of regressing $\mathbf{y} - \mathbf{X}_0\mathbf{b}$ on $\mathbf{1}$, minimized uniquely by the mean $\beta_0 = \bar{y} - \bar{\mathbf{x}}_0^\top \mathbf{b}$, with minimum $\|(\mathbf{I} - n^{-1}\mathbf{1}\mathbf{1}^\top)(\mathbf{y} - \mathbf{X}_0\mathbf{b})\|^2 = \|\tilde{\mathbf{y}} - \mathbf{X}\mathbf{b}\|^2$. So the joint minimum is the minimum over $\mathbf{b}$ of $\|\tilde{\mathbf{y}} - \mathbf{X}\mathbf{b}\|^2 + P(\mathbf{b})$, attained exactly at the pairs described. ■

From now on the regressors are centred and the response is centred, so $\mathbf{X}$ has no intercept column and $\mathbf{1}^\top \mathbf{X} = \mathbf{0}^\top$. A penalty also treats all coefficients as commensurable, so the regressors should be on a common scale ([Exercise \(C1\)](#)). In this chapter's examples every column has unit standard deviation, so $\mathbf{X}^\top \mathbf{X} = (n-1)\mathbf{R}$ with $\mathbf{R}$ the correlation matrix, and a coefficient is the change in mean response per standard deviation of its regressor.

27.2.2 The estimator

Definition 27.2.1 — Ridge regression

For $\lambda \geq 0$, a **ridge estimate** $\hat{\boldsymbol{\beta}}_\lambda^R$ minimizes

$$\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda\|\mathbf{b}\|^2. \quad (27.2.1)$$

The constant λ is the **ridge parameter** (or tuning parameter). The **ridge trace** is the curve $\lambda \mapsto \hat{\boldsymbol{\beta}}_\lambda^R$.

For $\lambda = 0$ this is least squares. For $\lambda > 0$ it is uniquely defined whatever the rank of $\mathbf{X}$, and its behaviour is transparent in the coordinates of Eq. 27.1.1. Let $\mathbf{X} = \sum_{j \leq r} d_j \mathbf{u}_j \mathbf{v}_j^\top$ be the SVD of $\mathbf{X}$, of rank r , and $c_j = \mathbf{u}_j^\top \mathbf{y}$.

Theorem 27.2.2 — Ridge regression

Let $\lambda > 0$.

- (a) (*Closed form.*) The criterion Eq. 27.2.1 has the unique minimizer

$$\hat{\boldsymbol{\beta}}_\lambda^R = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top \mathbf{y} = \sum_{j \leq r} \frac{d_j}{d_j^2 + \lambda} c_j \mathbf{v}_j.$$

If $r = p$, then $\hat{\boldsymbol{\beta}}_\lambda^R = \sum_j f_j(\lambda) \hat{\alpha}_j \mathbf{v}_j$ with **shrinkage factors** $f_j(\lambda) = d_j^2 / (d_j^2 + \lambda) \in (0, 1)$, decreasing in λ and smallest for the smallest d_j .

- (b) (*Fitted values.*) $\mathbf{X} \hat{\boldsymbol{\beta}}_\lambda^R = \mathbf{H}_\lambda \mathbf{y}$ with $\mathbf{H}_\lambda = \mathbf{X}(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top = \sum_{j \leq r} f_j(\lambda) \mathbf{u}_j \mathbf{u}_j^\top$. The **effective degrees of freedom** $\text{df}(\lambda) = \text{tr} \mathbf{H}_\lambda = \sum_{j \leq r} f_j(\lambda)$ decrease strictly from r (as $\lambda \rightarrow 0$) to 0 (as $\lambda \rightarrow \infty$).

- (c) (*Moments.*) If $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$ and $r = p$, then

$$E \hat{\boldsymbol{\beta}}_\lambda^R - \boldsymbol{\beta} = -\lambda (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \boldsymbol{\beta},$$

$$\text{Cov}(\hat{\boldsymbol{\beta}}_\lambda^R) = \sigma^2 \sum_j \frac{d_j^2}{(d_j^2 + \lambda)^2} \mathbf{v}_j \mathbf{v}_j^\top,$$

and, with $\boldsymbol{\alpha} = \mathbf{V}^\top \boldsymbol{\beta}$, the total mean squared error is

$$E \|\hat{\boldsymbol{\beta}}_\lambda^R - \boldsymbol{\beta}\|^2 = \sigma^2 \sum_j \frac{d_j^2}{(d_j^2 + \lambda)^2} + \lambda^2 \sum_j \frac{\alpha_j^2}{(d_j^2 + \lambda)^2}. \quad (27.2.2)$$

- (d) (*The path.*) Unless $\mathbf{X}^\top \mathbf{y} = \mathbf{0}$, $\|\hat{\boldsymbol{\beta}}_\lambda^R\|$ decreases strictly in λ , with limit 0 as $\lambda \rightarrow \infty$; and $\hat{\boldsymbol{\beta}}_\lambda^R \rightarrow \mathbf{X}^+ \mathbf{y}$, the least squares estimate of smallest norm, as $\lambda \rightarrow 0$.
- (e) (*Bayesian reading.*) If $\mathbf{Y} \mid \boldsymbol{\beta} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2 \mathbf{I})$ with σ^2 known and $\boldsymbol{\beta} \sim N_p(\mathbf{0}, (\sigma^2/\lambda) \mathbf{I})$, then $\boldsymbol{\beta} \mid \mathbf{Y} \sim N_p(\hat{\boldsymbol{\beta}}_\lambda^R, \sigma^2 (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1})$. With σ^2 unknown and the normal-inverse-gamma prior of Theorem 7.6.2 with $\mathbf{m}_0 = \mathbf{0}$ and $\mathbf{V}_0 = \lambda^{-1} \mathbf{I}$, the posterior mean of $\boldsymbol{\beta}$ is again $\hat{\boldsymbol{\beta}}_\lambda^R$.

Proof.

- (a) Uniqueness and the first formula are [Exercise \(A2\)](#): $\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}$ is positive definite, and [Proposition 1.11.2](#) applies. Complete $\mathbf{v}_1, \dots, \mathbf{v}_r$ to an orthonormal basis $\mathbf{v}_1, \dots, \mathbf{v}_p$ of $\mathbb{R}^p$. Then $\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I} = \sum_{j \leq r} (d_j^2 + \lambda) \mathbf{v}_j \mathbf{v}_j^\top + \sum_{j > r} \lambda \mathbf{v}_j \mathbf{v}_j^\top$, whose inverse has the same eigenvectors and reciprocal eigenvalues ([Theorem 1.7.2](#)). Since $\mathbf{X}^\top \mathbf{y} = \sum_{j \leq r} d_j c_j \mathbf{v}_j$, the second formula follows. When $r = p$, $d_j c_j / (d_j^2 + \lambda) = f_j(\lambda) c_j / d_j = f_j(\lambda) \hat{\alpha}_j$.
- (b) $\mathbf{X} \mathbf{v}_j = d_j \mathbf{u}_j$, so $\mathbf{X} \hat{\boldsymbol{\beta}}_\lambda^R = \sum_{j \leq r} f_j(\lambda) c_j \mathbf{u}_j = \sum_j f_j(\lambda) \mathbf{u}_j \mathbf{u}_j^\top \mathbf{y}$. The trace of $\mathbf{u}_j \mathbf{u}_j^\top$ is one. Each f_j decreases strictly from 1 to 0.
- (c) These are the formulas of [Exercise \(B1\)](#) in the present notation (its d_j and $\boldsymbol{\gamma}$ are our d_j^2 and $\boldsymbol{\alpha}$); they are also [Proposition 27.1.2\(a\)](#) with the factors $f_j(\lambda)$.
- (d) $\|\hat{\boldsymbol{\beta}}_\lambda^R\|^2 = \sum_{j \leq r} d_j^2 c_j^2 / (d_j^2 + \lambda)^2$. Every term is nonincreasing in λ and tends to zero, and a term with $c_j \neq 0$ decreases strictly. Some $c_j \neq 0$ iff $\mathbf{X}^\top \mathbf{y} \neq \mathbf{0}$. As $\lambda \rightarrow 0$, $d_j / (d_j^2 + \lambda) \rightarrow 1/d_j$, and $\sum_{j \leq r} (c_j/d_j) \mathbf{v}_j = \mathbf{X}^+ \mathbf{y}$ by [Theorem 10.4.1\(b\)](#).
- (e) With σ^2 known, the posterior density is proportional to $\exp\{-(\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda \|\boldsymbol{\beta}\|^2) / (2\sigma^2)\}$. Completing the square as in the proof of [Theorem 7.6.2](#), with $\mathbf{P}_0 = \lambda \mathbf{I}$ and $\mathbf{m}_0 = \mathbf{0}$,

$$\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda \|\boldsymbol{\beta}\|^2 = (\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}_\lambda^R)^\top (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}) (\boldsymbol{\beta} - \hat{\boldsymbol{\beta}}_\lambda^R) + C,$$

with C free of $\boldsymbol{\beta}$. This is the stated normal density. The last statement is [Proposition 7.6.3\(d\)](#). ■

Part (a) says what ridge does. It keeps the directions $\mathbf{v}_j$ and shrinks the coordinate along each by $f_j(\lambda)$: directions with $d_j^2 \gg \lambda$ are hardly touched, and those with $d_j^2 \ll \lambda$ are shrunk almost to zero, whatever the size of the coefficients. Comparing with the oracle factors $f_j^* = d_j^2 / (d_j^2 + \sigma^2 / \alpha_j^2)$ of [Proposition 27.1.2\(c\)](#), ridge is the oracle when all canonical coefficients have the same size, $\alpha_j^2 = \sigma^2 / \lambda$. Part (e) says the same in Bayesian terms: the prior $N(\mathbf{0}, (\sigma^2 / \lambda) \mathbf{I})$ treats every direction alike.

The effective degrees of freedom in (b) count each dimension by the fraction $f_j(\lambda)$ in which it is used; [Chapter 29](#) uses them in model-selection criteria, and [Exercise \(C1\)](#) gives them a second meaning.

Remark (Penalized and constrained forms). For any penalty $P \geq 0$, a minimizer $\hat{\mathbf{b}}$ of $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda P(\mathbf{b})$, with $\lambda > 0$, also minimizes $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ subject to $P(\mathbf{b}) \leq t$, where $t = P(\hat{\mathbf{b}})$. Indeed, if $P(\mathbf{b}) \leq t$, then

$$\begin{aligned} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 &\geq \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda\{P(\mathbf{b}) - t\} \\ &\geq \|\mathbf{y} - \mathbf{X}\hat{\mathbf{b}}\|^2 + \lambda\{P(\hat{\mathbf{b}}) - t\} = \|\mathbf{y} - \mathbf{X}\hat{\mathbf{b}}\|^2. \end{aligned}$$

So ridge is least squares restricted to a ball, $\|\mathbf{b}\|^2 \leq t$, whose radius is fixed by λ ([Exercise \(B3\)](#)). The lasso of [Section 27.4](#) replaces the ball by a cross-polytope.

27.2.3 Ridge beats least squares

[Exercise \(B1\)](#) showed that the total mean squared error of ridge falls as λ leaves 0. Hoerl and Kennard made the range explicit, and Theobald (1974) added the matrix sense.

Theorem 27.2.3 — Hoerl–Kennard

Let $\mathbf{X}$ have full column rank, $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2\mathbf{I}$ with $\sigma^2 > 0$, and let $\alpha_{\max}^2 = \max_j \alpha_j^2$ with $\boldsymbol{\alpha} = \mathbf{V}^\top \boldsymbol{\beta}$. Let $m(\lambda)$ be the total mean squared error [Eq. 27.2.2](#), so that $m(0) = \sigma^2 \sum_j d_j^{-2}$ is that of least squares.

- (a) $m(\lambda) < m(0)$ for every $0 < \lambda < 2\sigma^2/\alpha_{\max}^2$, and in particular for every $0 < \lambda < 2\sigma^2/\|\boldsymbol{\beta}\|^2$. If $\boldsymbol{\beta} = \mathbf{0}$, for every $\lambda > 0$.
- (b) m is strictly decreasing on $[0, \sigma^2/\alpha_{\max}^2]$.
- (c) $\hat{\boldsymbol{\beta}}_\lambda^R$ is at least as good as $\hat{\boldsymbol{\beta}}$ in the matrix sense iff

$$\frac{\lambda}{\sigma^2} \sum_j \frac{d_j^2 \alpha_j^2}{2d_j^2 + \lambda} \leq 1,$$

which holds whenever $0 < \lambda \leq 2\sigma^2/\|\boldsymbol{\beta}\|^2$.

Proof.

- (a) Compare term by term. The j th term of [Eq. 27.2.2](#) is below its value σ^2/d_j^2 at $\lambda = 0$ iff $d_j^2(\sigma^2 d_j^2 + \lambda^2 \alpha_j^2) < \sigma^2(d_j^2 + \lambda)^2$, that is, iff $\lambda^2 d_j^2 \alpha_j^2 < 2\lambda \sigma^2 d_j^2 + \lambda^2 \sigma^2$, or, dividing by $\lambda > 0$,

$$\lambda(d_j^2 \alpha_j^2 - \sigma^2) < 2\sigma^2 d_j^2.$$

If $d_j^2 \alpha_j^2 \leq \sigma^2$, this holds for every $\lambda > 0$. Otherwise it holds for $\lambda < 2\sigma^2 d_j^2/(d_j^2 \alpha_j^2 - \sigma^2)$, and the right side exceeds $2\sigma^2 d_j^2/(d_j^2 \alpha_j^2) = 2\sigma^2/\alpha_j^2 \geq 2\sigma^2/\alpha_{\max}^2$. So for $0 < \lambda < 2\sigma^2/\alpha_{\max}^2$ every term decreases, and so does the sum. Finally $\alpha_{\max}^2 \leq \|\boldsymbol{\alpha}\|^2 = \|\boldsymbol{\beta}\|^2$.

- (b) By [Exercise \(B1\)](#), in the present notation, $m'(\lambda) = 2 \sum_j d_j^2 (\lambda \alpha_j^2 - \sigma^2)/(d_j^2 + \lambda)^3$. For $0 \leq \lambda < \sigma^2/\alpha_{\max}^2$ every numerator is negative, so $m' < 0$ there, and m is strictly decreasing on the closed interval.
- (c) Write $\mathbf{S} = \mathbf{X}^\top \mathbf{X}$ and $\mathbf{A} = (\mathbf{S} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top$. In the notation of [Theorem 27.1.1\(c\)](#), all matrices involved have the eigenvectors $\mathbf{v}_j$, with eigenvalues

$$\Delta_{\mathbf{A}} : \sigma^2 \left(\frac{1}{d_j^2} - \frac{d_j^2}{(d_j^2 + \lambda)^2} \right) = \sigma^2 \frac{\lambda(2d_j^2 + \lambda)}{d_j^2(d_j^2 + \lambda)^2} > 0,$$

and the bias is $\boldsymbol{\delta} = -\sum_j \lambda \alpha_j (d_j^2 + \lambda)^{-1} \mathbf{v}_j$. So $\Delta_{\mathbf{A}}$ is positive definite and $\boldsymbol{\delta}^\top \Delta_{\mathbf{A}}^{-1} \boldsymbol{\delta} = \sum_j \lambda^2 \alpha_j^2 (d_j^2 + \lambda)^{-2} \cdot d_j^2 (d_j^2 + \lambda)^2 / \{\sigma^2 \lambda (2d_j^2 + \lambda)\}$, which is the stated sum. Each factor $d_j^2/(2d_j^2 + \lambda)$ is below $1/2$, so the sum is at most $\lambda \|\boldsymbol{\alpha}\|^2/(2\sigma^2) = \lambda \|\boldsymbol{\beta}\|^2/(2\sigma^2)$. Apply [Theorem 27.1.1\(c\)](#). ■

The theorem is an existence result. The good range of λ depends on the unknown $\boldsymbol{\beta}$ and σ^2 , and

it says nothing about a λ chosen from the data. Replacing $\boldsymbol{\beta}$ by $\hat{\boldsymbol{\beta}}$ in the bound is misleading, because $\|\hat{\boldsymbol{\beta}}\|^2$ overestimates $\|\boldsymbol{\beta}\|^2$ by $\sigma^2 \sum_j d_j^{-2}$ on average ([Exercise \(B3\)](#)), which is large exactly when ridge is needed. What the theorem does establish is that least squares is never the best member of the ridge family.

27.2.4 Choosing the ridge parameter

Hoerl and Kennard suggested choosing the smallest λ at which the ridge trace “stabilizes”, a subjective judgement. Hoerl, Kennard and Baldwin (1975) proposed the plug-in $\lambda = p\hat{\sigma}^2/\|\hat{\boldsymbol{\beta}}\|^2$, the optimum of [Exercise \(A2\)](#) with estimates substituted; since $\|\hat{\boldsymbol{\beta}}\|^2$ is too large on average, it tends to shrink too little under collinearity. A more defensible choice minimizes an estimate of prediction error. Because ridge is a linear smoother, $\hat{\mathbf{y}} = \mathbf{H}_\lambda \mathbf{y}$, the leave-one-out prediction errors need only one fit: the residual of case i divided by $1 - h_{ii}(\lambda)$, with $h_{ii}(\lambda)$ the i th diagonal entry of $\mathbf{H}_\lambda$ ([Exercise \(B1\)](#); add $1/n$ for an unpenalized intercept), the ridge version of [Theorem 20.3.1](#). **Generalized cross-validation** replaces each $h_{ii}(\lambda)$ by the average $\text{tr } \mathbf{H}_\lambda/n$:

$$\text{GCV}(\lambda) = \frac{n^{-1} \|\mathbf{y} - \mathbf{H}_\lambda \mathbf{y}\|^2}{(1 - \text{tr } \mathbf{H}_\lambda/n)^2}$$

(with an unpenalized intercept, $\text{tr } \mathbf{H}_\lambda$ becomes $1 + \text{df}(\lambda)$). [Chapter 29](#) develops both criteria for general linear smoothers ([Theorem 29.3.2](#) and [Definition 29.3.2](#)). A Bayesian alternative estimates the prior variance σ^2/λ from the marginal likelihood, an empirical Bayes idea that returns in [Section 27.5](#).

Example. (Ridge regression for Longley’s data)

Longley’s regression ([Example \(Longley’s regression\)](#)) relates total employment, in thousands, to six economic series over $n = 16$ years. With the regressors standardized, the eigenvalues d_j^2 of $\mathbf{X}^\top \mathbf{X}$ run from 69.05 down to 0.0057. The least squares coefficients, in thousands of persons per standard deviation, are 163 for the GNP deflator, -3560 for GNP, -1888 for unemployment, -719 for the armed forces, -355 for population and 8709 for the year. The GNP and YEAR coefficients are large and of opposite sign: the two series rose together, and the data can hardly separate them.

[Figure 27.2.1\(a\)](#) shows the ridge trace against the effective degrees of freedom. As λ grows, the GNP and YEAR coefficients approach each other, and the GNP coefficient changes sign at $\lambda = 0.0110$, where $\text{df} = 5.1$. Leave-one-out cross-validation chooses $\lambda = 0.0026$, with $\text{df} = 5.61$, and GCV chooses $\lambda = 0.0030$, with $\text{df} = 5.56$. Both prefer little shrinkage. At the leave-one-out choice the coefficients are -6 , -1809 , -1645 , -669 , -825 and 7415 . The largest changes are in the coefficients of GNP, YEAR and population, the three series that rose together, and the deflator coefficient is essentially zero. The minimized root mean squared leave-one-out error is 402, against 425 for least squares, but this minimum is optimistic, since the same errors chose λ . Choosing λ afresh within each leave-one-out fold (*nested* cross-validation) gives an honest 441: on these sixteen years tuned ridge does not predict better than least squares.

Panel (b) asks what the theorem guarantees in a world where the truth is the least squares fit, $\boldsymbol{\beta} = \hat{\boldsymbol{\beta}}$, with $\sigma = s = 304.9$. There, least squares has total mean squared error 19.33 million, and the best ridge estimate, at $\lambda = 0.0019$ with $\text{df} = 5.69$, has 15.01 million, a ratio of 0.777. [Theorem 27.2.3\(a\)](#) guarantees an improvement only for $\lambda < 0.00383$, and part (c) gives dominance in the matrix sense for $\lambda \leq 0.00200$; in fact the improvement continues up to $\lambda = 0.0058$. The ranges are narrow because this

Figure 27.2.1: Ridge regression for Longley's data. (a) The ridge trace: standardized coefficients against the effective degrees of freedom $df(\lambda)$; the vertical line marks the leave-one-out choice. (b) Variance, squared bias and total mean squared error of ridge, computed exactly from Eq. 27.2.2 when the true coefficients are the least squares estimates and $\sigma = s$; the dashed line is least squares.

“truth” inherits the least squares estimate's large components along the weak directions.

```

The script also checks the closed form against a direct solve, augmented least squares ([Exercise \(A1\)](#)) and the posterior mean of [Theorem 7.6.2](#), and the leave-one-out shortcut against sixteen refits.

27.2.5 Exercises

27.2.5.1 A. Check your understanding

Exercise A1.

Show that $\hat{\beta}_\lambda^R$ is the least squares estimate for the augmented data $\tilde{\mathbf{y}} = (\mathbf{y}^\top, \mathbf{0}^\top)^\top$ and $\tilde{\mathbf{X}} = (\mathbf{X}^\top, \sqrt{\lambda}\mathbf{I})^\top$. Show that $\kappa(\tilde{\mathbf{X}})^2 = (d_1^2 + \lambda)/(d_p^2 + \lambda)$, so ridge can be computed stably by QR ([Chapter 10](#)), and that the augmented problem has “residual sum of squares” $\|\mathbf{y} - \mathbf{X}\hat{\beta}_\lambda^R\|^2 + \lambda\|\hat{\beta}_\lambda^R\|^2$.

Solution. $\|\tilde{\mathbf{y}} - \tilde{\mathbf{X}}\mathbf{b}\|^2 = \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \|\mathbf{0} - \sqrt{\lambda}\mathbf{b}\|^2$, which is [Eq. 27.2.1](#), so the minimizers coincide and the minimum is the stated sum. $\tilde{\mathbf{X}}^\top\tilde{\mathbf{X}} = \mathbf{X}^\top\mathbf{X} + \lambda\mathbf{I}$ has eigenvalues $d_j^2 + \lambda$, and the singular values of $\tilde{\mathbf{X}}$ are their square roots ([Theorem 1.8.1](#)). The condition number is the ratio of the largest to the smallest ([Definition 1.8.1](#)).

Exercise A2.

Suppose $\mathbf{X}^\top\mathbf{X} = \mathbf{I}$. Show that $\hat{\beta}_\lambda^R = \hat{\beta}/(1 + \lambda)$, $\text{df}(\lambda) = p/(1 + \lambda)$, and that the value of λ minimizing the total mean squared error is $p\sigma^2/\|\hat{\beta}\|^2$.

27.2.5.2 B. Practice

Exercise B1.

Let $\hat{\boldsymbol{\beta}}_{\lambda,(i)}^R$ be the ridge estimate computed without case i (no intercept), and h_{ii} the i th diagonal entry of $\mathbf{H}_\lambda$. Show that

$$y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{\lambda,(i)}^R = \frac{y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_\lambda^R}{1 - h_{ii}}.$$

Solution. Put $\mathbf{K} = \mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}$ and $\mathbf{x} = \mathbf{x}_{(i)}$, so $h_{ii} = \mathbf{x}^\top \mathbf{K}^{-1} \mathbf{x} < 1$. Without case i the matrix is $\mathbf{K} - \mathbf{x}\mathbf{x}^\top$ and the right side is $\mathbf{X}^\top \mathbf{y} - \mathbf{x}y_i$. By [Eq. 1.6.7](#), $(\mathbf{K} - \mathbf{x}\mathbf{x}^\top)^{-1} = \mathbf{K}^{-1} + \mathbf{K}^{-1} \mathbf{x}\mathbf{x}^\top \mathbf{K}^{-1} / (1 - h_{ii})$. Hence

$$\mathbf{x}^\top \hat{\boldsymbol{\beta}}_{\lambda,(i)}^R = \left(\mathbf{x}^\top \mathbf{K}^{-1} + \frac{h_{ii} \mathbf{x}^\top \mathbf{K}^{-1}}{1 - h_{ii}} \right) (\mathbf{X}^\top \mathbf{y} - \mathbf{x}y_i) = \frac{\mathbf{x}^\top \hat{\boldsymbol{\beta}}_\lambda^R - h_{ii} y_i}{1 - h_{ii}},$$

and y_i minus this is $(y_i - \mathbf{x}^\top \hat{\boldsymbol{\beta}}_\lambda^R) / (1 - h_{ii})$. The argument is that of [Theorem 20.3.1](#) with $\mathbf{X}^\top \mathbf{X}$ replaced by $\mathbf{K}$; only the rank-one update is used.

Exercise B2.

Generalized ridge regression uses a separate constant for each principal direction: $\hat{\boldsymbol{\beta}}_{\mathbf{K}} = (\mathbf{X}^\top \mathbf{X} + \mathbf{V}\mathbf{K}\mathbf{V}^\top)^{-1} \mathbf{X}^\top \mathbf{y}$ with $\mathbf{K} = \text{diag}(k_1, \dots, k_p)$, $k_j \geq 0$. Show that its shrinkage factors are $d_j^2 / (d_j^2 + k_j)$, and that the choice $k_j = \sigma^2 / \alpha_j^2$ gives the oracle factors of [Proposition 27.1.2\(c\)](#).

Exercise B3.

Show that for every t with $0 < t < \|\hat{\boldsymbol{\beta}}\|^2$ (full column rank) there is exactly one $\lambda > 0$ with $\|\hat{\boldsymbol{\beta}}_\lambda^R\|^2 = t$, and that $\hat{\boldsymbol{\beta}}_\lambda^R$ is then the unique minimizer of $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ subject to $\|\mathbf{b}\|^2 \leq t$.

27.2.5.3 C. Going deeper**Exercise C1.**

For any estimator $\hat{\boldsymbol{\mu}} = \mathbf{S}\mathbf{Y}$ of $\boldsymbol{\mu} = \mathbf{E}(\mathbf{Y})$ with $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, show that $\sigma^{-2} \sum_i \text{Cov}(\hat{\mu}_i, Y_i) = \text{tr } \mathbf{S}$. Deduce that $\text{df}(\lambda)$ measures how strongly the ridge fit follows its own data, and that $\mathbf{E}\|\mathbf{Y} - \mathbf{H}_\lambda \mathbf{Y}\|^2 = \mathbf{E}\|\mathbf{H}_\lambda \mathbf{Y} - \boldsymbol{\mu}\|^2 + n\sigma^2 - 2\sigma^2 \text{df}(\lambda)$.

Exercise C2.

Let $p > n$. Show that $\hat{\boldsymbol{\beta}}_\lambda^R = \mathbf{X}^\top (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_n)^{-1} \mathbf{y}$, which needs only an $n \times n$ inverse, and that $\hat{\boldsymbol{\beta}}_\lambda^R \in \mathcal{C}(\mathbf{X}^\top)$. What is the limit as $\lambda \rightarrow 0$? [Chapter 28](#) studies this limit.

Solution. The identity $\mathbf{X}^\top (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_n) = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}_p) \mathbf{X}^\top$ gives $(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I}_p)^{-1} \mathbf{X}^\top = \mathbf{X}^\top (\mathbf{X}\mathbf{X}^\top + \lambda \mathbf{I}_n)^{-1}$ after multiplying by the two inverses. The right side is in $\mathcal{C}(\mathbf{X}^\top)$. By [Theorem 27.2.2\(d\)](#) the limit is $\mathbf{X}^+ \mathbf{y}$, the least squares solution of smallest norm, which

interpolates the data when $\text{rank}(\mathbf{X}) = n$.

27.3 Principal component regression

Ridge regression keeps every principal direction and shrinks each by a factor between zero and one. Principal component regression makes the factors zero or one: it keeps the directions in which the regressors vary most and discards the rest. Principal components (Hotelling 1933) are an old remedy for collinearity (Massy 1965), and [Proposition 10.4.3](#) computed the bias and variance of regression on the leading ones in uncentred form. This section proves when it beats least squares and makes precise the warning that goes with it.

27.3.1 Definition

Keep the conventions of [Section 27.2](#): $\mathbf{X}$ is $n \times p$, centred, of full column rank, with its columns on a common scale, and $\mathbf{X} = \mathbf{U}\mathbf{D}\mathbf{V}^\top$ with $d_1 \geq \dots \geq d_p > 0$.

Definition 27.3.1 — Principal component regression

The **principal components** of the regressors are the vectors $\mathbf{z}_j = \mathbf{X}\mathbf{v}_j = d_j\mathbf{u}_j$, $j = 1, \dots, p$. Their sample variances are $d_j^2/(n-1)$, they are mutually orthogonal, and $\mathbf{v}_j$ is the j th **loading vector**. For $0 \leq k \leq p$, the **principal component regression** estimate with k components is

$$\hat{\boldsymbol{\beta}}_k^{\text{PC}} = \sum_{j \leq k} \hat{\alpha}_j \mathbf{v}_j = \mathbf{V}_k \mathbf{V}_k^\top \hat{\boldsymbol{\beta}}, \quad \mathbf{V}_k = [\mathbf{v}_1, \dots, \mathbf{v}_k],$$

obtained by regressing $\mathbf{y}$ on $\mathbf{z}_1, \dots, \mathbf{z}_k$ and transforming the coefficients back.

Because the $\mathbf{z}_j$ are orthogonal, the coefficient of $\mathbf{z}_j$ in the regression on $\mathbf{z}_1, \dots, \mathbf{z}_k$ is $\mathbf{z}_j^\top \mathbf{y} / \|\mathbf{z}_j\|^2 = c_j/d_j = \hat{\alpha}_j$, the same for every $k \geq j$; the regression on the leading components is least squares with the trailing canonical coordinates set to zero. The shrinkage factors are $f_j = 1$ for $j \leq k$ and $f_j = 0$ for $j > k$.

Proposition 27.3.1 — Bias and variance of principal component regression

Let $E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, $\boldsymbol{\alpha} = \mathbf{V}^\top \boldsymbol{\beta}$ and $\tau_j^2 = d_j^2 \alpha_j^2 / \sigma^2$.

- $\hat{\boldsymbol{\beta}}_k^{\text{PC}}$ is the least squares estimate subject to the $p-k$ restrictions $\mathbf{v}_j^\top \mathbf{b} = 0$, $j > k$. Its fitted vector is $\mathbf{M}_k \mathbf{y}$, where $\mathbf{M}_k = \sum_{j \leq k} \mathbf{u}_j \mathbf{u}_j^\top$ is the orthogonal projection onto $\text{span}(\mathbf{z}_1, \dots, \mathbf{z}_k)$.
- $E \hat{\boldsymbol{\beta}}_k^{\text{PC}} - \boldsymbol{\beta} = -\sum_{j > k} \alpha_j \mathbf{v}_j$ and $\text{Cov}(\hat{\boldsymbol{\beta}}_k^{\text{PC}}) = \sigma^2 \sum_{j \leq k} d_j^{-2} \mathbf{v}_j \mathbf{v}_j^\top$. The total mean squared error is $\sum_{j > k} \alpha_j^2 + \sigma^2 \sum_{j \leq k} d_j^{-2}$, and the mean squared error of the fitted values is $E \|\mathbf{X} \hat{\boldsymbol{\beta}}_k^{\text{PC}} - \mathbf{X} \boldsymbol{\beta}\|^2 = k\sigma^2 + \sum_{j > k} d_j^2 \alpha_j^2$.

- (c) $\hat{\beta}_k^{\text{PC}}$ is at least as good as $\hat{\beta}$ in the matrix sense iff $\sum_{j>k} \tau_j^2 \leq 1$.
- (d) Among all estimators $\tilde{\beta}_f$ with every $f_j \in \{0, 1\}$, both mean squared errors in
- are minimized by keeping exactly the directions with $\tau_j^2 > 1$ (ties may go either way). Principal component regression with k components is this best selection iff $\tau_j^2 \geq 1$ for $j \leq k$ and $\tau_j^2 \leq 1$ for $j > k$.

Proof.

- (a) The restrictions say that $\mathbf{b} \in \text{span}(\mathbf{v}_1, \dots, \mathbf{v}_k)$, that is, $\mathbf{b} = \mathbf{V}_k \mathbf{g}$. Then $\mathbf{X}\mathbf{b} = \mathbf{U}_k \mathbf{D}_k \mathbf{g}$ with $\mathbf{U}_k, \mathbf{D}_k$ the leading blocks, and $\|\mathbf{y} - \mathbf{U}_k \mathbf{D}_k \mathbf{g}\|^2$ is minimized at $\mathbf{D}_k \mathbf{g} = \mathbf{U}_k^\top \mathbf{y}$, so $\mathbf{g} = (\hat{\alpha}_1, \dots, \hat{\alpha}_k)^\top$ and the fit is $\mathbf{U}_k \mathbf{U}_k^\top \mathbf{y} = \mathbf{M}_k \mathbf{y}$.
- (b) The moments are [Proposition 10.4.3](#), and the mean squared errors are [Proposition 27.1.2\(a\)](#) and (b) with the factors 0 and 1.
- (c) By [Theorem 27.1.1\(c\)](#) with the saving $\Delta_{\mathbf{A}} = \sigma^2 \sum_{j>k} d_j^{-2} \mathbf{v}_j \mathbf{v}_j^\top$, which is nonnegative definite with column space $\text{span}(\mathbf{v}_{k+1}, \dots, \mathbf{v}_p)$, and bias $\boldsymbol{\delta} = -\sum_{j>k} \alpha_j \mathbf{v}_j$, which lies in that column space. The Moore–Penrose inverse is $\Delta_{\mathbf{A}}^+ = \sigma^{-2} \sum_{j>k} d_j^2 \mathbf{v}_j \mathbf{v}_j^\top$, so $\boldsymbol{\delta}^\top \Delta_{\mathbf{A}}^+ \boldsymbol{\delta} = \sum_{j>k} d_j^2 \alpha_j^2 / \sigma^2$.
- (d) The losses are sums over directions, and by [Proposition 27.1.2\(d\)](#) the j th term is smaller with $f_j = 0$ than with $f_j = 1$ iff $\tau_j^2 < 1$. ■

By part (c), discarding directions improves the estimate of *every* linear combination exactly when the total signal they carry, in noise units, is at most one. Part (b) shows that the two losses charge a dropped direction differently: for β it costs α_j^2 and saves σ^2/d_j^2 , which is large when d_j is small; for the mean it costs $d_j^2 \alpha_j^2$ and saves only σ^2 . Collinearity is a problem for coefficients, not for fitted values ([Proposition 26.4.1](#)).

27.3.2 Low-variance components need not be irrelevant

Part (d) is the crux. The right directions to drop are those with small $\tau_j^2 = d_j^2 \alpha_j^2 / \sigma^2$; principal component regression drops those with small d_j^2 . The two orderings agree only if the α_j do not grow too fast as d_j shrinks, and nothing in the model says they should: the components are computed from $\mathbf{X}$ alone. Jolliffe (1982) gave published examples in which low-variance components were important predictors, and Hadi and Ling (1998) showed how a component with a tiny variance can carry most of a regression ([Exercise \(B2\)](#)).

The signal-to-noise ratios can be estimated: under normal errors $c_j^2/\sigma^2 - 1$ is unbiased for τ_j^2 , and the component t statistics $t_j = c_j/s$ estimate τ_j ([Exercise \(B1\)](#)). Part (d) then suggests keeping the components with $t_j^2 > 2$. Such a supervised selection is not a fixed projection, and the leave-one-out and standard-error formulas do not apply to it without adjustment ([Chapter 29](#)).

Example. (Principal components of Longley’s regressors)

Figure 27.3.1: Principal components of Longley’s regressors. (a) Share of the regressors’ variance (log scale, left) and the absolute component t statistic (right; dashed line at $\sqrt{2}$). (b) Leave-one-out root mean squared prediction error of principal component regression with the leading k components, of ridge regression against its effective degrees of freedom, and of the components with $t_j^2 > 2$, each for a fixed choice of components or λ .

The six standardized Longley regressors have principal components whose shares of the total variance are 76.723%, 19.589%, 3.390%, 0.249%, 0.043% and 0.006%, so the usual rules of thumb keep two or three. The component t statistics are 42.66, 5.40, 10.66, -0.55 , 3.96 and 1.72 (Figure 27.3.1(a)). The fifth component, with less than a two-thousandth of the variance, is nearly as strongly related to employment as the second, while the fourth, with more variance than the fifth and sixth together, is irrelevant.

Because principal component regression fits a projection ([Proposition 27.3.1\(a\)](#)), the leave-one-out prediction errors follow from [Theorem 20.3.1](#) with the leverages $1/n + \sum_{j \leq k} u_{ij}^2$. The root mean squared leave-one-out errors for $k = 0, 1, \dots, 6$ are 3627, 1109, 1067, 506, 606, 435 and 425, in thousands. Adding the fourth component makes predictions *worse*, and adding the fifth makes them much better; the best number of leading components is 6, which is least squares itself. The rule $t_j^2 > 2$ keeps components 1, 2, 3, 5, 6. Applied once to all sixteen years and then treated as fixed, it gives 392, but that figure ignores the selection. Redoing the selection within each fold (*nested* leave-one-out) gives 444, worse than least squares. Searching all 64 subsets of components picks 1, 2, 3, 5 with 389, optimistic for the same reason. With three leading components the coefficients are 1023, 1260, -1085 , -417 , 1070 and 966: all six regressors are retained, with the GNP and YEAR coefficients now positive and comparable.

```
import numpy as np
import statsmodels.api as sm
data = sm.datasets.longley.load_pandas().data
names = ["GNPDEFL", "GNP", "UNEMP", "ARMED", "POP", "YEAR"]
Z = data[names].to_numpy()
y = data["TOTEMP"].to_numpy()
n, p = Z.shape
X = (Z - Z.mean(axis=0)) / Z.std(axis=0, ddof=1)
yc = y - y.mean()
U, d, Vt = np.linalg.svd(X, full_matrices=False)
c = U.T @ yc #  $c_j = u_j^T y$ , the fitted
               coordinate of component  $j$ 
```

```

def fit_components(keep):
    """Least squares on the chosen component scores: coefficients and leave-one-out
    error."""
    keep = list(keep)
    beta = Vt[keep].T @ (c[keep] / d[keep])
    resid = yc - X @ beta
    h = 1 / n + np.sum(U[:, keep] ** 2, axis=1)           # leverages, intercept
    included
    return beta, np.mean((resid / (1 - h)) ** 2)

resid_ls = yc - U @ c
s = np.sqrt(resid_ls @ resid_ls / (n - p - 1))
t = c / s                                           # t statistic of each component
share = d ** 2 / np.sum(d ** 2)                   # share of the regressors' variance
for k in range(p + 1):
    beta_k, loo_k = fit_components(range(k))
    print(f"k = {k}  L00 = {loo_k:9.0f}  coefficients", np.round(beta_k, 0))
print("variance shares:", np.round(share, 5))
print("component t statistics:", np.round(t, 2))

```

27.3.3 Ridge and principal components compared

Both methods order the directions by d_j alone, ridge softly and principal components hard, and neither dominates. If the trailing canonical coefficients are zero, principal components with the right k is close to the oracle, while ridge must leave variance in the trailing directions or bias the leading ones; if all the α_j^2 are equal, ridge with $\lambda = \sigma^2/\alpha_j^2$ is the oracle and no zero-one choice matches it ([Exercise \(B3\)](#)). In the simulations of Frank and Friedman (1993) ridge was generally at least as good as principal components. For Longley's data neither method gains over least squares (leading components never do, and tuned ridge has nested leave-one-out error 441 against 425), because the fifth direction matters and both treat it as close to noise. Partial least squares, which builds its directions from $\mathbf{y}$ as well as $\mathbf{X}$, is one response ([Exercise \(C1\)](#)).

27.3.4 Exercises

27.3.4.1 A. Check your understanding

Exercise A1.

Show that for $k < p$ the estimate $\hat{\beta}_k^{\text{PC}}$ generally has no zero coordinates, so that principal component regression reduces dimension without selecting variables. When does it set the coefficient of regressor j to zero?

Exercise A2.

Show that the fitted values of principal component regression with k components, with an unpenalized intercept, are $(n^{-1}\mathbf{1}\mathbf{1}^\top + \mathbf{M}_k)\mathbf{y}$, that this matrix is an orthogonal projection of rank $k + 1$, and that its leverages are $1/n + \sum_{j \leq k} u_{ij}^2$. Why does [Theorem 20.3.1](#) apply to principal component regression but not to ridge regression?

27.3.4.2 B. Practice

Exercise B1.

Under the normal linear model with $\text{rank}(\mathbf{X}) = p < n - 1$ (centred data), show that the $c_j = \mathbf{u}_j^\top \mathbf{Y}$ are independent $N(d_j \alpha_j, \sigma^2)$, independent of the residual sum of squares, and that $t_j = c_j/s$ has a noncentral t distribution with $n - p - 1$ degrees of freedom and noncentrality τ_j . Show that $c_j^2/\sigma^2 - 1$ is unbiased for τ_j^2 .

Solution. $\mathbf{U}^\top \mathbf{Y}$ is normal with mean $\mathbf{U}^\top \mathbf{X} \boldsymbol{\beta} = \mathbf{D} \mathbf{V}^\top \boldsymbol{\beta} = \mathbf{D} \boldsymbol{\alpha}$ and covariance $\sigma^2 \mathbf{U}^\top \mathbf{U} = \sigma^2 \mathbf{I}$, so the c_j are independent with the stated laws. They are functions of the fitted values $\mathbf{M} \mathbf{Y} = \mathbf{U} \mathbf{U}^\top \mathbf{Y}$, which are independent of the residual sum of squares ([Theorem 7.5.1\(c\)](#)); with the intercept removed by centring the residual degrees of freedom are $n - p - 1$. Hence $t_j = (c_j/\sigma)/(s/\sigma)$ is a normal with mean τ_j (up to sign) divided by an independent $\sqrt{\chi^2(n - p - 1)/(n - p - 1)}$, which is the noncentral t ([Definition 4.1.3](#)). Finally $E(c_j^2/\sigma^2) = \text{Var}(c_j/\sigma) + \{E(c_j/\sigma)\}^2 = 1 + \tau_j^2$.

Exercise B2.

Let x_1, x_2 be standardized regressors with correlation $\rho = 0.99$ and let $E(Y) = x_1 - x_2$. Find the canonical coefficients and show that $\alpha_1 = 0$. Compute τ_1^2 and τ_2^2 with $n = 100$, unit-variance columns and $\sigma = 1$. Which principal component regression is best, and what does a one-component principal component regression estimate?

Solution. With $\mathbf{X}^\top \mathbf{X} = (n - 1)\mathbf{R}$, the eigenvectors are $\mathbf{v}_1 = (1, 1)^\top/\sqrt{2}$ and $\mathbf{v}_2 = (1, -1)^\top/\sqrt{2}$, with $d_1^2 = (n - 1)(1 + \rho)$ and $d_2^2 = (n - 1)(1 - \rho)$. For $\boldsymbol{\beta} = (1, -1)^\top$, $\alpha_1 = \mathbf{v}_1^\top \boldsymbol{\beta} = 0$ and $\alpha_2 = \sqrt{2}$. So $\tau_1^2 = 0$ and $\tau_2^2 = (n - 1)(1 - \rho) \cdot 2/\sigma^2 = 99 \times 0.01 \times 2 = 1.98$. By [Proposition 27.3.1\(d\)](#), the best zero-one selection keeps only the *second* component. Principal component regression with one component keeps the first, estimates $\alpha_1 = 0$ and has expected value $\mathbf{0}$: it discards the whole regression.

Exercise B3.

Consider a design with two principal directions. (i) If $\alpha_2 = 0 \neq \alpha_1$, show that the oracle factors of [Proposition 27.1.2\(c\)](#) are $(\tau_1^2/(1 + \tau_1^2), 0)$, that no ridge estimate attains them, and that principal component regression with $k = 1$ exceeds the oracle's total mean squared error by only $(\sigma^2/d_1^2)/(1 + \tau_1^2)$. (ii) If $\alpha_1^2 = \alpha_2^2 > 0$, show that ridge with $\lambda = \sigma^2/\alpha_1^2$ attains the oracle, and that every principal component regression is strictly worse.

Solution. Part (i): $\tau_2^2 = 0$ gives $f_2^* = 0$. Ridge has $f_2(\lambda) = d_2^2/(d_2^2 + \lambda) > 0$ for every finite λ , so it never attains $f_2^* = 0$. Principal components with $k = 1$ has factors $(1, 0)$. By [Proposition 27.1.2\(a\)](#) its first term is σ^2/d_1^2 against the oracle's $(\sigma^2/d_1^2)\tau_1^2/(1 + \tau_1^2)$, and the second terms are both zero; the difference is $(\sigma^2/d_1^2)/(1 + \tau_1^2)$. (ii) With $\alpha_1^2 = \alpha_2^2 = a$ and $\lambda = \sigma^2/a$, ridge has factors $d_j^2/(d_j^2 + \sigma^2/a) = d_j^2 a/(d_j^2 a + \sigma^2) = \tau_j^2/(1 + \tau_j^2)$, the oracle. Each term of [Proposition 27.1.2\(a\)](#) is a strictly convex quadratic in f_j , so the oracle is its unique minimizer, and since $0 < \tau_j^2/(1 + \tau_j^2) < 1$, every choice of factors in $\{0, 1\}$ is strictly worse.

27.3.4.3 C. Going deeper

Exercise C1.

The first direction of **partial least squares** is $\mathbf{w}_1 \propto \mathbf{X}^\top \mathbf{y}$, the direction maximizing the sample covariance of $\mathbf{X}\mathbf{w}$ with $\mathbf{y}$ over unit vectors $\mathbf{w}$. Show that $\mathbf{w}_1 \propto \sum_j d_j c_j \mathbf{v}_j$, and compare with the first principal direction $\mathbf{v}_1$. Show that the one-dimensional fit along $\mathbf{w}_1$ never ignores a direction j with $c_j \neq 0$.

27.4 The lasso

Ridge regression and principal components shrink, but neither selects ([Exercise \(A1\)](#)). Subset selection does, but it is a combinatorial search whose output jumps when the data change slightly. Tibshirani (1996) replaced the squared penalty of ridge by the sum of the absolute coefficients. The resulting **lasso** (“least absolute shrinkage and selection operator”) is convex, like ridge, and sets some coefficients exactly to zero, like subset selection; Chen, Donoho and Saunders (1998) introduced the same criterion as basis pursuit denoising. The theory for $p > n$ is in [Chapter 28](#), and generalizations in [Chapter 30](#).

27.4.1 Definition and optimality conditions

The conventions of [Section 27.2](#) remain: $\mathbf{X}$ is centred with columns on a common scale, $\mathbf{y}$ is centred, and the intercept is $\bar{y}$ ([Proposition 27.2.1](#)). Here $\mathbf{X}$ may have any rank.

Definition 27.4.1 — The lasso

For $\lambda \geq 0$, a **lasso estimate** $\hat{\boldsymbol{\beta}}_\lambda^L$ minimizes

$$L_\lambda(\mathbf{b}) = \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda \|\mathbf{b}\|_1, \quad \|\mathbf{b}\|_1 = \sum_j |b_j|. \quad (27.4.1)$$

This is the **penalized form**; the **constrained form** minimizes $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ subject to $\|\mathbf{b}\|_1 \leq t$. A vector $\mathbf{s}$ is a **subgradient** of $\|\cdot\|_1$ at $\mathbf{b}$, written $\mathbf{s} \in \partial \|\mathbf{b}\|_1$, if $s_j = \text{sign}(b_j)$ when $b_j \neq 0$ and $s_j \in [-1, 1]$ when $b_j = 0$. The **Karush–Kuhn–Tucker (KKT) conditions** for [Eq. 27.4.1](#) are

$$\mathbf{X}^\top (\mathbf{y} - \mathbf{X}\mathbf{b}) = \lambda \mathbf{s} \quad \text{for some } \mathbf{s} \in \partial \|\mathbf{b}\|_1; \quad (27.4.2)$$

that is, $|\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\mathbf{b})| \leq \lambda$ for every j , with $\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\mathbf{b}) = \lambda \text{sign}(b_j)$ whenever $b_j \neq 0$.

The factor $\frac{1}{2}$ removes a 2 from the KKT conditions; [Chapter 28](#) writes the criterion as $(2n)^{-1} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda \|\mathbf{b}\|_1$, whose λ is the present one divided by n . The KKT conditions say that no regressor’s inner product with the residual exceeds λ in absolute value, and that only regressors at the bound are active.

Theorem 27.4.1 — Lasso solutions

Let $\lambda > 0$.

- (a) L_λ has at least one minimizer, and the set of minimizers is convex.
- (b) $\mathbf{b}$ minimizes L_λ iff it satisfies the KKT conditions [Eq. 27.4.2](#).
- (c) All minimizers have the same fitted vector $\mathbf{X}\mathbf{b}$ and the same norm $\|\mathbf{b}\|_1$. If $\mathbf{X}$ has full column rank, the minimizer is unique.
- (d) $\mathbf{0}$ is a minimizer iff $\lambda \geq \lambda_{\max} = \|\mathbf{X}^\top \mathbf{y}\|_\infty = \max_j |\mathbf{x}_j^\top \mathbf{y}|$.
- (e) Every minimizer $\hat{\mathbf{b}}$ also minimizes $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ subject to $\|\mathbf{b}\|_1 \leq \|\hat{\mathbf{b}}\|_1$.

Proof.

- (a) L_λ is continuous and $L_\lambda(\mathbf{b}) \geq \lambda \|\mathbf{b}\|_1$, so the set $\{\mathbf{b} : L_\lambda(\mathbf{b}) \leq L_\lambda(\mathbf{0})\}$ is closed and bounded, and L_λ attains its minimum there. Both terms of L_λ are convex, so if $\mathbf{b}, \mathbf{b}'$ are minimizers, every point between them has value at most the minimum, and is a minimizer too.
- (b) *Sufficiency.* Let $\mathbf{b}$ satisfy [Eq. 27.4.2](#) with subgradient $\mathbf{s}$, and let $\mathbf{c}$ be arbitrary. Expanding the square,

$$\begin{aligned} \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{c}\|^2 &= \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 - (\mathbf{c} - \mathbf{b})^\top \mathbf{X}^\top (\mathbf{y} - \mathbf{X}\mathbf{b}) \\ &\quad + \frac{1}{2} \|\mathbf{X}(\mathbf{c} - \mathbf{b})\|^2 \\ &\geq \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 - \lambda \mathbf{s}^\top (\mathbf{c} - \mathbf{b}). \end{aligned}$$

Since $|s_j| \leq 1$ and $s_j b_j = |b_j|$, we have $\|\mathbf{c}\|_1 \geq \mathbf{s}^\top \mathbf{c} = \|\mathbf{b}\|_1 + \mathbf{s}^\top (\mathbf{c} - \mathbf{b})$. Adding λ times this to the previous inequality gives $L_\lambda(\mathbf{c}) \geq L_\lambda(\mathbf{b})$. *Necessity.* Let $\mathbf{b}$ be a minimizer, $\mathbf{r} = \mathbf{y} - \mathbf{X}\mathbf{b}$ and $g_j = \mathbf{x}_j^\top \mathbf{r}$. For fixed j consider $\phi(t) = L_\lambda(\mathbf{b} + t\mathbf{e}_j)$, which is minimized at $t = 0$. Its one-sided derivatives at zero are

$$\phi'(0^+) = -g_j + \lambda \sigma_+, \quad \phi'(0^-) = -g_j + \lambda \sigma_-,$$

with $\sigma_\pm = \text{sign}(b_j)$ if $b_j \neq 0$, and $\sigma_+ = 1, \sigma_- = -1$ if $b_j = 0$. A minimum at zero requires $\phi'(0^+) \geq 0 \geq \phi'(0^-)$. If $b_j \neq 0$ this gives $g_j = \lambda \text{sign}(b_j)$; if $b_j = 0$ it gives $-\lambda \leq g_j \leq \lambda$. These are the KKT conditions with $s_j = g_j/\lambda$.

- (c) Let $\mathbf{b}, \mathbf{b}'$ be minimizers with $\mathbf{X}\mathbf{b} \neq \mathbf{X}\mathbf{b}'$, and let $\mathbf{m} = (\mathbf{b} + \mathbf{b}')/2$. The function $\mathbf{u} \mapsto \|\mathbf{y} - \mathbf{u}\|^2$ is strictly convex, so $\|\mathbf{y} - \mathbf{X}\mathbf{m}\|^2 < \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}'\|^2$, while $\|\mathbf{m}\|_1 \leq \frac{1}{2} \|\mathbf{b}\|_1 + \frac{1}{2} \|\mathbf{b}'\|_1$. Then $L_\lambda(\mathbf{m}) < L_\lambda(\mathbf{b})$, a contradiction. Equal fitted vectors give equal residual sums of squares, and equal values of L_λ then force equal ℓ_1 norms. If $\mathbf{X}$ has full column rank, $\mathbf{X}\mathbf{b} = \mathbf{X}\mathbf{b}'$ implies $\mathbf{b} = \mathbf{b}'$.
- (d) At $\mathbf{b} = \mathbf{0}$ every s_j may be chosen in $[-1, 1]$, so [Eq. 27.4.2](#) holds iff $|\mathbf{x}_j^\top \mathbf{y}| \leq \lambda$ for all j . Apply (b).
- (e) This is the remark on penalized and constrained forms in [Section 27.2](#) with $P = \|\cdot\|_1$.

■

By (b) and (c), all solutions share the inner products $\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\mathbf{b})$ and vanish outside the set of j at which these equal $\pm\lambda$, a set determined by the data even when the solution is not.

The converse of (e) is Lagrangian duality for convex problems (Boyd and Vandenberghe 2004, chapter 5), which we shall not need.

The constrained forms show why the lasso produces exact zeros and ridge does not. The constrained estimate is where the smallest contour of $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$, an ellipsoid, touches the constraint region. The ridge ball has a single normal direction at each boundary point, so the contact lies on a coordinate subspace only by accident. The lasso's cross-polytope has vertices and edges in coordinate subspaces, each with a whole cone of normal directions, so for an open set of data the contact is at such a face and some coordinates are exactly zero. Algebraically, at $b_j = 0$ the subgradient may be anything in $[-1, 1]$.

27.4.2 The orthonormal case: soft thresholding

Under an orthonormal design the lasso, ridge regression and subset selection are all explicit. Define the **soft** and **hard thresholding** functions

$$S_\lambda(z) = \text{sign}(z) (|z| - \lambda)_+, \quad H_\lambda(z) = z \mathbf{1}\{|z| > \lambda\}.$$

Theorem 27.4.2 — Three kinds of shrinkage under an orthonormal design

Suppose $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, so that $\hat{\boldsymbol{\beta}} = \mathbf{X}^\top \mathbf{y}$, and let $\lambda > 0$.

- (a) (*Lasso.*) The unique minimizer of Eq. 27.4.1 is given by $\hat{\beta}_{\lambda,j}^L = S_\lambda(\hat{\beta}_j)$.
- (b) (*Ridge.*) The minimizer of Eq. 27.2.1 is $\hat{\boldsymbol{\beta}}/(1 + \lambda)$.
- (c) (*Subset selection.*) The minimizers of $\frac{1}{2}\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \frac{1}{2}\lambda^2 \#\{j : b_j \neq 0\}$ are given by $b_j = H_\lambda(\hat{\beta}_j)$ (with either choice when $|\hat{\beta}_j| = \lambda$), and for each k the best subset of size k consists of the k largest $|\hat{\beta}_j|$.

Proof. Since $\mathbf{X}^\top (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) = \mathbf{0}$, $\mathbf{y} - \mathbf{X}\mathbf{b} = (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) + \mathbf{X}(\hat{\boldsymbol{\beta}} - \mathbf{b})$ is an orthogonal sum, and $\|\mathbf{X}\mathbf{w}\| = \|\mathbf{w}\|$, so

$$\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 = \|\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\|^2 + \sum_j (\hat{\beta}_j - b_j)^2.$$

Each criterion therefore separates into one-dimensional problems. (a) Minimize $\frac{1}{2}(\hat{\beta}_j - b)^2 + \lambda|b|$ over b . For $b > 0$ the derivative is $b - \hat{\beta}_j + \lambda$, which vanishes at $b = \hat{\beta}_j - \lambda$, admissible iff $\hat{\beta}_j > \lambda$; symmetrically for $b < 0$; otherwise the convex function is minimized at $b = 0$. This is $S_\lambda(\hat{\beta}_j)$, and it is unique because the problem is strictly convex. (b) Minimize $(\hat{\beta}_j - b)^2 + \lambda b^2$, a quadratic with minimum at $\hat{\beta}_j/(1 + \lambda)$. (c) The j th problem costs $\frac{1}{2}\hat{\beta}_j^2$ with $b_j = 0$, and at best $\frac{1}{2}\lambda^2$, at $b_j = \hat{\beta}_j$, with $b_j \neq 0$. So $b_j = \hat{\beta}_j$ iff $\hat{\beta}_j^2 > \lambda^2$. For a fixed subset A of size k the residual sum of squares is $\|\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\|^2 + \sum_{j \notin A} \hat{\beta}_j^2$, smallest when A holds the k largest $|\hat{\beta}_j|$. ■

Figure 27.4.1(a) draws the three rules. Ridge shrinks every estimate by the same factor; hard thresholding keeps large estimates and kills small ones, with a jump at $\pm\lambda$; soft thresholding kills

small estimates and moves the others towards zero by λ , continuous like ridge and sparse like subset selection, at the price of a bias λ on large coefficients. Soft thresholding of independent normal estimates was analysed by Donoho and Johnstone (1994), whose threshold $\sigma\sqrt{2\log p}$ reappears in [Chapter 28](#). The lasso is also a posterior *mode* under independent Laplace priors (Tibshirani 1996; [Exercise \(B2\)](#)).

27.4.3 The lasso path

As λ decreases from $\lambda_{\max}$ the lasso moves from $\mathbf{0}$ towards a least squares fit, and the KKT conditions show that it does so along straight lines.

Proposition 27.4.3 — Piecewise linearity

Suppose that for all λ in an interval $[\lambda_1, \lambda_2]$ with $\lambda_1 > 0$ the lasso solution is unique, has the same active set $A = \{j : \hat{\beta}_{\lambda,j}^L \neq 0\}$ and the same signs $\mathbf{s}_A$, and that $\mathbf{X}_A$, the columns of $\mathbf{X}$ in A , has full column rank. Then on that interval

$$\hat{\beta}_{\lambda,A}^L = (\mathbf{X}_A^\top \mathbf{X}_A)^{-1}(\mathbf{X}_A^\top \mathbf{y} - \lambda \mathbf{s}_A),$$

an affine function of λ , and the other coordinates are zero.

Proof. The KKT equations for $j \in A$ read $\mathbf{X}_A^\top(\mathbf{y} - \mathbf{X}_A \hat{\beta}_{\lambda,A}^L) = \lambda \mathbf{s}_A$, and $\mathbf{X}_A^\top \mathbf{X}_A$ is invertible. ■

So the path is made of line segments joined where a variable enters or leaves the active set, and the whole path costs about as much as one least squares fit (Osborne, Presnell and Turlach 2000; Efron, Hastie, Johnstone and Tibshirani 2004; [Section 30.5](#) returns to this). A variable leaves when its affine path reaches zero, which happens with correlated regressors but never under an orthonormal design ([Exercise \(B3\)](#)).

27.4.4 Computing the lasso by coordinate descent

As a function of one coordinate b_j , with the others fixed, [Eq. 27.4.1](#) is a one-dimensional lasso, solved by soft thresholding. Cycling through the coordinates gives a simple, fast algorithm, the “shooting” method of Fu (1998), popularized by Friedman, Hastie, Höfling and Tibshirani (2007).

Lemma 27.4.4 — Coordinate updates

Fix $\mathbf{b}$ and j with $\mathbf{x}_j \neq \mathbf{0}$, and let $\mathbf{r}_{(j)} = \mathbf{y} - \sum_{k \neq j} \mathbf{x}_k b_k$ be the partial residual.

- (a) The minimizer of L_λ over b_j , with the other coordinates fixed, is $S_\lambda(\mathbf{x}_j^\top \mathbf{r}_{(j)})/\|\mathbf{x}_j\|^2$.
- (b) If $\mathbf{b}$ is unchanged by the update of every coordinate, then $\mathbf{b}$ satisfies the KKT conditions [Eq. 27.4.2](#), and is therefore a lasso solution.

Proof.

- (a) With $z = \mathbf{x}_j^\top \mathbf{r}_{(j)}$ and $q = \|\mathbf{x}_j\|^2$, $\frac{1}{2}\|\mathbf{r}_{(j)} - \mathbf{x}_j b_j\|^2 = \frac{1}{2}q(b_j - z/q)^2 + \text{const.}$ Dividing the one-dimensional criterion by q gives $\frac{1}{2}(b_j - z/q)^2 + (\lambda/q)|b_j|$, minimized by $S_{\lambda/q}(z/q) = S_\lambda(z)/q$ as in [Theorem 27.4.2\(a\)](#).
- (b) A fixed point has $b_j = S_\lambda(z_j)/q_j$ for every j , which by the one-dimensional case of [Theorem 27.4.1\(b\)](#) means $z_j - q_j b_j \in \lambda \partial|b_j|$. But $z_j - q_j b_j = \mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\mathbf{b})$. So [Eq. 27.4.2](#) holds, and [Theorem 27.4.1\(b\)](#) applies. ■

Cyclic coordinate descent for the lasso. Start from $\mathbf{b} = \mathbf{0}$ (or a warm start) and $\mathbf{r} = \mathbf{y} - \mathbf{X}\mathbf{b}$. Repeat until no coordinate changes by more than a tolerance: for $j = 1, \dots, p$, compute $z = \mathbf{x}_j^\top \mathbf{r} + \|\mathbf{x}_j\|^2 b_j$, set $b_j^{\text{new}} = S_\lambda(z)/\|\mathbf{x}_j\|^2$, update $\mathbf{r} \leftarrow \mathbf{r} - \mathbf{x}_j(b_j^{\text{new}} - b_j)$ and $b_j \leftarrow b_j^{\text{new}}$.

Each update lowers L_λ or leaves it unchanged. Tseng (2001) proved, for criteria that are smooth and convex plus a sum of convex functions of single coordinates, that every limit point of cyclic coordinate descent is a minimizer; we do not reproduce the proof. The lemma gives what a computation needs: at a fixed point the KKT conditions hold, and their violation can be measured. In practice the lasso is computed on a decreasing grid of λ from $\lambda_{\max}$, each solution the warm start for the next (Friedman, Hastie and Tibshirani 2010). Highly correlated regressors slow convergence, because single-coordinate moves zigzag along a narrow valley.

Example. (The lasso for Longley's data)

For the standardized Longley data, $\lambda_{\max} = 51813$, and the variables enter in the order GNP, UNEMP, ARMED, YEAR, POP; the GNP deflator has not entered by $\lambda_{\max}/1000$. [Figure 27.4.1\(b\)](#) shows the path against the ratio of $\|\hat{\boldsymbol{\beta}}_\lambda^L\|_1$ to the ℓ_1 norm of least squares. GNP, the regressor most correlated with employment, grows to over 3000; when YEAR enters, the two compete for the same direction, and GNP falls back to exactly zero and leaves the active set. Coordinate descent needs 42 sweeps at $\lambda_{\max}/2$, 157 at $\lambda_{\max}/50$ and 3479 at $\lambda_{\max}/1000$ for a tolerance of 10^{-10} : the zigzag effect of collinearity.

Leave-one-out cross-validation, refitting the path without each year in turn, chooses $\lambda = 130$, about $0.0025\lambda_{\max}$, with 3 nonzero coefficients: -1303 for unemployment, -484 for the armed forces and 4475 for the year. Its minimized root mean squared error is 373, but as with ridge the minimum is optimistic; nested leave-one-out gives 428, level with least squares (425). What the lasso offers here is a simpler fit of equal accuracy, not a better one, and its choice of YEAR over GNP is exactly the kind that collinearity makes fragile.

The script checks the solutions at five values of λ three ways: the KKT conditions hold to within $10^{-6}\lambda$; a brute-force search over all $3^6 = 729$ active sets and signs, solving the equations of [Proposition 27.4.3](#), finds the same solution; and a bound-constrained optimizer on the split $\mathbf{b} = \mathbf{u} - \mathbf{v}$, $\mathbf{u}, \mathbf{v} \geq \mathbf{0}$, finds no smaller criterion value.

```

27.4.5 Lasso, ridge and subset selection compared

[Theorem 27.4.2](#) suggests that hard thresholding suits a few large coefficients among zeros, proportional shrinkage many moderate ones, and soft thresholding lies between. A simulation with correlated regressors tests this.

Example. (Three coefficient patterns)

Fix a design with $n = 50$ and $p = 10$, its rows drawn once from a normal distribution with correlations $0.5^{|j-k|}$, and columns scaled to $\|\mathbf{x}_j\|^2 = n$; the errors are normal with $\sigma = 2$. The coefficients are *sparse*, $(3, -2, 1.5, 0, \dots, 0)$; *dense*, ten coefficients ± 0.5 with alternating signs; or *intermediate*, five coefficients ± 1 and five zeros. Each method's tuning constant (λ , or the subset size, with the best subsets found among all 1024) minimizes the error on an independent copy of the responses, an idealized validation set. The table gives the average of $\|\mathbf{X}\tilde{\boldsymbol{\beta}} - \mathbf{X}\boldsymbol{\beta}\|^2 / (p\sigma^2)$ over 300 data sets; least squares has expectation one ([Exercise \(B2\)](#)), and the Monte Carlo standard error of each entry is about 0.02.

Pattern	least squares	ridge	lasso	best subset
sparse	1.02	0.95	0.74	0.46
dense	0.99	0.73	0.83	1.03
intermediate	0.99	0.84	0.86	0.90

Best subset selection is far ahead in the sparse case and worst in the dense case, where it cannot shrink and finds no zeros; ridge is the reverse; the lasso is never best and never worst. In the intermediate case the paired difference between the lasso and ridge is 0.02 with a standard error of 0.01. Hastie, Tibshirani and Tibshirani (2020) reached similar conclusions in a much larger study, adding that the ranking depends strongly on the signal-to-noise ratio ([Figure 27.4.2](#) displays the table).

The cell below reruns the sparse scenario with 10 data sets; each one searches all 1024 subsets, so in the browser it may take half a minute. The script uses 300 per scenario.

```
import itertools
```

27.4.6 Exercises

27.4.6.1 A. Check your understanding

Exercise A1.

Suppose $\max_j |\mathbf{x}_j^\top \mathbf{y}|$ is attained at a single j^* . Show that for λ slightly below $\lambda_{\max}$ the lasso solution has one nonzero coordinate, j^* , with the sign of $\mathbf{x}_{j^*}^\top \mathbf{y}$ and absolute value $(|\mathbf{x}_{j^*}^\top \mathbf{y}| - \lambda) / \|\mathbf{x}_{j^*}\|^2$.

Solution. Try $\mathbf{b} = b\mathbf{e}_{j^*}$ with $b = \text{sign}(g)(|g| - \lambda)/q$, $g = \mathbf{x}_{j^*}^\top \mathbf{y}$, $q = \|\mathbf{x}_{j^*}\|^2$. Then $\mathbf{x}_{j^*}^\top (\mathbf{y} - \mathbf{X}\mathbf{b}) = g - qb = \lambda \text{sign}(g)$, as required. For $k \neq j^*$, $|\mathbf{x}_k^\top (\mathbf{y} - \mathbf{X}\mathbf{b})| \leq |\mathbf{x}_k^\top \mathbf{y}| + |b| |\mathbf{x}_k^\top \mathbf{x}_{j^*}|$. The first term is strictly less than $\lambda_{\max}$, and $b \rightarrow 0$ as $\lambda \rightarrow \lambda_{\max}$, so the bound is below λ for λ close enough to $\lambda_{\max}$. By Theorem 27.4.1(b) $\mathbf{b}$ is a solution; it is unique among

solutions supported on $\{j^*\}$, and every solution is supported on the set where the inner product with the residual equals $\pm\lambda$, which is $\{j^*\}$.

Exercise A2.

With an orthonormal design and $\hat{\boldsymbol{\beta}} = (3, -0.5, 1.2)^\top$, compute the lasso, ridge and hard-thresholding estimates of [Theorem 27.4.2](#) with $\lambda = 1$.

27.4.6.2 B. Practice

Exercise B1.

Suppose $\mathbf{x}_1 = \mathbf{x}_2$ and let $\hat{\mathbf{b}}$ be a lasso solution with $\hat{b}_1 + \hat{b}_2 = \gamma \neq 0$. Show that every $\mathbf{b}$ with $b_1 + b_2 = \gamma$, b_1, b_2 of the sign of γ , and the other coordinates as in $\hat{\mathbf{b}}$, is also a solution, whereas ridge regression gives $b_1 = b_2$.

Solution. Such a $\mathbf{b}$ has $\mathbf{X}\mathbf{b} = \mathbf{X}\hat{\mathbf{b}}$ and $|b_1| + |b_2| = |\gamma| \leq |\hat{b}_1| + |\hat{b}_2|$, so $L_\lambda(\mathbf{b}) \leq L_\lambda(\hat{\mathbf{b}})$, with equality by optimality. For ridge, replacing (b_1, b_2) by their average leaves $\mathbf{X}\mathbf{b}$ unchanged and does not increase $b_1^2 + b_2^2$, strictly decreasing it unless $b_1 = b_2$; since the ridge solution is unique, it has $b_1 = b_2$. The elastic net of [Chapter 30](#) combines the two penalties to get the ridge behaviour with lasso sparsity.

Exercise B2.

Let $\mathbf{Y} \mid \boldsymbol{\beta} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2 \mathbf{I})$ with σ^2 known, and let the β_j be independent with density $(\lambda/2\sigma^2) \exp(-\lambda|\beta_j|/\sigma^2)$. Show that the posterior mode is the lasso estimate. Is the posterior mean sparse?

Solution. The log posterior is $-\{\frac{1}{2}\|\mathbf{y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda\|\boldsymbol{\beta}\|_1\}/\sigma^2 + \text{const}$, maximized at the minimizer of [Eq. 27.4.1](#). The posterior mean is an average over a continuous distribution with positive density everywhere, so every coordinate is nonzero with probability one: the sparsity of the lasso is a property of the mode, not of the Bayesian model.

Exercise B3.

Under an orthonormal design, describe the lasso path: show that it is piecewise linear with kinks at $\lambda = |\hat{\beta}_j|$, that variables enter in decreasing order of $|\hat{\beta}_j|$, and that none ever leaves.

27.4.6.3 C. Going deeper

Exercise C1.

In the orthonormal case with normal errors, show that $\sigma^{-2} \sum_j \text{Cov}(S_\lambda(\hat{\beta}_j), \hat{\beta}_j) = \mathbb{E} \#\{j : |\hat{\beta}_j| > \lambda\}$: the expected number of nonzero coefficients plays the role of degrees of freedom (compare [Exercise \(C1\)](#)). Hint: integrate by parts, one coordinate at a time.

Exercise C2.

Show that for every $\lambda > 0$ there is a lasso solution with at most $\min(n, p)$ nonzero coordinates. Hint: if the active columns of a solution are linearly dependent, move along a direction in their null space that keeps the signs and the fitted vector until a coordinate hits zero.

27.5 Stein's paradox and James–Stein estimation

The shrinkage estimators so far beat least squares only for *some* parameter values, which is unavoidable for linear estimators ([Exercise \(B1\)](#)). Stein (1956) discovered that a *nonlinear* shrinkage can do better everywhere: when three or more means are estimated together under total squared error, the estimator that is at once least squares, maximum likelihood and best unbiased is inadmissible. James and Stein (1961) gave an explicit estimator that dominates it. This section proves their theorem and explains it as an empirical Bayes phenomenon.

27.5.1 The normal means problem

Let $\mathbf{Z} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ with σ^2 known, and measure an estimator $\hat{\boldsymbol{\theta}}(\mathbf{Z})$ by its **risk** $R(\boldsymbol{\theta}, \hat{\boldsymbol{\theta}}) = E\|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2$, its total mean squared error. The estimator $\mathbf{Z}$ has risk $p\sigma^2$ for every $\boldsymbol{\theta}$. An estimator **dominates** another if its risk is never larger and is smaller for some $\boldsymbol{\theta}$; an estimator dominated by none is **admissible**.

This is regression in canonical form. If $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, then $\hat{\boldsymbol{\beta}} \sim N_p(\boldsymbol{\beta}, \sigma^2 \mathbf{I})$ ([Theorem 7.5.1\(a\)](#)). For a general full-rank design, $\mathbf{Z} = (\mathbf{X}^\top \mathbf{X})^{1/2} \hat{\boldsymbol{\beta}}$ is $N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ with $\boldsymbol{\theta} = (\mathbf{X}^\top \mathbf{X})^{1/2} \boldsymbol{\beta}$, and for any estimator $\tilde{\boldsymbol{\beta}}$ with $\hat{\boldsymbol{\theta}} = (\mathbf{X}^\top \mathbf{X})^{1/2} \tilde{\boldsymbol{\beta}}$,

$$\|\hat{\boldsymbol{\theta}} - \boldsymbol{\theta}\|^2 = (\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta})^\top \mathbf{X}^\top \mathbf{X} (\tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}) = \|\mathbf{X}\tilde{\boldsymbol{\beta}} - \mathbf{X}\boldsymbol{\beta}\|^2,$$

the prediction loss at the design points, with the square root of [Theorem 1.7.6](#) as the change of coordinates.

27.5.2 Stein's lemma

The proof rests on an integration-by-parts identity for the normal distribution.

Lemma 27.5.1 — Stein's lemma

- (a) Let $Z \sim N(\mu, \sigma^2)$, and let $g : \mathbb{R} \rightarrow \mathbb{R}$ be absolutely continuous with $E|g'(Z)| < \infty$. Then $E[(Z - \mu)g(Z)] < \infty$ and

$$E[(Z - \mu)g(Z)] = \sigma^2 E g'(Z).$$

- (b) Let $\mathbf{Z} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$, and let $\mathbf{g} = (g_1, \dots, g_p) : \mathbb{R}^p \rightarrow \mathbb{R}^p$ be such that, for each i and almost every value of the other coordinates, g_i is absolutely continuous in z_i , with $E|\partial g_i(\mathbf{Z})/\partial z_i| < \infty$ and $E|(Z_i - \theta_i)g_i(\mathbf{Z})| < \infty$. Then

$$E[(\mathbf{Z} - \boldsymbol{\theta})^\top \mathbf{g}(\mathbf{Z})] = \sigma^2 E \sum_{i=1}^p \frac{\partial g_i}{\partial z_i}(\mathbf{Z}). \quad (27.5.1)$$

Proof.

- (a) Write $Z = \mu + \sigma W$ with $W \sim N(0, 1)$ and $h(w) = g(\mu + \sigma w)$, so that $h'(w) = \sigma g'(\mu + \sigma w)$. The claim becomes $E[Wh(W)] = E h'(W)$, so we may take $\mu = 0$, $\sigma = 1$, $g = h$. Let φ be the standard normal density. Since $\varphi'(t) = -t\varphi(t)$,

$$\begin{aligned} \varphi(w) &= \int_w^\infty t\varphi(t) dt \quad (w \geq 0), \\ \varphi(w) &= -\int_{-\infty}^w t\varphi(t) dt \quad (w \leq 0). \end{aligned}$$

Hence

$$\begin{aligned} E h'(W) &= \int_0^\infty h'(w) \int_w^\infty t\varphi(t) dt dw \\ &\quad - \int_{-\infty}^0 h'(w) \int_{-\infty}^w t\varphi(t) dt dw. \end{aligned}$$

The double integrals converge absolutely: replacing h' by $|h'|$ and t by $|t|$ gives $\int |h'(w)|\varphi(w) dw = E|h'(W)| < \infty$. By Fubini's theorem we may reverse the order of integration. The first term becomes $\int_0^\infty t\varphi(t) \int_0^t h'(w) dw dt = \int_0^\infty t\varphi(t)\{h(t) - h(0)\} dt$, and the second $-\int_{-\infty}^0 t\varphi(t) \int_t^0 h'(w) dw dt = \int_{-\infty}^0 t\varphi(t)\{h(t) - h(0)\} dt$, using absolute continuity of h . Their sum is $E[W\{h(W) - h(0)\}] = E[Wh(W)]$, since $EW = 0$. The same bound shows $E|W\{h(W) - h(0)\}| \leq E|h'(W)|$, so $E|Wh(W)| < \infty$.

- (b) The coordinates of $\mathbf{Z}$ are independent. Fix i and condition on the other coordinates $\mathbf{Z}_{-i}$. By Fubini, $E[|\partial g_i/\partial z_i| \mid \mathbf{Z}_{-i}] < \infty$ for almost every value of $\mathbf{Z}_{-i}$, and for those values part (a), applied to $z_i \mapsto g_i(\mathbf{Z})$ with $Z_i \sim N(\theta_i, \sigma^2)$, gives $E[(Z_i - \theta_i)g_i(\mathbf{Z}) \mid \mathbf{Z}_{-i}] = \sigma^2 E[\partial g_i(\mathbf{Z})/\partial z_i \mid \mathbf{Z}_{-i}]$. Take expectations and sum over i .

■

The lemma turns an expectation involving the unknown $\boldsymbol{\theta}$ into the expectation of a function of $\mathbf{Z}$ alone. Stein (1981) built a theory of risk estimation on it ([Exercise \(C2\)](#)), and it computes covariance degrees of freedom ([Exercise \(C1\)](#)) for nonlinear fits such as the lasso ([Exercise \(C1\)](#)).

27.5.3 The James–Stein theorem

Theorem 27.5.2 — James–Stein

Let $\mathbf{Z} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ with $p \geq 3$ and σ^2 known, and for a constant c let $\hat{\boldsymbol{\theta}}_c = (1 - c\sigma^2/\|\mathbf{Z}\|^2)\mathbf{Z}$. Then $E\|\mathbf{Z}\|^{-2} < \infty$ and:

- (a) $E\|\hat{\boldsymbol{\theta}}_c - \boldsymbol{\theta}\|^2 = p\sigma^2 - c\{2(p-2) - c\}\sigma^4 E\|\mathbf{Z}\|^{-2}$. This is below $p\sigma^2$ for every $\boldsymbol{\theta}$ iff $0 < c < 2(p-2)$, and smallest at $c = p-2$. The **James–Stein estimator** is

$$\hat{\boldsymbol{\theta}}^{\text{JS}} = \left(1 - \frac{(p-2)\sigma^2}{\|\mathbf{Z}\|^2}\right)\mathbf{Z},$$

with risk

$$E\|\hat{\boldsymbol{\theta}}^{\text{JS}} - \boldsymbol{\theta}\|^2 = p\sigma^2 - (p-2)^2\sigma^4 E\|\mathbf{Z}\|^{-2} < p\sigma^2. \quad (27.5.2)$$

- (b) With $\gamma = \|\boldsymbol{\theta}\|^2/\sigma^2$ and $K \sim \text{Poisson}(\gamma/2)$, $\sigma^2 E\|\mathbf{Z}\|^{-2} = E\{1/(p-2+2K)\}$. The risk of $\hat{\boldsymbol{\theta}}^{\text{JS}}$ depends on $\boldsymbol{\theta}$ only through γ , equals $2\sigma^2$ at $\boldsymbol{\theta} = \mathbf{0}$, increases strictly in γ , and tends to $p\sigma^2$ as $\gamma \rightarrow \infty$.

Proof. Finiteness. The density of $\mathbf{Z}$ is at most $(2\pi\sigma^2)^{-p/2}$, so

$$\begin{aligned} E\|\mathbf{Z}\|^{-2} &\leq (2\pi\sigma^2)^{-p/2} \int_{\|\mathbf{z}\| \leq 1} \|\mathbf{z}\|^{-2} d\mathbf{z} + 1 \\ &= (2\pi\sigma^2)^{-p/2} A_p \int_0^1 r^{p-3} dr + 1 < \infty, \end{aligned}$$

where A_p is the surface area of the unit sphere in $\mathbb{R}^p$ and the integral is finite because $p \geq 3$. (a) Apply Eq. 27.5.1 to $\mathbf{g}(\mathbf{z}) = \mathbf{z}/\|\mathbf{z}\|^2$. For $p \geq 3$ the other coordinates $\mathbf{Z}_{-i}$ are nonzero with probability one, and then g_i is a smooth function of z_i with

$$\frac{\partial g_i}{\partial z_i} = \frac{1}{\|\mathbf{z}\|^2} - \frac{2z_i^2}{\|\mathbf{z}\|^4}, \quad \left| \frac{\partial g_i}{\partial z_i} \right| \leq \frac{3}{\|\mathbf{z}\|^2}, \quad \sum_i \frac{\partial g_i}{\partial z_i} = \frac{p-2}{\|\mathbf{z}\|^2}.$$

The bound makes $E|\partial g_i/\partial z_i|$ finite, and $|(Z_i - \theta_i)g_i(\mathbf{Z})| \leq |Z_i - \theta_i|/\|\mathbf{Z}\|$ has finite expectation by the Cauchy–Schwarz inequality. So $E[(\mathbf{Z} - \boldsymbol{\theta})^\top \mathbf{Z}/\|\mathbf{Z}\|^2] = (p-2)\sigma^2 E\|\mathbf{Z}\|^{-2}$. Now expand

$$\|\hat{\boldsymbol{\theta}}_c - \boldsymbol{\theta}\|^2 = \|\mathbf{Z} - \boldsymbol{\theta}\|^2 - 2c\sigma^2 \frac{(\mathbf{Z} - \boldsymbol{\theta})^\top \mathbf{Z}}{\|\mathbf{Z}\|^2} + \frac{c^2\sigma^4}{\|\mathbf{Z}\|^2}$$

and take expectations: $p\sigma^2 - 2c(p-2)\sigma^4 E\|\mathbf{Z}\|^{-2} + c^2\sigma^4 E\|\mathbf{Z}\|^{-2}$. The factor $c\{2(p-2) - c\}$ is positive iff $0 < c < 2(p-2)$ and largest at $c = p-2$, where it equals $(p-2)^2$. (b) $\mathbf{Z}/\sigma \sim N_p(\boldsymbol{\theta}/\sigma, \mathbf{I})$, so $U = \|\mathbf{Z}\|^2/\sigma^2 \sim \chi^2(p, \gamma)$ (Definition 4.1.1), and by Theorem 4.1.2(d), given $K = k$, $U \sim \chi^2(p+2k)$. For $m \geq 3$, $E\{1/\chi^2(m)\} = 1/(m-2)$ (Exercise (A1)), which gives the formula. At $\gamma = 0$, $K = 0$ and the risk is $p\sigma^2 - (p-2)\sigma^2 = 2\sigma^2$. Since $E(1/U) = \int_0^\infty \Pr(U < 1/s) ds$ and each $\Pr(U < 1/s)$ decreases strictly in γ (Proposition 4.1.3), $E(1/U)$ decreases strictly and the risk increases. As $\gamma \rightarrow \infty$, $K \rightarrow \infty$ in probability and $1/(p-2+2K) \leq 1/(p-2)$, so $E\{1/(p-2+2K)\} \rightarrow 0$ by dominated convergence. ■

The shrinkage factor is close to one when $\|\mathbf{Z}\|^2$ is large compared with its null expectation $p\sigma^2$, and small when the data are consistent with $\boldsymbol{\theta} \approx \mathbf{0}$. Nothing is special about the origin: shrinking towards any point fixed in advance also dominates $\mathbf{Z}$, with the largest gains near that point (Exercise (B1)).

The paradox is that the coordinates need not be related. If θ_1 is a physical constant, θ_2 a crop yield and θ_3 a batting average, the James–Stein estimate of the crop yield depends on the

Figure 27.5.1: Risk of estimators of ten normal means with $\sigma = 1$, against $\|\theta\|^2$: the unbiased estimator $\mathbf{Z}$, James–Stein (exact, from the Poisson mixture), its positive part (simulated, 4000 draws per point), a fixed proportional shrinkage, and the best linear shrinkage for each θ .

other two measurements. The resolution is that the theorem concerns the *total* risk; a single coordinate's risk can exceed σ^2 (Exercise (B2)).

Example. (The risk function for ten means)

For $p = 10$ and $\sigma = 1$, the exact risk from Theorem 27.5.2(b) is 2 at $\theta = \mathbf{0}$, 4.784 at $\|\theta\|^2 = 5$, 7.587 at 20 and 9.257 at 80, always below the constant risk 10 of $\mathbf{Z}$ (Figure 27.5.1). The fixed shrinkage $\mathbf{Z}/(1 + 0.5)$, which is ridge regression with $\lambda = 0.5$ in an orthonormal design, has risk $(p + 0.25\|\theta\|^2)/2.25$ (Exercise (A2)). It beats James–Stein only on a middle range, $5.9 < \|\theta\|^2 < 36.6$. At the origin it is worse ($10/2.25 = 4.44$ against 2), it exceeds p once $\|\theta\|^2 > 5p = 50$, and it grows without bound. The dotted curve is the risk $p\|\theta\|^2/(p + \|\theta\|^2)$ of the best linear shrinkage $f\mathbf{Z}$ for each θ , the oracle of Proposition 27.1.2(c) with a common factor; James–Stein stays within 2 of it without knowing θ .

```
import numpy as np
from scipy import stats
p = 10

def js_risk(gamma, p=p):
    """Exact risk of  $(1 - (p-2)/\|Z\|^2) Z$  when  $Z \sim N_p(\theta, I)$  and  $\gamma = \|\theta\|^2$ ."""
    k = np.arange(0, 400)
    w = stats.poisson.pmf(k, gamma / 2)          #  $\|Z\|^2 \sim \chi^2(p, \gamma)$ :
    Poisson(gamma/2) mixture
    return p - (p - 2) * 2 * np.sum(w / (p - 2 + 2 * k))

def js(z, positive=False):
    factor = 1 - (len(z) - 2) / np.sum(z ** 2)
    return (max(factor, 0.0) if positive else factor) * z

rng = np.random.default_rng(27)
for gamma in [0.0, 5.0, 20.0, 80.0]:
    theta = np.sqrt(gamma / p) * np.ones(p)
```

```

Zs = theta + rng.normal(size=(2_000, p))
loss_js = np.mean([np.sum((js(z) - theta) ** 2) for z in Zs])
loss_pp = np.mean([np.sum((js(z, True) - theta) ** 2) for z in Zs])
print(f"||theta||^2 = {gamma:5.1f}: exact JS risk {js_risk(gamma):.3f}, "
      f"simulated {loss_js:.3f}, positive part {loss_pp:.3f} (MLE: {p})")

```

27.5.4 The positive part

When $\|\mathbf{Z}\|^2 < (p-2)\sigma^2$ the James–Stein factor is negative, and the estimator reverses the sign of every coordinate, which is absurd. Truncating the factor at zero helps.

Proposition 27.5.3 — Positive-part James–Stein

In the setting of [Theorem 27.5.2](#), the estimator

$$\hat{\boldsymbol{\theta}}^{\text{JS}+} = \left(1 - \frac{(p-2)\sigma^2}{\|\mathbf{Z}\|^2}\right)_+ \mathbf{Z}$$

has strictly smaller risk than $\hat{\boldsymbol{\theta}}^{\text{JS}}$ for every $\boldsymbol{\theta}$.

Proof. Write $\hat{\boldsymbol{\theta}}^{\text{JS}} = h\mathbf{Z}$ with $h = 1 - (p-2)\sigma^2/\|\mathbf{Z}\|^2$, and let $\psi = \max(-h, 0) \geq 0$, a function of $\|\mathbf{Z}\|$. Where $h \geq 0$ the estimators agree. Where $h < 0$, the positive part is $\mathbf{0}$, and

$$\|h\mathbf{Z} - \boldsymbol{\theta}\|^2 - \|\boldsymbol{\theta}\|^2 = h^2\|\mathbf{Z}\|^2 - 2h\boldsymbol{\theta}^\top\mathbf{Z} = \psi^2\|\mathbf{Z}\|^2 + 2\psi\boldsymbol{\theta}^\top\mathbf{Z}.$$

So the difference of risks is $\mathbb{E}[\psi^2\|\mathbf{Z}\|^2] + 2\mathbb{E}[\psi\boldsymbol{\theta}^\top\mathbf{Z}]$. The first term is positive, because $\Pr(h < 0) = \Pr\{\|\mathbf{Z}\|^2 < (p-2)\sigma^2\} > 0$. For the second, choose an orthogonal $\mathbf{Q}$ with $\mathbf{Q}\boldsymbol{\theta} = m\mathbf{e}_1$, $m = \|\boldsymbol{\theta}\|$. Then $\mathbf{w} = \mathbf{Q}\mathbf{Z} \sim N_p(m\mathbf{e}_1, \sigma^2\mathbf{I})$, $\|\mathbf{w}\| = \|\mathbf{Z}\|$ and $\boldsymbol{\theta}^\top\mathbf{Z} = mw_1$. Given $R = \sum_{i \geq 2} w_i^2$, which is independent of $w_1 \sim N(m, \sigma^2)$,

$$\begin{aligned} \mathbb{E}[\psi w_1 \mid R] &= \int_0^\infty \psi(\sqrt{t^2 + R}) t \{\varphi_\sigma(t - m) - \varphi_\sigma(t + m)\} dt \\ &\geq 0, \end{aligned}$$

where φ_σ is the $N(0, \sigma^2)$ density: the integrand pairs t with $-t$, and $(t-m)^2 \leq (t+m)^2$ for $t, m \geq 0$. (The expectations are finite since $\psi \leq (p-2)\sigma^2/\|\mathbf{Z}\|^2$.) Hence $\mathbb{E}[\psi\boldsymbol{\theta}^\top\mathbf{Z}] \geq 0$ and the risk difference is positive. ■

The positive-part estimator is itself inadmissible, but improvements on it are tiny (Lehmann and Casella 1998, chapter 5). For $p = 10$ its risk at the origin is $\mathbb{E}[\{1 - (p-2)/U\}_+^2 U] = 1.258$ with $U \sim \chi^2(10)$, against 2 for James–Stein, and the two curves in [Figure 27.5.1](#) merge as negative factors become rare.

27.5.5 The empirical Bayes explanation

Efron and Morris (1973) explained the paradox by drawing the means themselves from a normal distribution.

Proposition 27.5.4 — James–Stein as empirical Bayes

Let $\boldsymbol{\theta} \sim N_p(\mathbf{0}, \omega^2 \mathbf{I})$ and $\mathbf{Z} \mid \boldsymbol{\theta} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$, $p \geq 3$, and put $B = \sigma^2 / (\sigma^2 + \omega^2)$.

- (a) The posterior mean is $E(\boldsymbol{\theta} \mid \mathbf{Z}) = (1-B)\mathbf{Z}$, and its Bayes risk is $E\|(1-B)\mathbf{Z} - \boldsymbol{\theta}\|^2 = p\sigma^2(1-B)$.
- (b) Marginally $\mathbf{Z} \sim N_p(\mathbf{0}, (\sigma^2 + \omega^2)\mathbf{I})$, and $(p-2)\sigma^2/\|\mathbf{Z}\|^2$ is an unbiased estimator of B .
- (c) The Bayes risk of $\hat{\boldsymbol{\theta}}^{\text{JS}}$ is $p\sigma^2(1-B) + 2\sigma^2 B$.

Proof.

- (a) $(\boldsymbol{\theta}, \mathbf{Z})$ is jointly normal with $\text{Cov}(\boldsymbol{\theta}, \mathbf{Z}) = \omega^2 \mathbf{I}$ and $\text{Cov}(\mathbf{Z}) = (\sigma^2 + \omega^2)\mathbf{I}$. By [Theorem 3.5.2](#), $\boldsymbol{\theta} \mid \mathbf{Z} \sim N_p(\omega^2(\sigma^2 + \omega^2)^{-1}\mathbf{Z}, \sigma^2\omega^2(\sigma^2 + \omega^2)^{-1}\mathbf{I})$; the mean is $(1-B)\mathbf{Z}$, and the Bayes risk is the expected trace of the posterior covariance, $p\sigma^2\omega^2/(\sigma^2 + \omega^2) = p\sigma^2(1-B)$.
- (b) $\mathbf{Z} = \boldsymbol{\theta} + (\mathbf{Z} - \boldsymbol{\theta})$ is a sum of independent normal vectors. So $\|\mathbf{Z}\|^2/(\sigma^2 + \omega^2) \sim \chi^2(p)$, and $E\{(p-2)\sigma^2/\|\mathbf{Z}\|^2\} = (p-2)\sigma^2/\{(\sigma^2 + \omega^2)(p-2)\} = B$ by [Exercise \(A1\)](#).
- (c) Average [Eq. 27.5.2](#) over the prior: the Bayes risk is $p\sigma^2 - (p-2)^2\sigma^4 E\|\mathbf{Z}\|^{-2}$ with the marginal expectation $E\|\mathbf{Z}\|^{-2} = 1/\{(\sigma^2 + \omega^2)(p-2)\}$, which gives $p\sigma^2 - (p-2)\sigma^2 B = p\sigma^2(1-B) + 2\sigma^2 B$.

■

James–Stein plugs an unbiased estimate of B , based on the spread of the p observations, into the Bayes rule, and part (c) shows that not knowing ω^2 costs at most $2\sigma^2$ in total. This is the **empirical Bayes** idea: the ensemble of parameters supplies its own prior. [Theorem 27.5.2](#) says more, that the gain is guaranteed even if no such prior exists.

In an orthonormal design ridge regression is the Bayes rule $\mathbf{Z}/(1+\lambda)$ with $\omega^2 = \sigma^2/\lambda$ ([Theorem 27.2.2\(e\)](#)). A fixed λ is a guess at the prior variance, and a bad guess is punished without limit, as the fixed-shrinkage curve in [Figure 27.5.1](#) shows; choosing λ from the data is the regression version of James–Stein. With a general design the g -prior of [Proposition 7.6.3\(c\)](#) shrinks $\hat{\boldsymbol{\beta}}$ by the common factor $g/(1+g)$, and estimating that factor gives the next corollary.

27.5.6 Shrinking a regression with unknown variance

In regression σ^2 is unknown but estimated independently of $\hat{\boldsymbol{\beta}}$, which is enough.

Corollary 27.5.5 — James–Stein for regression

Assume the normal linear model with $\mathbf{X}$ of full column rank $p \geq 3$, let SSE have m degrees of freedom (so $\text{SSE}/\sigma^2 \sim \chi^2(m)$, independent of $\hat{\boldsymbol{\beta}}$), and for $c > 0$ let

$$\tilde{\boldsymbol{\beta}}_c = \left(1 - \frac{c \text{SSE}}{\hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top \mathbf{X} \hat{\boldsymbol{\beta}}}\right) \hat{\boldsymbol{\beta}}.$$

Then, with $\mathbf{Z} = (\mathbf{X}^\top \mathbf{X})^{1/2} \hat{\boldsymbol{\beta}}$,

$$\mathbb{E}[(\tilde{\boldsymbol{\beta}}_c - \boldsymbol{\beta})^\top \mathbf{X}^\top \mathbf{X} (\tilde{\boldsymbol{\beta}}_c - \boldsymbol{\beta})] = p\sigma^2 - cm \{2(p-2) - c(m+2)\} \sigma^4 \mathbb{E}\|\mathbf{Z}\|^{-2}.$$

So $\tilde{\boldsymbol{\beta}}_c$ dominates least squares in this loss iff $0 < c < 2(p-2)/(m+2)$, and the best constant is $c = (p-2)/(m+2)$. In terms of the F statistic $F = (\hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top \mathbf{X} \hat{\boldsymbol{\beta}}/p)/(\text{SSE}/m)$ for the hypothesis $\boldsymbol{\beta} = \mathbf{0}$, the shrinkage factor is $1 - cm/(pF)$.

Proof. By Theorem 7.5.1, $\hat{\boldsymbol{\beta}} \sim N_p(\boldsymbol{\beta}, \sigma^2(\mathbf{X}^\top \mathbf{X})^{-1})$ and SSE is independent of it. So $\mathbf{Z} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ with $\boldsymbol{\theta} = (\mathbf{X}^\top \mathbf{X})^{1/2} \boldsymbol{\beta}$, and the loss is $\|(1 - a/\|\mathbf{Z}\|^2)\mathbf{Z} - \boldsymbol{\theta}\|^2$ with $a = c \text{SSE}$. Conditionally on SSE, a is a constant and the computation in the proof of Theorem 27.5.2(a), with $c\sigma^2$ replaced by a , gives the conditional risk $p\sigma^2 - \{2a(p-2)\sigma^2 - a^2\} \mathbb{E}\|\mathbf{Z}\|^{-2}$. Now $\mathbb{E}(a) = cm\sigma^2$ and $\mathbb{E}(a^2) = c^2\sigma^4 \mathbb{E}\{\chi^2(m)^2\} = c^2m(m+2)\sigma^4$ (Theorem 4.1.2(b)). Taking expectations gives the formula, and $c\{2(p-2) - c(m+2)\}$ is positive iff $0 < c < 2(p-2)/(m+2)$ and largest at the midpoint. The last statement is $\text{SSE}/(\hat{\boldsymbol{\beta}}^\top \mathbf{X}^\top \mathbf{X} \hat{\boldsymbol{\beta}}) = m/(pF)$. ■

The factor $1 - (p-2)m/\{(m+2)pF\}$ is close to $1 - 1/F$ when p and m are large: a regression that clearly fits is barely shrunk, and one indistinguishable from noise is shrunk hard. The loss concerns fitted values, not individual coefficients. Shrinking towards the fit of a reduced model, using its F statistic, works in the same way when the full model has at least three more parameters (Exercise (C1)).

Example. (James–Stein for Longley's regression)

For Longley's six slopes there are $m = 9$ residual degrees of freedom and the overall F statistic is 330.3. The James–Stein factor with $c = (p-2)/(m+2)$ is 0.99835: the regression fits far too well for shrinkage towards zero to help. The script therefore also simulates responses at Longley's design with the least squares estimates divided by 60 as the truth, a weak signal whose noncentrality $\boldsymbol{\beta}^\top \mathbf{X}^\top \mathbf{X} \boldsymbol{\beta}/\sigma^2$ is about 0.6, with σ equal to Longley's s . Over 20000 simulated data sets the ratio of the James–Stein prediction risk to that of least squares is 0.501.

```
import statsmodels.api as sm
data = sm.datasets.longley.load_pandas().data
Zr = data.drop(columns="TOTEMP").to_numpy()
y = data["TOTEMP"].to_numpy()
n, k = Zr.shape
Xc = Zr - Zr.mean(axis=0)                                # centred slopes; the
intercept is ybar
```

```

yc = y - y.mean()
b = np.linalg.lstsq(Xc, yc, rcond=None)[0]
m = n - k - 1 # residual degrees of freedom
sse = np.sum((yc - Xc @ b) ** 2)
fit_ss = b @ Xc.T @ Xc @ b # b^T X^T X b, the regression
    sum of squares
F = (fit_ss / k) / (sse / m)
factor = 1 - (k - 2) / (m + 2) * sse / fit_ss
print(f"F = {F:.1f}; James-Stein factor {factor:.5f} = 1 - (k-2) m / ((m+2) k F)")

```

27.5.7 Exercises

27.5.7.1 A. Check your understanding

Exercise A1.

Show that $E\{1/\chi^2(m)\} = 1/(m-2)$ for $m \geq 3$ and that the expectation is infinite for $m \leq 2$. Deduce that the risk of the James–Stein estimator at $\boldsymbol{\theta} = \mathbf{0}$ is $2\sigma^2$ for every $p \geq 3$, however large p is.

Solution. With the $\chi^2(m)$ density $x^{m/2-1}e^{-x/2}/\{2^{m/2}\Gamma(m/2)\}$,

$$E \frac{1}{\chi^2(m)} = \frac{\int_0^\infty x^{m/2-2} e^{-x/2} dx}{2^{m/2}\Gamma(m/2)} = \frac{2^{m/2-1}\Gamma(m/2-1)}{2^{m/2}\Gamma(m/2)} = \frac{1}{2(m/2-1)} = \frac{1}{m-2},$$

where the integral converges at zero iff $m/2 - 2 > -1$, that is, $m > 2$. At $\boldsymbol{\theta} = \mathbf{0}$, $\|\mathbf{Z}\|^2/\sigma^2 \sim \chi^2(p)$, so Eq. 27.5.2 gives $p\sigma^2 - (p-2)^2\sigma^2/(p-2) = 2\sigma^2$.

27.5.7.2 B. Practice

Exercise B1.

- (a) Show that for a fixed $\boldsymbol{\theta}_0$, the estimator $\boldsymbol{\theta}_0 + (1 - (p-2)\sigma^2/\|\mathbf{Z} - \boldsymbol{\theta}_0\|^2)(\mathbf{Z} - \boldsymbol{\theta}_0)$ has risk $p\sigma^2 - (p-2)^2\sigma^4 E\|\mathbf{Z} - \boldsymbol{\theta}_0\|^{-2}$. (b) Lindley's estimator shrinks towards the grand mean: $\hat{\theta}_i = \bar{Z} + (1 - (p-3)\sigma^2/S)(Z_i - \bar{Z})$ with $S = \sum_i (Z_i - \bar{Z})^2$. Show that it dominates $\mathbf{Z}$ when $p \geq 4$.

Solution.

- (a) $\mathbf{Z} - \boldsymbol{\theta}_0 \sim N_p(\boldsymbol{\theta} - \boldsymbol{\theta}_0, \sigma^2 \mathbf{I})$, and the estimation error is that of the James–Stein estimator of $\boldsymbol{\theta} - \boldsymbol{\theta}_0$ from $\mathbf{Z} - \boldsymbol{\theta}_0$; apply Eq. 27.5.2.
- (b) Choose an orthogonal $\mathbf{Q}$ whose first row is $\mathbf{1}^\top/\sqrt{p}$. In the coordinates $\mathbf{w} = \mathbf{QZ}$, the first coordinate is $\sqrt{p}\bar{Z}$ and the remaining $p-1$ are a N_{p-1} vector with squared length S . The estimator leaves the first coordinate alone and applies James–Stein in dimension $p-1 \geq 3$ to the others, so its risk is σ^2 plus less than $(p-1)\sigma^2$ (Theorem 27.5.2).

Exercise B2.

Let p be large and $\boldsymbol{\theta} = (\sqrt{p}\sigma, 0, \dots, 0)^\top$. Using the approximation $\|\mathbf{Z}\|^2 \approx \|\boldsymbol{\theta}\|^2 + p\sigma^2$, show that the James–Stein estimate of θ_1 has mean squared error of roughly $p\sigma^2/4$, far above the σ^2 of Z_1 . Why does this not contradict [Theorem 27.5.2](#)?

Solution. With $\|\mathbf{Z}\|^2 \approx 2p\sigma^2$, the factor is about $1 - (p-2)/(2p) \approx \frac{1}{2}$, so $\hat{\theta}_1 \approx Z_1/2$, with bias $-\theta_1/2$ and squared bias $p\sigma^2/4$. Halving the other $p-1$ coordinates, whose means are zero, cuts each of their risks from σ^2 to about $\sigma^2/4$. The total is roughly $p\sigma^2/4 + (p-1)\sigma^2/4 \approx p\sigma^2/2 < p\sigma^2$. One coordinate pays heavily for the others' gains; the theorem only controls the sum.

Exercise B3.

In [Proposition 27.5.4](#), show that the ratio of the Bayes risk of James–Stein to that of the Bayes rule is $1 + 2\sigma^2/(p\omega^2)$. When is the cost of estimating ω^2 negligible?

27.5.7.3 C. Going deeper**Exercise C1.**

Let $\mathbf{P}$ be the orthogonal projection onto a fixed q -dimensional subspace of $\mathbb{R}^p$, with $p-q \geq 3$. Show that $\mathbf{P}\mathbf{Z} + (1 - (p-q-2)\sigma^2/\|(\mathbf{I}-\mathbf{P})\mathbf{Z}\|^2)(\mathbf{I}-\mathbf{P})\mathbf{Z}$ dominates $\mathbf{Z}$, and translate this into shrinking a regression fit towards a nested reduced model using its F statistic.

Exercise C2.

Let $\hat{\boldsymbol{\theta}} = \mathbf{Z} + \mathbf{g}(\mathbf{Z})$ with $\mathbf{g}$ satisfying the conditions of [Lemma 27.5.1](#). Show that

$$\hat{R} = p\sigma^2 + \|\mathbf{g}(\mathbf{Z})\|^2 + 2\sigma^2 \sum_i \frac{\partial g_i}{\partial z_i}(\mathbf{Z})$$

is unbiased for the risk of $\hat{\boldsymbol{\theta}}$ (Stein's unbiased risk estimate). Compute it for James–Stein and for soft thresholding $\hat{\theta}_i = S_\lambda(Z_i)$; how could it choose λ ?

27.6 Summary and Notes

27.6.1 Summary

Idea.

1. Mean squared error is variance plus squared bias. A linear estimator beats least squares in the matrix sense iff its squared bias, measured in the metric of the covariance it saves, is at most one ([Theorem 27.1.1](#)); none wins for every $\boldsymbol{\beta}$ ([Exercise](#)

- (B1)).
2. Shrinking the j th canonical coordinate is governed by its signal-to-noise ratio $\tau_j^2 = d_j^2 \alpha_j^2 / \sigma^2$: the oracle factor is $\tau_j^2 / (1 + \tau_j^2)$, and dropping the direction helps iff $\tau_j^2 < 1$ ([Proposition 27.1.2](#)).
 3. Ridge regression shrinks the j th direction by $d_j^2 / (d_j^2 + \lambda)$, has effective degrees of freedom $\sum_j d_j^2 / (d_j^2 + \lambda)$, and is the posterior mean under an exchangeable normal prior ([Theorem 27.2.2](#)). Every $\lambda < 2\sigma^2 / \max_j \alpha_j^2$ beats least squares, and every $\lambda \leq 2\sigma^2 / \|\boldsymbol{\beta}\|^2$ does so in the matrix sense ([Theorem 27.2.3](#)).
 4. Principal component regression keeps the leading k directions, and beats least squares in the matrix sense iff the dropped directions carry total signal $\sum_{j>k} \tau_j^2 \leq 1$. The directions worth dropping are those with small τ_j^2 , not small d_j^2 ([Proposition 27.3.1](#), [Example \(Principal components of Longley's regressors\)](#)). Tuning or selecting from the data makes the minimized leave-one-out error optimistic; nested cross-validation is honest.
 5. The lasso minimizes $\frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda \|\mathbf{b}\|_1$. Its solutions are the solutions of the KKT conditions and share one fitted vector ([Definition 27.4.1](#), [Theorem 27.4.1](#)). Under an orthonormal design it is soft thresholding, against proportional shrinkage for ridge and hard thresholding for subset selection ([Theorem 27.4.2](#)). Coordinate descent computes it by repeated soft thresholding ([Lemma 27.4.4](#)).
 6. By simulation, best subset selection wins when a few coefficients are large, ridge wins when many are moderate, and the lasso sits between ([Example \(Three coefficient patterns\)](#)).
 7. With Stein's lemma ([Lemma 27.5.1](#)), the James–Stein estimator $(1 - (p-2)\sigma^2 / \|\mathbf{Z}\|^2)\mathbf{Z}$ has risk below $p\sigma^2$ for every $\boldsymbol{\theta}$ when $p \geq 3$ ([Theorem 27.5.2](#)), its positive part does better still ([Proposition 27.5.3](#)), and in regression, with an estimated variance, the factor is about $1 - 1/F$ ([Corollary 27.5.5](#)).
 8. James–Stein is an empirical Bayes rule: it estimates the shrinkage factor $\sigma^2 / (\sigma^2 + \omega^2)$ of a normal prior without bias, and pays at most $2\sigma^2$ for not knowing ω^2 ([Proposition 27.5.4](#)). Ridge with a fixed λ is the same rule with a guessed prior variance.

27.6.2 Notes and sources

Coverage. Christensen (2020, sections 13.3–13.5) treats canonical form, principal component and ridge regression; Sen and Srivastava (1990, chapter 12) add a Stein-type shrinkage of least squares; Fahrmeir, Kneib, Lang and Marx (2021, section 4.2) present ridge and the lasso as penalized least squares. This chapter organizes them around the shrinkage factors of [Proposition 27.1.2](#). Examples, simulations and exercises are the book's own.

Mean squared error. The matrix comparison of estimators and its equivalence with every quadratic loss are due to Theobald (1974), who used them for the matrix-sense part of [Theorem 27.2.3](#).

Ridge regression. Hoerl and Kennard (1970) named the method, introduced the ridge trace and proved the existence theorem. The same regularization of ill-posed problems is due to Tikhonov (Tikhonov and Arsenin 1977). Generalized cross-validation for ridge is due to Golub, Heath and Wahba (1979). Hoerl, Kennard and Baldwin (1975) proposed the plug-in choice of λ , and Draper and Van Nostrand (1979) review the debate over data-chosen λ .

Principal components. Hotelling (1933) introduced principal components and Massy (1965) regression on them. The warnings about low-variance components are from Jolliffe (1982) and Hadi and Ling (1998); Jolliffe (2002) is the standard monograph. Frank and Friedman (1993) compare principal components, partial least squares and ridge regression.

The lasso. Tibshirani (1996) introduced the lasso, Chen, Donoho and Saunders (1998) the same criterion as basis pursuit, and Park and Casella (2008) a Bayesian version. Tibshirani (2013) treats uniqueness and sparsity of solutions ([Exercise \(C2\)](#)). Path algorithms are due to Osborne, Presnell and Turlach (2000) and Efron, Hastie, Johnstone and Tibshirani (2004); coordinate descent to Fu (1998), Friedman, Hastie, Höfling and Tibshirani (2007) and Friedman, Hastie and Tibshirani (2010), with convergence theory by Tseng (2001). Donoho and Johnstone (1994) analysed soft thresholding, and Hastie, Tibshirani and Tibshirani (2020) compare subset selection and the lasso at scale. Hastie, Tibshirani and Wainwright (2015) and Hastie, Tibshirani and Friedman (2009, chapter 3) cover these methods for prediction.

Stein's paradox. The inadmissibility of $\mathbf{Z}$ for $p \geq 3$ is due to Stein (1956), and the explicit estimator, including an estimated variance, to James and Stein (1961). The proof through [Lemma 27.5.1](#) follows Stein (1981); the empirical Bayes reading is from Efron and Morris (1973). Lehmann and Casella (1998, chapter 5) discuss admissibility and the positive-part estimator; Efron and Hastie (2016, chapter 7) link James–Stein and ridge regression.

Chapter 28

High-Dimensional Regression: $p > n$

Every chapter so far has assumed, openly or quietly, that there are more observations than coefficients. Once $p > n$ the columns of $\mathbf{X}$ cannot be linearly independent, least squares fits the data exactly whatever they are, and no individual coefficient is estimable. This chapter asks what can still be done. The first answer is to keep least squares and pick the shortest of its many solutions. Its risk can be computed exactly, and it produces the “double descent” curve. The second answer is to assume that only a few coefficients matter and to use the lasso. Here a restricted form of the eigenvalue conditions of Part II replaces full rank, and short non-asymptotic proofs show that the lasso predicts and estimates almost as well as an oracle that knew which coefficients were zero. Selecting exactly the right variables needs a stronger condition, which can fail even when prediction is good. The chapter ends with inference. Intervals computed after selection are wrong, and a one-step correction of the lasso restores approximately normal estimates of single coefficients.

What you need. [Chapter 1](#) (the singular value decomposition, [Theorem 1.8.1](#), and the Moore–Penrose inverse, [Definition 1.3.2](#)), [Chapter 6](#) (projections, minimum-norm least squares, [Proposition 6.10.1](#), and the Frisch–Waugh–Lovell theorem, [Theorem 6.6.2](#)), [Chapter 8](#) (estimable functions, [Theorem 8.2.2](#)), [Chapter 10](#) (least squares through the SVD, [Theorem 10.4.1](#)), [Chapter 13](#) (the union bound, [Theorem 13.4.1](#)) and [Chapter 14](#) (random regressors and the inverse Wishart mean, [Lemma 14.2.4](#)). From this part: the lasso, its optimality conditions and soft thresholding ([Chapter 27](#), [Definition 27.4.1](#) and [Theorem 27.4.2](#)) and ridge regression ([Theorem 27.2.2](#)). Selection bias and cross-validation ([Chapter 29](#)) are referred to but not needed.

- [Support recovery](#)
- [Post-selection and debiased inference](#)
- [Summary and notes](#)

28.1 Minimum-norm interpolation

Gene expression studies measure tens of thousands of genes on a few hundred patients, and a model with many splines, interactions or random features easily has more columns than rows. This section asks what least squares does when $p > n$. It does not fail, but it no longer picks out one answer, and we study the answer that the SVD and the common algorithms return.

28.1.1 Least squares when p exceeds n

Suppose $\text{rank}(\mathbf{X}) = n < p$, the usual case (a matrix with continuously distributed entries has full rank with probability one). Three consequences follow from Parts I and II.

First, $\mathcal{C}(\mathbf{X}) = \mathbb{R}^n$, so $\mathbf{M} = \mathbf{I}$: every least squares fit reproduces the data, the residuals are zero, $R^2 = 1$, and the estimator s^2 of [Theorem 5.6.1](#) has $n - r = 0$ in its denominator. The data contain no internal information about σ^2 .

Second, $\mathcal{N}(\mathbf{X})$ has dimension $p - n \geq 1$, and the least squares estimates form the affine set $\mathbf{X}^+\mathbf{y} + \mathcal{N}(\mathbf{X})$ ([Theorem 10.4.1](#)). Coefficient vectors that differ by an element of $\mathcal{N}(\mathbf{X})$ give the same mean, so the data cannot tell them apart.

Third, $\lambda^\top \beta$ is estimable iff $\lambda \in \mathcal{C}(\mathbf{X}^\top)$ ([Theorem 8.2.2](#)), and a coordinate vector $\mathbf{e}_j$ lies in the n -dimensional row space only if it is orthogonal to $\mathcal{N}(\mathbf{X})$, which fails for generic designs. For a generic $\mathbf{X}$ with $p > n$, *no single coefficient is estimable*. Any method that answers questions about individual coefficients is adding information, explicitly or through its algorithm.

Example. (Two interpolators)

Take $n = 4$ observations on $p = 6$ regressors, with the design of the listing below and $\mathbf{y} = (1, 2, 0, -1)^\top$. The minimum-norm solution $\hat{\beta}^+ = \mathbf{X}^+\mathbf{y}$ ([Proposition 1.4.3](#), [Proposition 6.10.1](#)) has length 1.322. Adding twice a unit vector of $\mathcal{N}(\mathbf{X})$ gives a second solution of length 2.398. Both reproduce $\mathbf{y}$ exactly. They disagree about the coefficients: the first, for instance, is -0.002 in one and -0.059 in the other. They also disagree about predictions at a point that was not observed: at $\mathbf{x}_0 = \mathbf{1}$ they predict 2.131 and 2.588. The data give no reason to prefer either. The minimum-norm solution is singled out by a choice, not by the data.

```
import numpy as np

rng = np.random.default_rng(2801)
n, p = 4, 6
X = np.round(rng.normal(size=(n, p)), 1)           # a 4 x 6 design, rank 4
y = np.array([1.0, 2.0, 0.0, -1.0])

b_plus = X.T @ np.linalg.solve(X @ X.T, y)         # X^T (X X^T)^{-1} y
print("min-norm solution ", np.round(b_plus, 3))
print("residual norm      ", np.linalg.norm(y - X @ b_plus))

# another interpolator: add a null-space vector of X
_, _, Vt = np.linalg.svd(X)
b_other = b_plus + 2.0 * Vt[-1]                    # Vt[-1] spans part of N(X)
print("other solution     ", np.round(b_other, 3))
```

```

print("residual norm      ", np.linalg.norm(y - X @ b_other))
print("norms", np.linalg.norm(b_plus), np.linalg.norm(b_other))

x0 = np.ones(p) # a new point
print("predictions at x0:", x0 @ b_plus, x0 @ b_other)

```

28.1.2 The minimum-norm solution

In this chapter the singular values of $\mathbf{X}$ are written $d_1 \geq \dots \geq d_r > 0$, so that σ stays free for the error standard deviation. By [Theorem 1.8.1](#),

$$\mathbf{X} = \sum_{i=1}^r d_i \mathbf{u}_i \mathbf{v}_i^\top, \quad \mathbf{X}^+ = \sum_{i=1}^r d_i^{-1} \mathbf{v}_i \mathbf{u}_i^\top,$$

with orthonormal $\mathbf{u}_1, \dots, \mathbf{u}_r \in \mathbb{R}^n$ and $\mathbf{v}_1, \dots, \mathbf{v}_r \in \mathbb{R}^p$. The matrix

$$\mathbf{P} = \mathbf{X}^+ \mathbf{X} = \sum_{i=1}^r \mathbf{v}_i \mathbf{v}_i^\top \quad (28.1.1)$$

is the orthogonal projection onto the row space $\mathcal{C}(\mathbf{X}^\top) = \text{span}(\mathbf{v}_1, \dots, \mathbf{v}_r)$. The next theorem collects what is known about $\hat{\boldsymbol{\beta}}^+ = \mathbf{X}^+ \mathbf{y}$ when $p > n$. Part (a) restates earlier results in the form needed here. Parts (b) and (c) show that $\hat{\boldsymbol{\beta}}^+$ is what two common procedures produce when they are pushed to the limit. Part (d) gives its bias and variance.

Theorem 28.1.1 — The minimum-norm interpolator

Let $\mathbf{X}$ be $n \times p$ with rank r and singular values $d_1 \geq \dots \geq d_r > 0$, and let $\hat{\boldsymbol{\beta}}^+ = \mathbf{X}^+ \mathbf{y}$.

- (a) (*Characterization.*) The least squares estimates are the vectors $\hat{\boldsymbol{\beta}}^+ + \mathbf{v}$ with $\mathbf{v} \in \mathcal{N}(\mathbf{X})$. Among them $\hat{\boldsymbol{\beta}}^+$ is the only one in $\mathcal{C}(\mathbf{X}^\top)$, and it has the smallest Euclidean norm. If $r = n$, then $\hat{\boldsymbol{\beta}}^+ = \mathbf{X}^\top (\mathbf{X} \mathbf{X}^\top)^{-1} \mathbf{y}$ and every least squares estimate interpolates: $\mathbf{X} \hat{\boldsymbol{\beta}}^+ = \mathbf{y}$.
- (b) (*Ridgeless limit.*) For $\lambda > 0$ let $\hat{\boldsymbol{\beta}}_\lambda = (\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top \mathbf{y}$ be the ridge estimate. Then $\|\hat{\boldsymbol{\beta}}_\lambda - \hat{\boldsymbol{\beta}}^+\| \leq (\lambda/d_r^2) \|\hat{\boldsymbol{\beta}}^+\|$, so $\hat{\boldsymbol{\beta}}_\lambda \rightarrow \hat{\boldsymbol{\beta}}^+$ as $\lambda \downarrow 0$.
- (c) (*Gradient descent.*) Let $\mathbf{b}_0 \in \mathbb{R}^p$, $0 < \eta < 2/d_1^2$ and $\mathbf{b}_{t+1} = \mathbf{b}_t + \eta \mathbf{X}^\top (\mathbf{y} - \mathbf{X} \mathbf{b}_t)$. Then $\mathbf{b}_t \rightarrow \hat{\boldsymbol{\beta}}^+ + (\mathbf{I} - \mathbf{P}) \mathbf{b}_0$. In particular, gradient descent started at $\mathbf{b}_0 = \mathbf{0}$ converges to $\hat{\boldsymbol{\beta}}^+$.
- (d) (*Bias and variance.*) If $\mathbf{E}(\mathbf{Y}) = \mathbf{X} \boldsymbol{\beta}$ and $\text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{I}$, then $\mathbf{E}(\mathbf{X}^+ \mathbf{Y}) = \mathbf{P} \boldsymbol{\beta}$ and $\text{Cov}(\mathbf{X}^+ \mathbf{Y}) = \sigma^2 \sum_{i \leq r} d_i^{-2} \mathbf{v}_i \mathbf{v}_i^\top$. For every $\mathbf{a} \in \mathbb{R}^p$,

$$\mathbf{E}(\mathbf{a}^\top \mathbf{X}^+ \mathbf{Y} - \mathbf{a}^\top \boldsymbol{\beta})^2 = (\mathbf{a}^\top (\mathbf{I} - \mathbf{P}) \boldsymbol{\beta})^2 + \sigma^2 \sum_{i=1}^r \frac{(\mathbf{a}^\top \mathbf{v}_i)^2}{d_i^2}, \quad (28.1.2)$$

and $\mathbf{E} \|\mathbf{X}^+ \mathbf{Y} - \boldsymbol{\beta}\|^2 = \|(\mathbf{I} - \mathbf{P}) \boldsymbol{\beta}\|^2 + \sigma^2 \sum_{i \leq r} d_i^{-2}$.

Proof.

- (a) The first two statements are [Theorem 10.4.1](#), and [Proposition 1.4.3](#) applied to the normal equations of [Theorem 6.4.2](#); $\hat{\beta}^+ = \sum_i (\mathbf{u}_i^\top \mathbf{y} / d_i) \mathbf{v}_i$ lies in $\text{span}(\mathbf{v}_1, \dots, \mathbf{v}_r) = \mathcal{C}(\mathbf{X}^\top)$. If $r = n$, then $\mathbf{X}\mathbf{X}^\top$ is a nonsingular $n \times n$ matrix, and $\mathbf{X}^\top(\mathbf{X}\mathbf{X}^\top)^{-1}$ satisfies the four conditions of [Definition 1.3.2](#), so it equals $\mathbf{X}^+$. Moreover $\mathcal{C}(\mathbf{X}) = \mathbb{R}^n$, so the projection onto $\mathcal{C}(\mathbf{X})$ is $\mathbf{I}$ and every least squares fit equals $\mathbf{y}$.
- (b) Write $c_i = \mathbf{u}_i^\top \mathbf{y}$. By [Theorem 27.2.2\(a\)](#), $\hat{\beta}_\lambda = \sum_{i \leq r} d_i c_i \mathbf{v}_i / (d_i^2 + \lambda)$, and [Theorem 27.2.2\(d\)](#) gives the limit $\hat{\beta}^+ = \sum_{i \leq r} (c_i / d_i) \mathbf{v}_i$; only the rate is new. Subtracting, $\hat{\beta}^+ - \hat{\beta}_\lambda = \sum_{i \leq r} \{\lambda / (d_i^2 + \lambda)\} (c_i / d_i) \mathbf{v}_i$, so by orthonormality $\|\hat{\beta}^+ - \hat{\beta}_\lambda\|^2 \leq (\lambda / d_r^2)^2 \sum_i (c_i / d_i)^2 = (\lambda / d_r^2)^2 \|\hat{\beta}^+\|^2$.
- (c) Complete $\mathbf{v}_1, \dots, \mathbf{v}_r$ to an orthonormal basis of $\mathbb{R}^p$ with vectors $\mathbf{v}_{r+1}, \dots, \mathbf{v}_p$ spanning $\mathcal{N}(\mathbf{X})$. Since $\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\mathbf{b}) = \sum_{i \leq r} d_i (c_i - d_i \mathbf{v}_i^\top \mathbf{b}) \mathbf{v}_i$, the coordinates of $\mathbf{b}_t$ evolve separately:

$$\mathbf{v}_i^\top \mathbf{b}_{t+1} = (1 - \eta d_i^2) \mathbf{v}_i^\top \mathbf{b}_t + \eta d_i c_i \quad (i \leq r), \quad \mathbf{v}_i^\top \mathbf{b}_{t+1} = \mathbf{v}_i^\top \mathbf{b}_t \quad (i > r).$$

For $i \leq r$, subtracting the fixed point c_i / d_i gives $\mathbf{v}_i^\top \mathbf{b}_t - c_i / d_i = (1 - \eta d_i^2)^t (\mathbf{v}_i^\top \mathbf{b}_0 - c_i / d_i) \rightarrow 0$, because $0 < \eta d_i^2 < 2$. The coordinates with $i > r$ never move. So $\mathbf{b}_t \rightarrow \sum_{i \leq r} (c_i / d_i) \mathbf{v}_i + \sum_{i > r} (\mathbf{v}_i^\top \mathbf{b}_0) \mathbf{v}_i = \hat{\beta}^+ + (\mathbf{I} - \mathbf{P}) \mathbf{b}_0$.

- (d) $\mathbf{E}(\mathbf{X}^+ \mathbf{Y}) = \mathbf{X}^+ \mathbf{X} \boldsymbol{\beta} = \mathbf{P} \boldsymbol{\beta}$, and $\text{Cov}(\mathbf{X}^+ \mathbf{Y}) = \sigma^2 \mathbf{X}^+ (\mathbf{X}^+)^T = \sigma^2 \sum_i d_i^{-2} \mathbf{v}_i \mathbf{v}_i^\top$ ([Theorem 2.2.1](#)). The mean squared error of $\mathbf{a}^\top \mathbf{X}^+ \mathbf{Y}$ is its squared bias $(\mathbf{a}^\top (\mathbf{P} - \mathbf{I}) \boldsymbol{\beta})^2$ plus its variance, which is [Eq. 28.1.2](#). Summing [Eq. 28.1.2](#) over $\mathbf{a} = \mathbf{e}_1, \dots, \mathbf{e}_p$ gives the last formula. ■

Parts (b) and (c) explain why $\hat{\beta}^+$ matters although nobody chooses it on purpose. Gradient iterates started at zero never leave $\mathcal{C}(\mathbf{X}^\top)$, because every gradient $\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\mathbf{b})$ lies in it. Algorithms for large models are typically started near zero and run until the training error vanishes, and in the linear case they return the minimum-norm interpolator. This is called the *implicit regularization* of the algorithm.

```
for lam in [1.0, 0.1, 0.01, 0.001]:
    b_ridge = np.linalg.solve(X.T @ X + lam * np.eye(p), X.T @ y)
    print(f"lambda = {lam:6.3f}    distance to min-norm {np.linalg.norm(b_ridge -
    b_plus):.2e}")

# gradient descent on ||y - X b||^2 / 2 started at zero
step = 1.0 / np.linalg.norm(X, 2) ** 2
b = np.zeros(p)
for t in range(5000):
    b = b + step * X.T @ (y - X @ b)
print("gradient descent: distance to min-norm", np.linalg.norm(b - b_plus))
```

For the design of [Example \(Two interpolators\)](#) the ridge estimate at $\lambda = 0.01$ is within 0.0132 of $\hat{\beta}^+$, and the distance shrinks in proportion to λ , as part (b) predicts.

In part (d), the bias $(\mathbf{I} - \mathbf{P}) \boldsymbol{\beta}$ is the component of $\boldsymbol{\beta}$ in the null space, which the data cannot see and the minimum-norm solution sets to zero. The variance is the familiar σ^2 / d_i^2 of [Theo-](#)

rem 10.4.1, summed over the directions the data do see. So $\mathbf{a}^\top \hat{\boldsymbol{\beta}}^+$ is unbiased for all $\boldsymbol{\beta}$ exactly when $\mathbf{a}^\top \boldsymbol{\beta}$ is estimable (Exercise (A2)). For any other $\mathbf{a}$, its bias depends on the invisible part of $\boldsymbol{\beta}$ and can be anything.

28.1.3 The risk with random regressors

To say whether interpolation predicts well, the design must be random, since prediction is at new regressor values. The cleanest case has independent standard normal regressors, where both terms of part (d) can be averaged exactly.

Proposition 28.1.2 — Risk under isotropic regressors

Let the rows of $\mathbf{X}$ be independent $N_p(\mathbf{0}, \mathbf{I}_p)$ vectors, let $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$ independent of $\mathbf{X}$, and let $\mathbf{x}_0 \sim N_p(\mathbf{0}, \mathbf{I}_p)$ be independent of both. The prediction risk $\mathcal{R} = E(\mathbf{x}_0^\top \mathbf{X}^+ \mathbf{Y} - \mathbf{x}_0^\top \boldsymbol{\beta})^2$ is

$$\mathcal{R} = \begin{cases} \sigma^2 \frac{p}{n-p-1}, & p \leq n-2, \\ \|\boldsymbol{\beta}\|^2 \left(1 - \frac{n}{p}\right) + \sigma^2 \frac{n}{p-n-1}, & p \geq n+2. \end{cases} \quad (28.1.3)$$

Proof. Given $\mathbf{X}$ and $\mathbf{Y}$, the vector $\hat{\boldsymbol{\beta}}^+ = \mathbf{X}^+ \mathbf{Y}$ is fixed and $E\{(\mathbf{x}_0^\top (\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}))^2 \mid \mathbf{X}, \mathbf{Y}\} = \|\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}\|^2$, because $\text{Cov}(\mathbf{x}_0) = \mathbf{I}$. So $\mathcal{R} = E\|\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}\|^2$, and by Theorem 28.1.1(d) applied conditionally on $\mathbf{X}$,

$$\mathcal{R} = E\|(\mathbf{I} - \mathbf{P})\boldsymbol{\beta}\|^2 + \sigma^2 E \sum_{i=1}^r d_i^{-2}.$$

Case $p \leq n-2$. $\mathbf{X}^\top \mathbf{X} = \sum_i \mathbf{x}_{(i)} \mathbf{x}_{(i)}^\top$ has the Wishart law $W_p(n, \mathbf{I})$ (Definition 14.2.1), so by Lemma 14.2.4 it is nonsingular with probability one and $E(\mathbf{X}^\top \mathbf{X})^{-1} = \mathbf{I}/(n-p-1)$. Then $r = p$, $\mathbf{P} = \mathbf{I}$, the bias term vanishes, and $\sum_i d_i^{-2} = \text{tr}(\mathbf{X}^\top \mathbf{X})^{-1}$ has mean $p/(n-p-1)$.

Case $p \geq n+2$. The p columns of $\mathbf{X}$ are independent $N_n(\mathbf{0}, \mathbf{I}_n)$ vectors, so $\mathbf{X}\mathbf{X}^\top \sim W_n(p, \mathbf{I}_n)$. By Lemma 14.2.4 again, $\mathbf{X}\mathbf{X}^\top$ is nonsingular with probability one, so $r = n$. The numbers d_i^2 are also the eigenvalues of $\mathbf{X}\mathbf{X}^\top$, so $\sum_i d_i^{-2} = \text{tr}(\mathbf{X}\mathbf{X}^\top)^{-1}$, with mean $n/(p-n-1)$. For the bias, let $\mathbf{Q}$ be any orthogonal $p \times p$ matrix. The rows of $\mathbf{X}\mathbf{Q}$ are independent $N_p(\mathbf{0}, \mathbf{Q}^\top \mathbf{Q}) = N_p(\mathbf{0}, \mathbf{I})$ vectors (Theorem 3.3.1), so $\mathbf{X}\mathbf{Q}$ has the same law as $\mathbf{X}$. One checks from Definition 1.3.2 that $(\mathbf{X}\mathbf{Q})^+ = \mathbf{Q}^\top \mathbf{X}^+$, so the row-space projection of $\mathbf{X}\mathbf{Q}$ is $\mathbf{Q}^\top \mathbf{P} \mathbf{Q}$. Hence $\bar{\mathbf{P}} = \mathbf{E} \mathbf{P}$ satisfies $\bar{\mathbf{P}} = \mathbf{Q}^\top \bar{\mathbf{P}} \mathbf{Q}$ for every orthogonal $\mathbf{Q}$. Then $\mathbf{u}^\top \bar{\mathbf{P}} \mathbf{u}$ takes the same value c at every unit vector $\mathbf{u}$, since any unit vector is $\mathbf{Q} \mathbf{e}_1$ for some $\mathbf{Q}$. A symmetric matrix whose quadratic form is constant on the unit sphere is $c\mathbf{I}$, by Theorem 1.7.7. Taking traces, $pc = E \text{tr} \mathbf{P} = E r = n$. Therefore $E\|(\mathbf{I} - \mathbf{P})\boldsymbol{\beta}\|^2 = \boldsymbol{\beta}^\top (\mathbf{I} - E \mathbf{P}) \boldsymbol{\beta} = \|\boldsymbol{\beta}\|^2 (1 - n/p)$. ■

Below $p = n$ the fit is unbiased and its variance grows like $p/(n-p-1)$, which explodes as p

approaches n . Above $p = n$ the variance *falls* again, like $n/(p - n - 1)$. The fit has to interpolate n noisy values, and with many more directions available the interpolator can spread the noise over them thinly. The price is the bias: the fit recovers only the fraction n/p of $\|\boldsymbol{\beta}\|^2$. The formulas do not cover $|p - n| \leq 1$.

28.1.4 Double descent

In applications p is usually a choice, such as the number of basis functions. To compare choices of p on one problem, let the response depend on a pool of D features and let the fit use only the first p . The features left out act as extra noise.

Corollary 28.1.3 — Fitting the first p of D features

Let $\mathbf{x} \sim N_D(\mathbf{0}, \mathbf{I}_D)$, $Y = \mathbf{x}^\top \boldsymbol{\beta} + \varepsilon$ with $\varepsilon \sim N(0, \sigma^2)$ independent of $\mathbf{x}$, and let n independent copies be observed. For $p \leq D$, split $\boldsymbol{\beta} = (\boldsymbol{\beta}_{(1)}^\top, \boldsymbol{\beta}_{(2)}^\top)^\top$ into its first p and last $D - p$ entries, write $\omega^2 = \|\boldsymbol{\beta}_{(2)}\|^2$, fit the minimum-norm least squares estimate $\hat{\boldsymbol{\beta}}^+$ (Proposition 6.10.1) to the first p features, and predict with $(\hat{\boldsymbol{\beta}}^+, \mathbf{0}^\top)^\top$. With $\sigma_p^2 = \sigma^2 + \omega^2$, the excess prediction risk at an independent new $\mathbf{x}_0$ is ω^2 plus the right-hand side of Eq. 28.1.3 with $\boldsymbol{\beta}_{(1)}$ in place of $\boldsymbol{\beta}$ and σ_p^2 in place of σ^2 .

Proof. Split $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2]$ in the same way. Then $\mathbf{Y} = \mathbf{X}_1 \boldsymbol{\beta}_{(1)} + (\mathbf{X}_2 \boldsymbol{\beta}_{(2)} + \boldsymbol{\varepsilon})$. The entries of $\mathbf{X}_2$ are independent of $\mathbf{X}_1$, so the bracket is a $N_n(\mathbf{0}, \sigma_p^2 \mathbf{I})$ vector independent of $\mathbf{X}_1$. Proposition 28.1.2 applies with $\mathbf{X}_1$, $\boldsymbol{\beta}_{(1)}$ and σ_p^2 , and gives $E\|\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}_{(1)}\|^2$. At the new point, the prediction error $\mathbf{x}_{0,1}^\top (\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}_{(1)}) - \mathbf{x}_{0,2}^\top \boldsymbol{\beta}_{(2)}$ is a sum of two uncorrelated terms with mean zero, so its mean square is $E\|\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}_{(1)}\|^2 + \omega^2$. ■

Example. (Two shapes of signal)

Take $n = 50$ observations, a pool of $D = 200$ features, $\sigma^2 = 0.25$ and $\|\boldsymbol{\beta}\|^2 = 1$. Figure 28.1.1 plots the exact risk of Corollary 28.1.3 against p for two coefficient vectors, with simulated values as a check. It also shows the risk of ridge regression (Theorem 27.2.2) with the best penalty for each p .

In panel (a) all 200 coefficients are equal, so each feature left out adds to the noise. No model with $p < n$ beats predicting zero, which has risk 1.000. The risk climbs to 12.31 at $p = 45$, is 12.94 at $p = 55$, and then falls. The overall minimum is at $p = 200$: 0.834. Here the best prediction comes from interpolating with every feature.

In panel (b) the coefficients decay geometrically, and the classical picture holds: a small model with $p = 9$ has risk 0.078, and nothing to the right of the peak comes close. At $p = D$ the risk is 0.834 again. When all features are used, Eq. 28.1.3 depends on $\boldsymbol{\beta}$ only through $\|\boldsymbol{\beta}\|$.

A risk curve that falls, peaks at $p = n$ and falls again is called **double descent**. Three cautions keep it in proportion.

Figure 28.1.1: Excess prediction risk of the minimum-norm least squares fit on the first p of $D = 200$ isotropic features, with $n = 50$ (vertical line) and $\sigma^2 = 0.25$: the exact formula of [Corollary 28.1.3](#) (line) and simulation (dots), and ridge regression with the best penalty for each p . The dotted line is the risk of predicting zero. (a) Equal coefficients. (b) Geometrically decaying coefficients.

- *The peak belongs to the estimator, not to the problem.* It comes from the variance term $\sigma^2 \sum_i d_i^{-2}$, large when the smallest nonzero singular value is near zero, as for $p \approx n$. Ridge with the best penalty has no peak, and its best values, 0.811 and 0.073, are slightly below the best minimum-norm values, as [Theorem 28.1.1\(b\)](#) requires.
- *The second descent need not win.* That depends on how the signal is spread, as the panels show.
- *Isotropic features are a special case.* Hastie, Montanari, Rosset and Tibshirani (2022) treat general covariances as $n, p \rightarrow \infty$ with p/n fixed, and Bartlett, Long, Lugosi and Tsigler (2020) find when interpolation is *benign*, with risk still tending to that of the best predictor.

```
import numpy as np

def exact_risk(p, n, beta, sigma2):
    """Excess prediction risk of min-norm least squares on the first p of D
    isotropic features."""
    kept, left = np.sum(beta[:p] ** 2), np.sum(beta[p:] ** 2)
    noise = sigma2 + left # omitted features act as extra noise
    if p == 0:
        return left
    if p <= n - 2:
        return left + noise * p / (n - p - 1)
    if p >= n + 2:
        return left + kept * (1 - n / p) + noise * n / (p - n - 1)
    return np.inf # |p - n| <= 1: not covered by the formula

def simulated_risk(p, n, beta, sigma2, reps, rng, lams=()):
    """Average over designs of the conditional risk given X; also ridge for each
    penalty."""
    bS, left = beta[:p], np.sum(beta[p:] ** 2)
    noise = sigma2 + left
    out, ridge = [], np.zeros(len(lams))
```

```

for _ in range(reps):
    X = rng.normal(size=(n, p))
    _, d, Vt = np.linalg.svd(X, full_matrices=False)
    c = Vt @ bS                                     # coordinates of beta_S in the
row space
    bias2 = bS @ bS - c @ c                         # ||(I - P) beta_S||^2
    out.append(left + bias2 + noise * np.sum(1 / d ** 2))
    if len(lams):
        shrink = d ** 2 / (d ** 2 + np.asarray(lams)[: , None]) # one row per
penalty
        ridge += left + bias2 + np.sum(((1 - shrink) * c) ** 2, axis=1) \
            + noise * np.sum(shrink ** 2 / d ** 2, axis=1)
return np.mean(out), np.std(out) / np.sqrt(reps), ridge / reps

n, D, sigma2 = 20, 100, 0.25
beta = np.full(D, 1 / np.sqrt(D))                 # signal spread evenly, ||beta
||^2 = 1
rng = np.random.default_rng(2802)
for p in [5, 10, 15, 25, 40, 100]:
    sim, se, _ = simulated_risk(p, n, beta, sigma2, reps=200, rng=rng)
    print(f"p = {p:3d}: formula {exact_risk(p, n, beta, sigma2):.3f} simulation {
sim:.3f}")

```

For the rest of the chapter we take a different route. Instead of letting the algorithm decide which of the many solutions to report, we *assume* that the truth is simple: only a few coefficients are nonzero. That assumption is strong, but it is explicit, and it can be exploited through the lasso.

28.1.5 Exercises

28.1.5.1 A. Check your understanding

Exercise A1.

Let $\mathbf{X}$ be $n \times p$ with an intercept column and $\text{rank}(\mathbf{X}) = n < p$. Show that every least squares fit has $R^2 = 1$, and explain why neither the F test of [Theorem 11.1.1](#) nor the residual-based diagnostics of [Chapter 20](#) can be used. What are the leverages h_{ii} ?

Exercise A2.

In the setting of [Theorem 28.1.1\(d\)](#), show that $\mathbf{a}^\top \mathbf{X}^+ \mathbf{Y}$ is unbiased for $\mathbf{a}^\top \boldsymbol{\beta}$ for every $\boldsymbol{\beta}$ iff $\mathbf{a} \in \mathcal{C}(\mathbf{X}^\top)$. Show also that for such $\mathbf{a}$ its variance is $\sigma^2 \mathbf{a}^\top (\mathbf{X}^\top \mathbf{X})^+ \mathbf{a}$, and that it equals the least squares estimator $\mathbf{a}^\top \hat{\boldsymbol{\beta}}$ of [Theorem 6.4.4](#) for any least squares estimate $\hat{\boldsymbol{\beta}}$.

Solution. The bias is $\mathbf{a}^\top (\mathbf{P} - \mathbf{I}) \boldsymbol{\beta}$, which vanishes for all $\boldsymbol{\beta}$ iff $(\mathbf{I} - \mathbf{P}) \mathbf{a} = \mathbf{0}$, that is, iff $\mathbf{a} \in \mathcal{C}(\mathbf{P}) = \mathcal{C}(\mathbf{X}^\top)$. The variance is $\sigma^2 \sum_i (\mathbf{a}^\top \mathbf{v}_i)^2 / d_i^2$, and $\sum_i d_i^{-2} \mathbf{v}_i \mathbf{v}_i^\top$ is the Moore–Penrose inverse of $\mathbf{X}^\top \mathbf{X} = \sum_i d_i^2 \mathbf{v}_i \mathbf{v}_i^\top$ ([Theorem 1.8.1](#)). Finally, any least squares estimate is $\hat{\boldsymbol{\beta}}^+ + \mathbf{v}$ with $\mathbf{v} \in \mathcal{N}(\mathbf{X})$, and $\mathbf{a}^\top \mathbf{v} = 0$ because $\mathbf{a} \in \mathcal{C}(\mathbf{X}^\top) = \mathcal{N}(\mathbf{X})^\perp$, so $\mathbf{a}^\top \hat{\boldsymbol{\beta}} = \mathbf{a}^\top \hat{\boldsymbol{\beta}}^+$.

28.1.5.2 B. Practice

Exercise B1.

Show directly from the update in [Theorem 28.1.1\(c\)](#) that $(\mathbf{I} - \mathbf{P})\mathbf{b}_t = (\mathbf{I} - \mathbf{P})\mathbf{b}_0$ for all t . Deduce that gradient descent started at $\mathbf{b}_0$ returns the least squares estimate closest to $\mathbf{b}_0$.

Exercise B2.

Fix $\mathbf{X}$ of rank r and let $m(\lambda) = \mathbb{E}\|\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}\|^2$ for the ridge estimate, with $m(0)$ the risk of $\hat{\boldsymbol{\beta}}^+$ in [Theorem 28.1.1\(d\)](#). Show that

$$m(\lambda) = \|(\mathbf{I} - \mathbf{P})\boldsymbol{\beta}\|^2 + \sum_{i=1}^r \left[\left(\frac{\lambda}{d_i^2 + \lambda} \right)^2 (\mathbf{v}_i^\top \boldsymbol{\beta})^2 + \sigma^2 \frac{d_i^2}{(d_i^2 + \lambda)^2} \right],$$

and that $m'(0) < 0$ whenever $\sigma > 0$. So some ridge estimate beats the minimum-norm interpolator for every $\boldsymbol{\beta}$. Compare [Theorem 27.2.3](#).

Solution. The linear representation in [Theorem 27.2.2\(a\)](#) holds for any rank r . Applied to $\mathbb{E}(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}$, whose coordinates are $\mathbf{u}_i^\top \mathbf{X}\boldsymbol{\beta} = d_i \mathbf{v}_i^\top \boldsymbol{\beta}$, it gives $\mathbb{E} \hat{\boldsymbol{\beta}}_\lambda = \sum_{i \leq r} \{d_i^2 / (d_i^2 + \lambda)\} (\mathbf{v}_i^\top \boldsymbol{\beta}) \mathbf{v}_i$, and the covariance is $\sigma^2 \sum_{i \leq r} d_i^2 (d_i^2 + \lambda)^{-2} \mathbf{v}_i \mathbf{v}_i^\top$, as in [Theorem 27.2.2\(c\)](#). What $r < p$ adds is the bias component $-(\mathbf{I} - \mathbf{P})\boldsymbol{\beta}$ in the null space, orthogonal to the rest of the bias $-\sum_i \{\lambda / (d_i^2 + \lambda)\} (\mathbf{v}_i^\top \boldsymbol{\beta}) \mathbf{v}_i$; it contributes $\|(\mathbf{I} - \mathbf{P})\boldsymbol{\beta}\|^2$. Adding the squared bias and the trace of the covariance gives $m(\lambda)$. Differentiating term by term, the first bracket has derivative $2\lambda d_i^2 (\mathbf{v}_i^\top \boldsymbol{\beta})^2 / (d_i^2 + \lambda)^3$, which is zero at $\lambda = 0$. The second has derivative $-2\sigma^2 d_i^2 / (d_i^2 + \lambda)^3$, which equals $-2\sigma^2 / d_i^4 < 0$ at $\lambda = 0$. Hence $m'(0) = -2\sigma^2 \sum_i d_i^{-4} < 0$, and $m(\lambda) < m(0)$ for small $\lambda > 0$.

28.1.5.3 C. Going deeper

Exercise C1.

Check [Eq. 28.1.3](#) for $n = 1$ directly. With one observation $(\mathbf{x}, y)$, show that $\hat{\boldsymbol{\beta}}^+ = \mathbf{x}y / \|\mathbf{x}\|^2$, and use $\mathbb{E}(1/\chi^2(p)) = 1/(p-2)$ for $p \geq 3$ to show that $\mathcal{R} = \|\boldsymbol{\beta}\|^2(1 - 1/p) + \sigma^2/(p-2)$.

Solution. Here $\mathbf{X} = \mathbf{x}^\top$ and $\mathbf{X}\mathbf{X}^\top = \|\mathbf{x}\|^2$, so $\hat{\boldsymbol{\beta}}^+ = \mathbf{x}y / \|\mathbf{x}\|^2$ and $\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta} = -(\mathbf{I} - \mathbf{x}\mathbf{x}^\top / \|\mathbf{x}\|^2)\boldsymbol{\beta} + \mathbf{x}\varepsilon / \|\mathbf{x}\|^2$, a sum of orthogonal vectors. So

$$\|\hat{\boldsymbol{\beta}}^+ - \boldsymbol{\beta}\|^2 = \|\boldsymbol{\beta}\|^2 - \frac{(\mathbf{x}^\top \boldsymbol{\beta})^2}{\|\mathbf{x}\|^2} + \frac{\varepsilon^2}{\|\mathbf{x}\|^2}.$$

The matrix $\mathbf{P} = \mathbf{x}\mathbf{x}^\top / \|\mathbf{x}\|^2$ is the row-space projection, and the rotation argument in the proof of [Proposition 28.1.2](#) gives $\mathbb{E} \mathbf{P} = \mathbf{I}/p$, so $\mathbb{E}(\mathbf{x}^\top \boldsymbol{\beta})^2 / \|\mathbf{x}\|^2 = \boldsymbol{\beta}^\top (\mathbb{E} \mathbf{P}) \boldsymbol{\beta} = \|\boldsymbol{\beta}\|^2/p$. And $\|\mathbf{x}\|^2 \sim \chi^2(p)$ is independent of ε , so $\mathbb{E} \varepsilon^2 / \|\mathbf{x}\|^2 = \sigma^2/(p-2)$. This agrees with [Eq. 28.1.3](#) at $n = 1$.

Exercise C2.

In [Proposition 28.1.2](#) let $n, p \rightarrow \infty$ with $n/p \rightarrow \gamma \in (0, 1)$ and $\|\beta\|^2$ fixed. Show that $\mathcal{R} \rightarrow \|\beta\|^2(1 - \gamma) + \sigma^2\gamma/(1 - \gamma)$, and that this is below the risk $\|\beta\|^2$ of predicting zero iff $\|\beta\|^2/\sigma^2 > 1/(1 - \gamma)$. What happens to the limit as $\gamma \rightarrow 0$?

28.2 Restricted eigenvalue conditions

In Parts II and III, the precision of least squares was governed by the smallest eigenvalue of $\mathbf{X}^\top \mathbf{X}$: the worst variance of $\mathbf{a}^\top \hat{\beta}$ over unit vectors $\mathbf{a}$ is $\sigma^2/\lambda_{\min}(\mathbf{X}^\top \mathbf{X})$ ([Proposition 19.6.1](#)). When $p > n$ that eigenvalue is zero. This section explains which weaker condition takes its place once β is assumed sparse, and shows with numbers how demanding it is.

28.2.1 Notation

Throughout Sections 28.2–28.5 the columns of $\mathbf{X}$ are scaled so that $\|\mathbf{x}_j\|^2 = n$ for every j , and $\hat{\Sigma} = \mathbf{X}^\top \mathbf{X}/n$ is the sample Gram matrix, with unit diagonal. For a vector $\mathbf{v} \in \mathbb{R}^p$ and a set $S \subseteq \{1, \dots, p\}$, $\mathbf{v}_S$ is the vector that agrees with $\mathbf{v}$ on S and is zero off S , so that $\mathbf{v} = \mathbf{v}_S + \mathbf{v}_{S^c}$. The ℓ_1 and ℓ_∞ norms are $\|\mathbf{v}\|_1 = \sum_j |v_j|$ and $\|\mathbf{v}\|_\infty = \max_j |v_j|$, and $\|\mathbf{v}\|$ is still the Euclidean norm. The **support** of β is $S = \{j : \beta_j \neq 0\}$, and $s = |S|$. A vector with at most s nonzero entries is **s -sparse**. By Cauchy–Schwarz ([Proposition 1.1.1](#)), for every $\mathbf{v}$,

$$\|\mathbf{v}_S\|_1 \leq \sqrt{s} \|\mathbf{v}_S\| \leq \sqrt{s} \|\mathbf{v}\|. \quad (28.2.1)$$

28.2.2 Sparsity restores identifiability

If β is only known to lie in $\mathbb{R}^p$, then β and $\beta + \mathbf{v}$ with $\mathbf{v} \in \mathcal{N}(\mathbf{X})$ give the same mean, and nothing can separate them. If β is known to be sparse, most of those alternatives are excluded.

Proposition 28.2.1 — Identifiability of sparse vectors

Distinct s -sparse vectors $\beta \neq \beta'$ always have $\mathbf{X}\beta \neq \mathbf{X}\beta'$ iff every set of $2s$ columns of $\mathbf{X}$ is linearly independent. In particular this requires $2s \leq n$.

Proof. If β, β' are s -sparse and $\mathbf{X}\beta = \mathbf{X}\beta'$, then $\mathbf{v} = \beta - \beta'$ is a vector in $\mathcal{N}(\mathbf{X})$ with at most $2s$ nonzero entries. It is zero if every $2s$ columns are independent. Conversely, if some $2s$ columns are dependent, there is a nonzero $\mathbf{v} \in \mathcal{N}(\mathbf{X})$ supported on them. Split its support into two sets of at most s indices, T_1 and T_2 , and put $\beta = \mathbf{v}_{T_1}$, $\beta' = -\mathbf{v}_{T_2}$. These are distinct s -sparse vectors with $\mathbf{X}\beta - \mathbf{X}\beta' = \mathbf{X}\mathbf{v} = \mathbf{0}$. Finally, $2s$ vectors in $\mathbb{R}^n$ can be independent only if $2s \leq n$. ■

Identifiability is a statement about exactly sparse vectors and noiseless data. For estimation we need a quantitative version that allows for noise and for estimates that are only approximately sparse. The key observation, proved in [Section 28.3](#), is that the error of the lasso, $\Delta = \hat{\beta}_\lambda - \beta$, lies with high probability in a particular cone. Its ℓ_1 mass off the support is at most three times its mass on the support. Curvature of the least squares criterion is needed only in the directions of that cone.

28.2.3 Two conditions on a cone

Definition 28.2.1 — Compatibility and restricted eigenvalue conditions

Let $S \subseteq \{1, \dots, p\}$ have $s \geq 1$ elements, and let

$$\mathcal{K}(S) = \{\mathbf{v} \in \mathbb{R}^p : \|\mathbf{v}_{S^c}\|_1 \leq 3\|\mathbf{v}_S\|_1\}. \quad (28.2.2)$$

The **compatibility constant** and the **restricted eigenvalue** of the design for S are

$$\phi^2(S) = \min_{\mathbf{v} \in \mathcal{K}(S), \mathbf{v} \neq \mathbf{0}} \frac{\mathbf{v}^\top \hat{\Sigma} \mathbf{v}}{\|\mathbf{v}_S\|_1^2}, \quad \kappa^2(S) = \min_{\mathbf{v} \in \mathcal{K}(S), \mathbf{v} \neq \mathbf{0}} \frac{\mathbf{v}^\top \hat{\Sigma} \mathbf{v}}{\|\mathbf{v}\|^2}.$$

The design satisfies the **compatibility condition** for S if $\phi^2(S) > 0$, and the **restricted eigenvalue condition** for S if $\kappa^2(S) > 0$. The same definitions with a nonnegative definite matrix Σ in place of $\hat{\Sigma}$ give $\phi_\Sigma^2(S)$ and $\kappa_\Sigma^2(S)$.

A nonzero $\mathbf{v} \in \mathcal{K}(S)$ has $\mathbf{v}_S \neq \mathbf{0}$, since otherwise $\|\mathbf{v}_{S^c}\|_1 \leq 0$. So both ratios are defined. Both are unchanged when $\mathbf{v}$ is rescaled, and the sets $\{\mathbf{v} \in \mathcal{K}(S) : \|\mathbf{v}\| = 1\}$ and $\{\mathbf{v} \in \mathcal{K}(S) : \|\mathbf{v}_S\|_1 = 1\}$ are closed and bounded. So the minima are attained, which justifies writing min. The constant 3 comes from the choice of penalty in [Section 28.3](#). Other choices give other constants and the same theory.

The cone contains the s -dimensional subspace of vectors supported on S but no larger subspace ([Exercise \(C1\)](#)). So the null space of $\mathbf{X}$, of dimension at least $p - n$, can still avoid it.

Proposition 28.2.2 — Basic facts

- (a) $\lambda_{\min}(\hat{\Sigma}) \leq \kappa^2(S) \leq \phi^2(S)$. If $p > n$, then $\lambda_{\min}(\hat{\Sigma}) = 0$.
- (b) $\kappa^2(S) > 0$ iff $\phi^2(S) > 0$ iff $\mathcal{N}(\mathbf{X}) \cap \mathcal{K}(S) = \{\mathbf{0}\}$.
- (c) (*Transfer.*) If Σ is symmetric and $\max_{j,k} |\hat{\Sigma}_{jk} - \Sigma_{jk}| \leq \delta$, then $\kappa^2(S) \geq \kappa_\Sigma^2(S) - 16s\delta$ and $\phi^2(S) \geq \phi_\Sigma^2(S) - 16s\delta$.
- (d) (*Coherence.*) If $\mu = \max_{j \neq k} |\hat{\Sigma}_{jk}|$ is the **mutual coherence** of the scaled design, then $\kappa^2(S) \geq 1 - 16s\mu$ and $\phi^2(S) \geq 1 - 16s\mu$.

Proof.

- (a) The first inequality holds because $\kappa^2(S)$ minimizes the Rayleigh quotient of $\hat{\Sigma}$ over a subset of nonzero vectors, while $\lambda_{\min}(\hat{\Sigma})$ minimizes it over all of them ([Theo-](#)

rem 1.7.7). For the second, Eq. 28.2.1 gives $\|\mathbf{v}_S\|_1^2 \leq s\|\mathbf{v}\|^2$, so $s\mathbf{v}^\top \hat{\Sigma} \mathbf{v} / \|\mathbf{v}_S\|_1^2 \geq \mathbf{v}^\top \hat{\Sigma} \mathbf{v} / \|\mathbf{v}\|^2 \geq \kappa^2(S)$ for every $\mathbf{v} \in \mathcal{K}(S)$. If $p > n$, then $\text{rank}(\hat{\Sigma}) \leq n < p$, so $\hat{\Sigma}$ is singular.

- (b) $\mathbf{v}^\top \hat{\Sigma} \mathbf{v} = \|\mathbf{X}\mathbf{v}\|^2/n$ vanishes iff $\mathbf{X}\mathbf{v} = \mathbf{0}$. Since the minima are attained, each constant is zero iff some nonzero $\mathbf{v} \in \mathcal{K}(S)$ has $\mathbf{X}\mathbf{v} = \mathbf{0}$.
- (c) For $\mathbf{v} \in \mathcal{K}(S)$, $\|\mathbf{v}\|_1 = \|\mathbf{v}_S\|_1 + \|\mathbf{v}_{S^c}\|_1 \leq 4\|\mathbf{v}_S\|_1$. Hence

$$|\mathbf{v}^\top (\hat{\Sigma} - \Sigma) \mathbf{v}| \leq \sum_{j,k} |v_j| |v_k| \delta = \delta \|\mathbf{v}\|_1^2 \leq 16\delta \|\mathbf{v}_S\|_1^2 \leq 16s\delta \|\mathbf{v}\|^2,$$

the last step by Eq. 28.2.1. Dividing by $\|\mathbf{v}\|^2$ gives $\mathbf{v}^\top \hat{\Sigma} \mathbf{v} / \|\mathbf{v}\|^2 \geq \kappa_{\Sigma}^2(S) - 16s\delta$. Dividing the middle bound by $\|\mathbf{v}_S\|_1^2/s$ gives $s\mathbf{v}^\top \hat{\Sigma} \mathbf{v} / \|\mathbf{v}_S\|_1^2 \geq \phi_{\Sigma}^2(S) - 16s\delta$.

- (d) Take $\Sigma = \mathbf{I}$ in (c), with $\delta = \mu$ (the diagonals agree). Then $\kappa_{\mathbf{I}}^2(S) = 1$, and $\phi_{\mathbf{I}}^2(S) \geq \kappa_{\mathbf{I}}^2(S) = 1$ by (a) applied to $\mathbf{I}$.

■

By (b) the two conditions agree about *whether* the constants vanish, but by (a) their sizes, which enter the bounds, can differ a great deal: a lower bound on $\kappa^2(S)$ is the stronger assumption. The fast prediction rate of Section 28.3 uses $\phi^2(S)$, the ℓ_2 bound $\kappa^2(S)$. Part (c) carries a population condition to the sample when $\hat{\Sigma}$ is uniformly close to Σ , and (d) is the case $\Sigma = \mathbf{I}$.

28.2.4 When the conditions hold

Populations. If $\lambda_{\min}(\Sigma) > 0$, part (a) applied to Σ gives $\phi_{\Sigma}^2(S) \geq \kappa_{\Sigma}^2(S) \geq \lambda_{\min}(\Sigma)$. For example, the equicorrelation matrix $\Sigma = (1 - \rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top$, $0 \leq \rho < 1$, has $\mathbf{v}^\top \Sigma \mathbf{v} = (1 - \rho)\|\mathbf{v}\|^2 + \rho(\mathbf{1}^\top \mathbf{v})^2 \geq (1 - \rho)\|\mathbf{v}\|^2$, so both constants are at least $1 - \rho$ for every p and S . The difficulty lies in going from Σ to $\hat{\Sigma}$ when $p > n$.

Random designs. Suppose the rows of $\mathbf{X}$ are independent $N_p(\mathbf{0}, \Sigma)$ vectors with unit variances. A union bound over the p^2 entries of $\hat{\Sigma} - \Sigma$, each an average of n products of normal variables, gives $\max_{j,k} |\hat{\Sigma}_{jk} - \Sigma_{jk}| \leq C\sqrt{\log p/n}$ with high probability once $n \geq C'\log p$. The tail bound for each entry is not the normal bound of the next section, since products of normal variables have heavier tails; it is a Bernstein-type inequality, not proved here (see Wainwright 2019, chapter 2). Part (c) then gives a positive restricted eigenvalue once n exceeds a multiple of $s^2 \log p$. This is wasteful, because it bounds $\mathbf{v}^\top (\hat{\Sigma} - \Sigma) \mathbf{v}$ by the worst entry. Raskutti, Wainwright and Yu (2010) proved, by an argument we do not reproduce, that with probability tending to one

$$\frac{\|\mathbf{X}\mathbf{v}\|}{\sqrt{n}} \geq c_1 \|\Sigma^{1/2} \mathbf{v}\| - c_2 \sqrt{\frac{\log p}{n}} \|\mathbf{v}\|_1 \quad \text{for all } \mathbf{v} \in \mathbb{R}^p,$$

for constants $c_1, c_2 > 0$. On the cone, $\|\mathbf{v}\|_1 \leq 4\sqrt{s}\|\mathbf{v}\|$, so this gives $\kappa(S) \geq c_1 \lambda_{\min}(\Sigma)^{1/2} - 4c_2 \sqrt{s \log p/n}$, which is positive once n exceeds a multiple of $s \log p$, possibly far smaller than p .

28.2.5 When they fail

The conditions fail when a vector of the cone is (nearly) invisible to $\mathbf{X}$.

Duplicated columns. If $\mathbf{x}_k = \mathbf{x}_j$ with $j \in S$ and $k \notin S$, then $\mathbf{v} = \mathbf{e}_j - \mathbf{e}_k$ has $\|\mathbf{v}_{S^c}\|_1 = \|\mathbf{v}_S\|_1 = 1$,

so it lies in the cone, and $\mathbf{X}\mathbf{v} = \mathbf{0}$. Both constants are zero. Nearly equal columns give nearly zero constants ([Exercise \(B1\)](#)). No estimator can say whether the effect belongs to $\mathbf{x}_j$ or to its copy.

Short combinations of inactive columns. More generally, suppose an active column is a combination of inactive ones, $\mathbf{x}_j = \mathbf{X}_{S^c}\mathbf{a}$ with $\|\mathbf{a}\|_1 \leq 3$. Then $\mathbf{v} = \mathbf{e}_j - \mathbf{a}$ (with $\mathbf{a}$ placed in the coordinates of S^c) lies in the cone and $\mathbf{X}\mathbf{v} = \mathbf{0}$. When $p > n$ the inactive columns usually span $\mathbb{R}^n$, so the conditions require every such combination to have a large ℓ_1 norm.

Too many active variables for the sample size. Even with independent regressors and a population compatibility constant of one, the sample constant can be close to zero if s is large relative to $n/\log p$. A combination of hundreds of inactive columns with total ℓ_1 weight 3 can then imitate $\mathbf{X}_S\mathbf{v}_S$ closely. The next example measures this.

Example. (Compatibility constants of Gaussian designs)

Take $p = 1000$ regressors, $S = \{1, \dots, s\}$, and three random designs, with columns scaled so that $\|\mathbf{x}_j\|^2 = n$: independent standard normal entries with $n = 200$ (the design used in [Section 28.3](#)) and with $n = 400$, and equicorrelated normal regressors with $\rho = 0.5$ and $n = 400$. The compatibility constant is a minimum of a convex quadratic over the cone. For each sign pattern of $\mathbf{v}_S$ the problem is convex, and a duality gap certifies the computed value. The table gives $\phi^2(S)$ and the mutual coherence μ ; its rows are labelled by the common correlation ρ .

Design	μ	$s = 1$	$s = 2$	$s = 5$	Population
$\rho = 0$, $n = 200$	0.350	0.328	0.146	0.0045	1
$\rho = 0$, $n = 400$	0.238	0.479	0.384	0.177	1
$\rho = 0.5$, $n = 400$	0.641	0.266	0.192	0.089	≥ 0.5

The sample constants lie far below the population values, even for $s = 1$, and fall quickly with s . At $n = 200$ and $s = 5$ the constant 0.0045 makes the fast-rate bound of the next section numerically useless for that design; doubling n helps a great deal. The coherence bound of [Proposition 28.2.2\(d\)](#) is useless throughout: with $\mu = 0.350$, $1 - 16s\mu$ is -4.60 already at $s = 1$.

```

Remark (Checking the conditions in practice). The constants depend on the unknown S and cannot be checked from data. They describe the designs for which the theory is informative: those in which no short combination of columns imitates another. With groups of nearly equivalent regressors, common in genomics, the lasso may still predict well (by the slow rate of [Section 28.3](#)), but its choice among them is arbitrary.

28.2.6 Exercises

28.2.6.1 A. Check your understanding

Exercise A1.

Let $p = 2$ and $S = \{1\}$. Sketch $\mathcal{K}(S)$ and show that it is not convex. Show that for general S it is the union of 2^s convex cones, one for each sign pattern of $\mathbf{v}_S$. This is why the example above solves one convex problem per sign pattern.

28.2.6.2 B. Practice

Exercise B1.

Let $j \in S$ and $k \notin S$. Show that $\phi^2(S) \leq s\|\mathbf{x}_j - \mathbf{x}_k\|^2/n$ and $\kappa^2(S) \leq \|\mathbf{x}_j - \mathbf{x}_k\|^2/(2n)$. If $\mathbf{x}_j^\top \mathbf{x}_k/n = r$ (the cosine of the angle between the two columns, which is their sample correlation when the columns are centred), conclude that $\phi^2(S) \leq 2s(1 - r)$.

Solution. Take $\mathbf{v} = \mathbf{e}_j - \mathbf{e}_k \in \mathcal{K}(S)$. Then $\|\mathbf{v}_S\|_1 = 1$, $\|\mathbf{v}\|^2 = 2$ and $\mathbf{v}^\top \hat{\Sigma} \mathbf{v} = \|\mathbf{x}_j - \mathbf{x}_k\|^2/n$, which gives both bounds. With $\|\mathbf{x}_j\|^2 = \|\mathbf{x}_k\|^2 = n$, $\|\mathbf{x}_j - \mathbf{x}_k\|^2/n = 2 - 2\mathbf{x}_j^\top \mathbf{x}_k/n = 2(1 - r)$.

Exercise B2.

For $\Sigma = (1 - \rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top$ with $0 \leq \rho < 1$ and $p \geq 2$, show that $\kappa_\Sigma^2(S) = 1 - \rho$ for every S . Is the equicorrelation structure a hard case for the restricted eigenvalue condition?

Solution. The lower bound $1 - \rho$ was shown in the text. For equality, it is enough to find a nonzero $\mathbf{v} \in \mathcal{K}(S)$ with $\mathbf{1}^\top \mathbf{v} = 0$, since then $\mathbf{v}^\top \Sigma \mathbf{v} = (1 - \rho)\|\mathbf{v}\|^2$. If $s \geq 2$, take $\mathbf{e}_j - \mathbf{e}_k$ with $j, k \in S$. If $s = 1$, take $\mathbf{e}_j - \mathbf{e}_k$ with $S = \{j\}$ and any $k \neq j$; it lies in the cone because $1 \leq 3$. The population condition is therefore as good as the smallest eigenvalue, and equicorrelation is not a hard case in the population. It is harder in the sample (the table above), and harder still for exact support recovery, as [Section 28.4](#) shows for a related design.

28.2.6.3 C. Going deeper

Exercise C1.

Show that every linear subspace contained in $\mathcal{K}(S)$ has dimension at most s , and that the bound is attained. Deduce that if $\dim \mathcal{N}(\mathbf{X}) > p - s$ then the conditions fail for every S of size s , whereas $\dim \mathcal{N}(\mathbf{X}) = p - n$ with $n \geq s$ is not excluded by this dimension count.

Exercise C2.

(Exact recovery by ℓ_1 minimization.) Say $\mathbf{X}$ has the **null space property** for S if every nonzero $\mathbf{v} \in \mathcal{N}(\mathbf{X})$ has $\|\mathbf{v}_{S^c}\|_1 > \|\mathbf{v}_S\|_1$. Show that this holds iff, for every β supported on S , β is the unique solution of: minimize $\|\mathbf{b}\|_1$ subject to $\mathbf{X}\mathbf{b} = \mathbf{X}\beta$. Relate the property to [Proposition 28.2.2\(b\)](#) with the constant 3 replaced by 1.

Solution. Suppose the property holds, β is supported on S , and $\mathbf{X}\mathbf{b} = \mathbf{X}\beta$ with $\mathbf{b} \neq \beta$. Then $\mathbf{v} = \mathbf{b} - \beta \in \mathcal{N}(\mathbf{X})$ is nonzero, and $\mathbf{b}_S = \beta + \mathbf{v}_S$, $\mathbf{b}_{S^c} = \mathbf{v}_{S^c}$, so $\|\mathbf{b}\|_1 \geq \|\beta\|_1 - \|\mathbf{v}_S\|_1 + \|\mathbf{v}_{S^c}\|_1 > \|\beta\|_1$. So β is the unique minimizer. Conversely, if some nonzero

$\mathbf{v} \in \mathcal{N}(\mathbf{X})$ has $\|\mathbf{v}_{S^c}\|_1 \leq \|\mathbf{v}_S\|_1$, put $\boldsymbol{\beta} = \mathbf{v}_S$ and $\mathbf{b} = -\mathbf{v}_{S^c}$. Then $\mathbf{X}\mathbf{b} = \mathbf{X}\boldsymbol{\beta} - \mathbf{X}\mathbf{v} = \mathbf{X}\boldsymbol{\beta}$, $\mathbf{b} \neq \boldsymbol{\beta}$ and $\|\mathbf{b}\|_1 \leq \|\boldsymbol{\beta}\|_1$, so $\boldsymbol{\beta}$ is not the unique minimizer. The property says exactly that $\mathcal{N}(\mathbf{X})$ meets the cone $\{\|\mathbf{v}_{S^c}\|_1 \leq \|\mathbf{v}_S\|_1\}$ only at zero. This is part (b) with the constant 1 in place of 3. The noisy problem needs the larger cone because the penalty must also absorb the noise.

28.3 Prediction and estimation bounds for the lasso

This section proves that the lasso works when $p > n$, in the form of explicit inequalities valid for every n and p . The proofs use three ingredients: the lasso minimizes its criterion, the largest of p normal variables is small, and the conditions of [Section 28.2](#) hold.

28.3.1 Setting

Throughout this section and the next two, $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ with $\mathbf{X}$ a fixed $n \times p$ matrix whose columns satisfy $\|\mathbf{x}_j\|^2 = n$, $\boldsymbol{\varepsilon} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$, and p possibly much larger than n . The support of $\boldsymbol{\beta}$ is S , with $s = |S|$. A **lasso estimate** is any

$$\hat{\boldsymbol{\beta}}_\lambda \in \arg \min_{\mathbf{b} \in \mathbb{R}^p} \left\{ \frac{1}{2n} \|\mathbf{Y} - \mathbf{X}\mathbf{b}\|^2 + \lambda \|\mathbf{b}\|_1 \right\}, \quad \lambda > 0. \quad (28.3.1)$$

This is the lasso of [Definition 27.4.1](#) with the penalty measured per observation. Other scalings of the criterion only rename λ . By [Theorem 27.4.1](#), a minimizer exists, all minimizers share the fitted values $\mathbf{X}\hat{\boldsymbol{\beta}}_\lambda$ and the norm $\|\hat{\boldsymbol{\beta}}_\lambda\|_1$, and the optimality conditions of [Definition 27.4.1](#) are necessary and sufficient. When $p > n$ the minimizer need not be unique, and everything below holds for every minimizer. In the present scaling they say that $\mathbf{b}$ is a lasso estimate iff

$$\begin{aligned} \frac{1}{n} \mathbf{X}^\top (\mathbf{Y} - \mathbf{X}\mathbf{b}) &= \lambda \mathbf{z} \quad \text{with} \\ z_j &= \text{sign}(b_j) \text{ if } b_j \neq 0, \quad |z_j| \leq 1 \text{ if } b_j = 0. \end{aligned} \quad (28.3.2)$$

In words, every column's correlation with the residual is at most λ in absolute value, and exactly λ , with the sign of the coefficient, for every column in the fit. The error of the estimate is written $\boldsymbol{\Delta} = \hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}$.

The benchmark is the **oracle** estimator, least squares on the columns in S , which could be computed if S were known. If $\mathbf{X}_S$ has full column rank and $\mathbf{M}_S$ is the projection onto $\mathcal{C}(\mathbf{X}_S)$, its fitted values are $\mathbf{M}_S \mathbf{Y} = \mathbf{X}_S \boldsymbol{\beta} + \mathbf{M}_S \boldsymbol{\varepsilon}$, so its in-sample prediction error is $E\|\mathbf{M}_S \boldsymbol{\varepsilon}\|^2/n = \sigma^2 \text{tr}(\mathbf{M}_S)/n = \sigma^2 s/n$ ([Proposition 6.3.4](#)). No estimator that does not know S can be expected to do this well. The question is how much is lost.

28.3.2 The basic inequality

Lemma 28.3.1 — Basic inequality

Every lasso estimate satisfies

$$\frac{1}{2n} \|\mathbf{X}\Delta\|^2 \leq \frac{1}{n} \boldsymbol{\varepsilon}^\top \mathbf{X}\Delta + \lambda(\|\boldsymbol{\beta}\|_1 - \|\hat{\boldsymbol{\beta}}_\lambda\|_1). \quad (28.3.3)$$

Proof. The criterion at $\hat{\boldsymbol{\beta}}_\lambda$ is at most its value at $\boldsymbol{\beta}$:

$$\frac{1}{2n} \|\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}_\lambda\|^2 + \lambda\|\hat{\boldsymbol{\beta}}_\lambda\|_1 \leq \frac{1}{2n} \|\mathbf{Y} - \mathbf{X}\boldsymbol{\beta}\|^2 + \lambda\|\boldsymbol{\beta}\|_1.$$

Since $\mathbf{Y} - \mathbf{X}\boldsymbol{\beta} = \boldsymbol{\varepsilon}$ and $\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}_\lambda = \boldsymbol{\varepsilon} - \mathbf{X}\Delta$, the left side contains $\|\boldsymbol{\varepsilon} - \mathbf{X}\Delta\|^2 = \|\boldsymbol{\varepsilon}\|^2 - 2\boldsymbol{\varepsilon}^\top \mathbf{X}\Delta + \|\mathbf{X}\Delta\|^2$. Cancelling $\|\boldsymbol{\varepsilon}\|^2/(2n)$ and rearranging gives Eq. 28.3.3. ■

The inequality compares a quadratic in Δ on the left with a linear noise term and a difference of ℓ_1 norms on the right. By Hölder's inequality, $|\boldsymbol{\varepsilon}^\top \mathbf{X}\Delta|/n \leq \|\mathbf{X}^\top \boldsymbol{\varepsilon}/n\|_\infty \|\Delta\|_1$. So the noise enters only through the largest correlation between the errors and a column of $\mathbf{X}$,

$$\|\mathbf{X}^\top \boldsymbol{\varepsilon}/n\|_\infty = \max_{j \leq p} \frac{|\mathbf{x}_j^\top \boldsymbol{\varepsilon}|}{n}.$$

The strategy is to choose λ large enough to dominate this quantity with high probability.

28.3.3 The noise event

Lemma 28.3.2 — Maximum of normal variables

Let $W_1, \dots, W_m$ be normal random variables, not necessarily independent, with mean zero and variances at most v . For every $t > 0$,

$$\Pr\left(\max_{j \leq m} |W_j| > t\right) \leq 2m \exp\left(-\frac{t^2}{2v}\right). \quad (28.3.4)$$

In particular $\max_j |W_j| \leq \sqrt{2v \log(2m/\delta)}$ with probability at least $1 - \delta$.

Proof. Let $W \sim N(0, v_j)$ with $0 < v_j \leq v$. For $u > 0$, the function e^{uw} is increasing, so Markov's inequality ($\Pr(U \geq a) \leq \mathbb{E}U/a$ for $U \geq 0$) and the normal moment generating function (Theorem 3.2.1) give

$$\Pr(W > t) = \Pr(e^{uW} \geq e^{ut}) \leq e^{-ut} \mathbb{E} e^{uW} = \exp\left(\frac{1}{2}u^2 v_j - ut\right).$$

The exponent is smallest at $u = t/v_j$, where it equals $-t^2/(2v_j) \leq -t^2/(2v)$. By symmetry $\Pr(|W| > t) \leq 2e^{-t^2/(2v)}$, and this holds trivially when $v_j = 0$. The union bound (Theorem 13.4.1(a)) over $j = 1, \dots, m$ gives Eq. 28.3.4. Setting the right side equal to

δ and solving for t gives the last statement. ■

Each $\mathbf{x}_j^\top \boldsymbol{\varepsilon}/n$ is normal with mean zero and variance $\sigma^2 \|\mathbf{x}_j\|^2/n^2 = \sigma^2/n$. For $0 < \delta < 1$ put

$$\lambda_0 = \sigma \sqrt{\frac{2 \log(2p/\delta)}{n}}, \quad \mathcal{T} = \left\{ \|\mathbf{X}^\top \boldsymbol{\varepsilon}/n\|_\infty \leq \lambda_0 \right\}. \quad (28.3.5)$$

By Lemma 28.3.2, $\Pr(\mathcal{T}) \geq 1 - \delta$, whatever the correlations among the columns. The threshold grows only like $\sqrt{\log p}$, which is why $p \gg n$ is not hopeless.

28.3.4 Prediction bounds

Theorem 28.3.3 — Prediction bounds for the lasso

Let $\lambda \geq 2\lambda_0$, and suppose the event $\mathcal{T}$ of Eq. 28.3.5 occurs. Then every lasso estimate satisfies:

- (a) (*Cone.*) $\frac{1}{n} \|\mathbf{X}\boldsymbol{\Delta}\|^2 + \lambda \|\boldsymbol{\Delta}_{S^c}\|_1 \leq 3\lambda \|\boldsymbol{\Delta}_S\|_1$. In particular $\boldsymbol{\Delta} \in \mathcal{K}(S)$.
- (b) (*Slow rate.*) $\frac{1}{n} \|\mathbf{X}\boldsymbol{\Delta}\|^2 \leq 3\lambda \|\boldsymbol{\beta}\|_1$, with no condition on $\mathbf{X}$.
- (c) (*Fast rate.*) If $\phi^2(S) > 0$, then $\frac{1}{n} \|\mathbf{X}\boldsymbol{\Delta}\|^2 \leq \frac{9\lambda^2 s}{\phi^2(S)}$.

Consequently, with $\lambda = 2\lambda_0$, with probability at least $1 - \delta$,

$$\frac{1}{n} \|\mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta})\|^2 \leq \min \left\{ 6\sigma \|\boldsymbol{\beta}\|_1 \sqrt{\frac{2 \log(2p/\delta)}{n}}, \frac{72 \sigma^2}{\phi^2(S)} \frac{s \log(2p/\delta)}{n} \right\}. \quad (28.3.6)$$

Proof. On $\mathcal{T}$, Hölder's inequality gives $|\boldsymbol{\varepsilon}^\top \mathbf{X}\boldsymbol{\Delta}|/n \leq \lambda_0 \|\boldsymbol{\Delta}\|_1 \leq (\lambda/2) \|\boldsymbol{\Delta}\|_1$.

- (a) Because $\boldsymbol{\beta}$ vanishes off S , $\|\hat{\boldsymbol{\beta}}_\lambda\|_1 = \|\boldsymbol{\beta}_S + \boldsymbol{\Delta}_S\|_1 + \|\boldsymbol{\Delta}_{S^c}\|_1 \geq \|\boldsymbol{\beta}\|_1 - \|\boldsymbol{\Delta}_S\|_1 + \|\boldsymbol{\Delta}_{S^c}\|_1$. Substituting both bounds in Eq. 28.3.3, and writing $\|\boldsymbol{\Delta}\|_1 = \|\boldsymbol{\Delta}_S\|_1 + \|\boldsymbol{\Delta}_{S^c}\|_1$,

$$\begin{aligned} \frac{1}{2n} \|\mathbf{X}\boldsymbol{\Delta}\|^2 &\leq \frac{\lambda}{2} (\|\boldsymbol{\Delta}_S\|_1 + \|\boldsymbol{\Delta}_{S^c}\|_1) + \lambda (\|\boldsymbol{\Delta}_S\|_1 - \|\boldsymbol{\Delta}_{S^c}\|_1) \\ &= \frac{3\lambda}{2} \|\boldsymbol{\Delta}_S\|_1 - \frac{\lambda}{2} \|\boldsymbol{\Delta}_{S^c}\|_1. \end{aligned}$$

Multiplying by 2 gives the inequality. Its left side is at least $\lambda \|\boldsymbol{\Delta}_{S^c}\|_1$, so $\|\boldsymbol{\Delta}_{S^c}\|_1 \leq 3\|\boldsymbol{\Delta}_S\|_1$.

(b) Use instead $\|\Delta\|_1 \leq \|\hat{\beta}_\lambda\|_1 + \|\beta\|_1$ in Eq. 28.3.3:

$$\begin{aligned} \frac{1}{2n} \|\mathbf{X}\Delta\|^2 &\leq \frac{\lambda}{2} (\|\hat{\beta}_\lambda\|_1 + \|\beta\|_1) + \lambda \|\beta\|_1 - \lambda \|\hat{\beta}_\lambda\|_1 \\ &\leq \frac{3\lambda}{2} \|\beta\|_1. \end{aligned}$$

(c) Write $a = \|\mathbf{X}\Delta\|/\sqrt{n}$. By (a), $\Delta \in \mathcal{K}(S)$, so Definition 28.2.1 gives $\phi^2(S) \leq s a^2 / \|\Delta_S\|_1^2$, that is, $\|\Delta_S\|_1 \leq \sqrt{s} a / \phi(S)$. (If $\Delta = \mathbf{0}$ there is nothing to prove.) Then (a) gives $a^2 \leq 3\lambda \|\Delta_S\|_1 \leq 3\lambda \sqrt{s} a / \phi(S)$, so $a \leq 3\lambda \sqrt{s} / \phi(S)$.

For Eq. 28.3.6, substitute $\lambda = 2\lambda_0$ in (b) and (c), and use $\Pr(\mathcal{T}) \geq 1 - \delta$.

■

The **slow rate** needs nothing of $\mathbf{X}$: the lasso predicts consistently whenever $\|\beta\|_1 \sqrt{\log p/n} \rightarrow 0$, which allows p to grow exponentially in n . Greenshtein and Ritov (2004) called this *persistence*. The **fast rate**, of order $\sigma^2 s \log p/n$, loses against the oracle's $\sigma^2 s/n$ a factor $\log p$ and the constant $72/\phi^2(S)$. The logarithm cannot be removed: no estimator that does not know S has worst-case error below a multiple of $\sigma^2 s \log(p/s)/n$ under mild conditions on the design (Raskutti, Wainwright and Yu 2011; not proved here). The constants are not sharp.

Idea. The proof has two separate parts. A *probabilistic* part shows that the noise is small in the ℓ_∞ norm dual to the penalty, at the level $\lambda_0 \asymp \sigma \sqrt{\log p/n}$. A *deterministic* part says that on this event the estimate's error lies in a cone and is controlled by the geometry of $\mathbf{X}$ on that cone. Changing the noise distribution changes only the first part. Changing the penalty changes the norm and the cone.

28.3.5 Estimation bounds

Prediction error measures Δ through $\mathbf{X}$. Bounds on the coefficients themselves need the design to separate the directions of the cone, which is what the restricted eigenvalue measures.

Theorem 28.3.4 — Estimation bounds for the lasso

Let $\lambda \geq 2\lambda_0$, and suppose $\mathcal{T}$ occurs. Then every lasso estimate satisfies:

- (a) if $\phi^2(S) > 0$, then $\|\hat{\beta}_\lambda - \beta\|_1 \leq \frac{4\lambda s}{\phi^2(S)}$;
- (b) if $\kappa^2(S) > 0$, then $\|\hat{\beta}_\lambda - \beta\| \leq \frac{3\lambda\sqrt{s}}{\kappa^2(S)}$.

With $\lambda = 2\lambda_0$, both hold with probability at least $1 - \delta$, and then $\|\hat{\beta}_\lambda - \beta\|_1 \leq 8\lambda_0 s / \phi^2(S)$ and $\|\hat{\beta}_\lambda - \beta\| \leq 6\lambda_0 \sqrt{s} / \kappa^2(S)$.

Proof. Keep the notation $a = \|\mathbf{X}\Delta\|/\sqrt{n}$ of the previous proof.

- (a) Add $\lambda \|\Delta_S\|_1$ to both sides of Theorem 28.3.3(a), and use $\|\Delta_S\|_1 \leq \sqrt{s} a / \phi(S)$ and

$$2xy \leq x^2 + y^2:$$

$$a^2 + \lambda \|\Delta\|_1 \leq 4\lambda \|\Delta_S\|_1 \leq 2 \cdot a \cdot \frac{2\lambda\sqrt{s}}{\phi(S)} \leq a^2 + \frac{4\lambda^2 s}{\phi^2(S)}.$$

Cancel a^2 and divide by λ .

(b) By [Theorem 28.3.3\(a\)](#) and [Eq. 28.2.1](#), and since $\Delta \in \mathcal{K}(S)$, by [Definition 28.2.1](#),

$$\kappa^2(S) \|\Delta\|^2 \leq a^2 \leq 3\lambda \|\Delta_S\|_1 \leq 3\lambda\sqrt{s} \|\Delta\|.$$

Dividing by $\|\Delta\|$ (when it is not zero) gives the bound.

■

With $\lambda \asymp \sigma\sqrt{\log p/n}$, the ℓ_2 error is of order $\sigma\sqrt{s \log p/n}$. The oracle has ℓ_2 error of order $\sigma\sqrt{s/n}$. Again only a logarithm is lost. Bickel, Ritov and Tsybakov (2009) proved bounds of this form for the lasso and the Dantzig selector together. The compatibility condition was introduced by van de Geer (see van de Geer and Bühlmann 2009), and Bühlmann and van de Geer (2011, chapter 6) present the prediction bound in the form given here.

Remark (What the theorems assume, and what they do not). The theorems are *deterministic* on $\mathcal{T}$; normality entered only through $\Pr(\mathcal{T}) \geq 1 - \delta$, so errors with light (sub-Gaussian) tails need the same λ_0 up to a constant. For a random design they apply conditionally on $\mathbf{X}$. The choice λ_0 needs σ ; the *square-root lasso* of Belloni, Chernozhukov and Wang (2011), which minimizes $\|\mathbf{Y} - \mathbf{X}\mathbf{b}\|/\sqrt{n} + \lambda\|\mathbf{b}\|_1$, and the *scaled lasso* of Sun and Zhang (2012) avoid this. In practice λ is chosen by cross-validation ([Chapter 29](#)), without these guarantees.

28.3.6 The bounds in numbers

Example. (How tight are the bounds?)

Take the independent Gaussian design of [Example \(Compatibility constants of Gaussian designs\)](#) with $n = 200$ and $p = 1000$, five nonzero coefficients equal to ± 1 , $\sigma = 1$ and $\delta = 0.05$. Then $\lambda_0 = 0.3255$. In 200 simulated data sets the event $\mathcal{T}$ occurred in a fraction 0.990, more than the guaranteed 0.95, because the Chernoff bound and the union bound are both conservative. The cone property of [Theorem 28.3.3\(a\)](#) held in a fraction 1.000 of the data sets.

At the theoretical choice $\lambda = 2\lambda_0 = 0.651$ the average prediction error $\|\mathbf{X}\Delta\|^2/n$ is 2.3643, against the oracle's $\sigma^2 s/n = 0.025$. The slow-rate bound $3\lambda\|\beta\|_1$ is 9.77. With the compatibility constant 0.00447 of this design, the fast-rate bound is 4269.8 (computed from the unrounded values), which is useless here. The same is true of the ℓ_1 bound 2914.8, against an actual average ℓ_1 error of 3.594.

Almost all of the error at $\lambda = 2\lambda_0$ is shrinkage. The lasso pulls each selected coefficient towards zero by about λ , and $s\lambda^2 = 2.12$ is close to the observed error. Panel (a) of [Figure 28.3.1](#) shows the whole path. The smallest average error on the path is 0.1893, at $\lambda \approx 0.39\lambda_0$, well below the theoretical choice. Below that the lasso admits many false variables and the error rises again, to 0.587 at $\lambda = 0.1\lambda_0$.

Figure 28.3.1: The lasso with $n = 200$, $s = 5$, $\sigma = 1$. (a) Average prediction error $\|\mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta})\|^2/n$ and average number of selected variables (divided by 100) along the path for $p = 1000$, against λ/λ_0 . The vertical line is the theoretical choice $\lambda = 2\lambda_0$, the dotted line the oracle error. (b) Prediction error at $\lambda = 2\lambda_0$ as p grows (logarithmic axis), with two standard errors.

Panel (b) holds $n = 200$ and $s = 5$ fixed and lets p grow from 100 to 5000 (the first p columns of one larger design), with $\lambda = 2\lambda_0$ for each p . The error grows from 1.818 to 2.665, a factor of 1.466, close to the ratio 1.472 of the values of $\log(2p/\delta)$. The error tracks the λ_0^2 in the bounds, which is logarithmic in p . The theorem gives only upper bounds, so this agreement is an observation about the example, not a consequence of the theorem.

The bounds are worst-case statements over designs and noise vectors, and for a particular design they can be very loose. What they get right is the *form* of the dependence on s , p and n , with one tuning parameter of order $\sigma\sqrt{\log p/n}$ that works for all sparse $\boldsymbol{\beta}$. They also expose the cost of shrinkage, an error of order $s\lambda^2$ even when the right variables are selected, which motivates the next two sections.

28.3.7 Exercises

28.3.7.1 A. Check your understanding

Exercise A1.

By Theorem 27.4.1(d), $\mathbf{0}$ is a lasso estimate iff $\lambda \geq \lambda_{\max} = \|\mathbf{X}^\top \mathbf{Y}\|_\infty / n$ (check this from Eq. 28.3.2). Show that it is then the only lasso estimate. Why does the theory above not rule out $2\lambda_0 > \lambda_{\max}$, and what happens then?

Solution. All lasso estimates have the same ℓ_1 norm (Theorem 27.4.1(c)), and that of $\mathbf{0}$ is zero; so every lasso estimate is $\mathbf{0}$. If $2\lambda_0 > \lambda_{\max}$ and $\lambda \geq \lambda_{\max}$, the lasso returns $\mathbf{0}$, and the theorems still hold: the error is $-\beta$, and the bounds then say that β is small compared with the noise level. They are not violated, only uninformative.

Exercise A2.

Show that for every $\mathbf{b} \in \mathbb{R}^p$ a lasso estimate satisfies

$$\frac{1}{2n} \|\mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta})\|^2 \leq \frac{1}{2n} \|\mathbf{X}(\mathbf{b} - \boldsymbol{\beta})\|^2 + \frac{1}{n} \boldsymbol{\varepsilon}^\top \mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \mathbf{b}) + \lambda(\|\mathbf{b}\|_1 - \|\hat{\boldsymbol{\beta}}_\lambda\|_1),$$

and that $\mathbf{b} = \boldsymbol{\beta}$ gives [Lemma 28.3.1](#). Deduce that on $\mathcal{T}$, with $\lambda \geq 2\lambda_0$,

$$\frac{1}{n} \|\mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta})\|^2 \leq \min_{\mathbf{b} \in \mathbb{R}^p} \left\{ \frac{1}{n} \|\mathbf{X}(\mathbf{b} - \boldsymbol{\beta})\|^2 + 3\lambda \|\mathbf{b}\|_1 \right\}.$$

This oracle inequality suits an approximately sparse $\boldsymbol{\beta}$: $\mathbf{b}$ can keep its large entries and drop the small ones.

Solution. Compare the criterion [Eq. 28.3.1](#) at $\hat{\boldsymbol{\beta}}_\lambda$ and at $\mathbf{b}$, expanding $\|\mathbf{X}(\boldsymbol{\beta} - \mathbf{b}) + \boldsymbol{\varepsilon}\|^2 = \|\mathbf{X}(\mathbf{b} - \boldsymbol{\beta})\|^2 - 2\boldsymbol{\varepsilon}^\top \mathbf{X}(\mathbf{b} - \boldsymbol{\beta}) + \|\boldsymbol{\varepsilon}\|^2$ and likewise at $\hat{\boldsymbol{\beta}}_\lambda$; the $\|\boldsymbol{\varepsilon}\|^2$ terms cancel. On $\mathcal{T}$, Hölder's inequality gives $|\boldsymbol{\varepsilon}^\top \mathbf{X}(\hat{\boldsymbol{\beta}}_\lambda - \mathbf{b})|/n \leq \lambda_0 \|\hat{\boldsymbol{\beta}}_\lambda - \mathbf{b}\|_1 \leq (\lambda/2)(\|\hat{\boldsymbol{\beta}}_\lambda\|_1 + \|\mathbf{b}\|_1)$. So the right side is at most $\|\mathbf{X}(\mathbf{b} - \boldsymbol{\beta})\|^2/(2n) + \frac{3}{2}\lambda \|\mathbf{b}\|_1 - \frac{1}{2}\lambda \|\hat{\boldsymbol{\beta}}_\lambda\|_1$. Drop the last term, multiply by 2, and minimize over $\mathbf{b}$. At $\mathbf{b} = \boldsymbol{\beta}$ this is the slow rate of [Theorem 28.3.3\(b\)](#). An analogue with $\lambda^2 s/\phi^2$ in place of $3\lambda \|\mathbf{b}\|_1$, under a compatibility condition, is in Bühlmann and van de Geer (2011, chapter 6).

28.3.7.2 B. Practice**Exercise B1.**

Let $p \leq n$ and $\hat{\boldsymbol{\Sigma}} = \mathbf{I}$. Using [Theorem 27.4.2](#), the lasso estimate is $\hat{\beta}_{\lambda,j} = \text{sign}(z_j)(|z_j| - \lambda)_+$ with $\mathbf{z} = \mathbf{X}^\top \mathbf{Y}/n = \boldsymbol{\beta} + \mathbf{X}^\top \boldsymbol{\varepsilon}/n$. On $\mathcal{T}$, with $\lambda \geq 2\lambda_0$, show that $\hat{\beta}_{\lambda,j} = 0$ for $j \notin S$, that $|\hat{\beta}_{\lambda,j} - \beta_j| \leq \lambda + \lambda_0$ for $j \in S$, and hence $\|\mathbf{X}\boldsymbol{\Delta}\|^2/n \leq \frac{9}{4}\lambda^2 s$. Show also that if every $|\beta_j|$, $j \in S$, exceeds $\lambda + \lambda_0$, then $\|\mathbf{X}\boldsymbol{\Delta}\|^2/n \geq \frac{1}{4}\lambda^2 s$. So the order $\lambda^2 s$ of [Theorem 28.3.3\(c\)](#) is attained.

Solution. With $\hat{\boldsymbol{\Sigma}} = \mathbf{I}$, $\|\mathbf{X}\boldsymbol{\Delta}\|^2/n = \|\boldsymbol{\Delta}\|^2$. For $j \notin S$, $|z_j| = |\mathbf{x}_j^\top \boldsymbol{\varepsilon}|/n \leq \lambda_0 < \lambda$, so the estimate is zero. For $j \in S$, soft thresholding moves z_j by at most λ , and $|z_j - \beta_j| \leq \lambda_0$, so $|\hat{\beta}_{\lambda,j} - \beta_j| \leq \lambda + \lambda_0 \leq \frac{3}{2}\lambda$. Summing squares over S gives the upper bound. If $|\beta_j| > \lambda + \lambda_0$, then $|z_j| > \lambda$, so $\hat{\beta}_{\lambda,j} = z_j - \lambda \text{sign}(z_j)$ with the sign of β_j , and $|\hat{\beta}_{\lambda,j} - \beta_j| \geq \lambda - \lambda_0 \geq \lambda/2$. Summing gives the lower bound. The error of order $\lambda^2 s$ is pure shrinkage.

28.3.7.3 C. Going deeper**Exercise C1.**

(*The Dantzig selector.*) Candès and Tao (2007) proposed to estimate $\boldsymbol{\beta}$ by a solution $\tilde{\boldsymbol{\beta}}$ of: minimize $\|\mathbf{b}\|_1$ subject to $\|\mathbf{X}^\top (\mathbf{Y} - \mathbf{X}\mathbf{b})\|_\infty/n \leq \lambda_0$. On $\mathcal{T}$, show that $\boldsymbol{\beta}$ is feasible, that $\boldsymbol{\Delta} = \tilde{\boldsymbol{\beta}} - \boldsymbol{\beta}$ satisfies $\|\boldsymbol{\Delta}_{S^c}\|_1 \leq \|\boldsymbol{\Delta}_S\|_1$, and that $\|\mathbf{X}\boldsymbol{\Delta}\|^2/n \leq 16\lambda_0^2 s/\phi^2(S)$.

Solution. On $\mathcal{T}$, $\|\mathbf{X}^\top (\mathbf{Y} - \mathbf{X}\boldsymbol{\beta})\|_\infty/n = \|\mathbf{X}^\top \boldsymbol{\varepsilon}\|_\infty/n \leq \lambda_0$, so $\boldsymbol{\beta}$ is feasible and $\|\tilde{\boldsymbol{\beta}}\|_1 \leq \|\boldsymbol{\beta}\|_1$. The argument of [Theorem 28.3.3\(a\)](#) gives $\|\boldsymbol{\beta}\|_1 \geq \|\tilde{\boldsymbol{\beta}}\|_1 \geq \|\boldsymbol{\beta}\|_1 - \|\boldsymbol{\Delta}_S\|_1 +$

$\|\Delta_{S^c}\|_1$, which is the cone property with constant 1. Since both $\tilde{\beta}$ and β are feasible, $\|\mathbf{X}^\top \mathbf{X} \Delta\|_\infty / n \leq 2\lambda_0$, and by Hölder $\|\mathbf{X} \Delta\|^2 / n = \Delta^\top \mathbf{X}^\top \mathbf{X} \Delta / n \leq 2\lambda_0 \|\Delta\|_1 \leq 4\lambda_0 \|\Delta_S\|_1$. The cone with constant 1 lies inside $\mathcal{K}(S)$, so $\|\Delta_S\|_1 \leq \sqrt{s} \|\mathbf{X} \Delta\| / (\sqrt{n} \phi(S))$. Combining, $\|\mathbf{X} \Delta\| / \sqrt{n} \leq 4\lambda_0 \sqrt{s} / \phi(S)$, and squaring gives the bound.

28.4 Support recovery

Good prediction does not require the right variables: the bounds of [Section 28.3](#) allow false variables with small coefficients and missed true ones. Often, though, the variables are the object of interest. This section asks when the lasso selects *exactly* the right variables with the right signs. The answer needs a condition on the design much stronger than those of [Section 28.2](#), and it fails in simple, realistic examples.

28.4.1 Uniqueness

The question “which variables does the lasso select?” needs an answer that does not depend on which minimizer is reported.

Lemma 28.4.1 — Uniqueness of the lasso fit

- (a) All lasso estimates at a given λ have the same fitted values $\mathbf{X} \hat{\beta}_\lambda$ and the same ℓ_1 norm. Hence they share the vector $\hat{\mathbf{z}} = \mathbf{X}^\top (\mathbf{Y} - \mathbf{X} \hat{\beta}_\lambda) / (n\lambda)$ of [Eq. 28.3.2](#).
- (b) Let $\hat{\beta}_\lambda$ be a lasso estimate with support $\hat{S}$. If $|\hat{z}_j| < 1$ for every $j \notin \hat{S}$ and $\mathbf{X}_{\hat{S}}$ has full column rank, then $\hat{\beta}_\lambda$ is the only lasso estimate.

Proof.

- (a) The first statement is [Theorem 27.4.1\(c\)](#). The vector $\hat{\mathbf{z}}$ depends on $\hat{\beta}_\lambda$ only through $\mathbf{X} \hat{\beta}_\lambda$.
- (b) Let $\mathbf{b}$ be any lasso estimate. By (a) its optimality conditions [Eq. 28.3.2](#) hold with the same $\hat{\mathbf{z}}$. If $b_j \neq 0$ then $\hat{z}_j = \text{sign}(b_j)$, so $|\hat{z}_j| = 1$ and $j \in \hat{S}$. Thus $\mathbf{b}$ is supported on $\hat{S}$, and $\mathbf{X}_{\hat{S}} \mathbf{b}_{\hat{S}} = \mathbf{X} \mathbf{b} = \mathbf{X} \hat{\beta}_\lambda = \mathbf{X}_{\hat{S}} \hat{\beta}_{\lambda, \hat{S}}$. Full column rank of $\mathbf{X}_{\hat{S}}$ gives $\mathbf{b} = \hat{\beta}_\lambda$. ■

28.4.2 The irrepresentable condition

When will the lasso choose exactly S ? Suppose for a moment that it does, with the correct signs $\mathbf{z}_S = \text{sign}(\beta_S)$. Then [Eq. 28.3.2](#) on S determines the estimate: $\mathbf{X}_S^\top (\mathbf{Y} - \mathbf{X}_S \hat{\beta}_S) / n = \lambda \mathbf{z}_S$, so

$$\begin{aligned} \hat{\beta}_S &= (\mathbf{X}_S^\top \mathbf{X}_S)^{-1} (\mathbf{X}_S^\top \mathbf{Y} - n\lambda \mathbf{z}_S) \\ &= \beta_S + (\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{X}_S^\top \boldsymbol{\varepsilon} - \lambda \hat{\Sigma}_{SS}^{-1} \mathbf{z}_S, \end{aligned} \tag{28.4.1}$$

where $\hat{\Sigma}_{SS} = \mathbf{X}_S^\top \mathbf{X}_S / n$. The estimate is least squares on the true support, shifted towards zero by $\lambda \hat{\Sigma}_{SS}^{-1} \mathbf{z}_S$. For each $k \notin S$, the optimality conditions also require $|\mathbf{x}_k^\top (\mathbf{Y} - \mathbf{X}_S \hat{\boldsymbol{\beta}}_S)| \leq n\lambda$. Since $\mathbf{Y} - \mathbf{X}_S \hat{\boldsymbol{\beta}}_S = (\mathbf{I} - \mathbf{M}_S) \boldsymbol{\varepsilon} + n\lambda \mathbf{X}_S (\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{z}_S$, where $\mathbf{M}_S$ projects onto $\mathcal{C}(\mathbf{X}_S)$, this reads

$$\left| \underbrace{\mathbf{x}_k^\top \mathbf{X}_S (\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{z}_S}_{a_k} + \frac{\mathbf{x}_k^\top (\mathbf{I} - \mathbf{M}_S) \boldsymbol{\varepsilon}}{n\lambda} \right| \leq 1. \quad (28.4.2)$$

The first term does not involve the noise at all. The vector $(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{X}_S^\top \mathbf{x}_k$ holds the least squares coefficients of $\mathbf{x}_k$ on the active columns, and a_k is their sum weighted by the true signs. If an inactive column is well explained by the active ones, with coefficients that line up with the signs of $\boldsymbol{\beta}_S$, then $|a_k|$ is large and the condition is hard to meet.

Definition 28.4.1 — Irrepresentable and beta-min conditions

Let $\mathbf{X}_S$ have full column rank. The design satisfies the **irrepresentable condition** for $\boldsymbol{\beta}$ with margin $\eta \in (0, 1]$ if

$$\max_{k \notin S} |\mathbf{x}_k^\top \mathbf{X}_S (\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \text{sign}(\boldsymbol{\beta}_S)| \leq 1 - \eta.$$

A **beta-min condition** is a lower bound on $\beta_{\min} = \min_{j \in S} |\beta_j|$.

The condition depends on the design and on the signs of the true coefficients, but not on their sizes. It holds with $\eta = 1$ when the inactive columns are orthogonal to the active ones. It is much stronger than the compatibility condition. van de Geer and Bühlmann (2009) compare the two and show that a uniform version of the irrepresentable condition implies compatibility; the example below shows that the converse fails.

28.4.3 Sufficient conditions

Theorem 28.4.2 — Sign recovery by the lasso

Suppose $\lambda_{\min}(\hat{\Sigma}_{SS}) \geq C_{\min} > 0$ and the irrepresentable condition holds with margin η . Let $\lambda > 0$, put $g = \lambda \|\hat{\Sigma}_{SS}^{-1} \text{sign}(\boldsymbol{\beta}_S)\|_\infty$, and suppose $\beta_{\min} > g$. Consider the events

$$\mathcal{A} = \left\{ \max_{k \notin S} \frac{|\mathbf{x}_k^\top (\mathbf{I} - \mathbf{M}_S) \boldsymbol{\varepsilon}|}{n} < \eta\lambda \right\},$$

$$\mathcal{B} = \left\{ \|(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{X}_S^\top \boldsymbol{\varepsilon}\|_\infty < \beta_{\min} - g \right\}.$$

- (a) On $\mathcal{A} \cap \mathcal{B}$ the lasso estimate is unique and $\text{sign}(\hat{\boldsymbol{\beta}}_\lambda) = \text{sign}(\boldsymbol{\beta})$. In particular its support is exactly S .
- (b) The probabilities of the complements satisfy

$$\Pr(\mathcal{A}^c) \leq 2(p - s) \exp\left\{-\frac{n\eta^2\lambda^2}{2\sigma^2}\right\}, \quad \Pr(\mathcal{B}^c) \leq 2s \exp\left\{-\frac{nC_{\min}(\beta_{\min} - g)^2}{2\sigma^2}\right\}.$$

(c) Consequently, if

$$\lambda = \frac{\sigma}{\eta} \sqrt{\frac{2 \log\{4(p-s)/\delta\}}{n}} \quad \text{and} \quad \beta_{\min} \geq g + \sigma \sqrt{\frac{2 \log(4s/\delta)}{nC_{\min}}},$$

the lasso recovers the signs of $\boldsymbol{\beta}$ with probability at least $1 - \delta$.

Proof.

(a) Construct a candidate and check that it is optimal. This is the *primal–dual witness* argument. Let $\mathbf{z}_S = \text{sign}(\boldsymbol{\beta}_S)$, let $\check{\boldsymbol{\beta}}$ be zero off S with $\check{\boldsymbol{\beta}}_S$ given by the right side of Eq. 28.4.1, and let $\check{\mathbf{z}} = \mathbf{X}^\top (\mathbf{Y} - \mathbf{X}\check{\boldsymbol{\beta}})/(n\lambda)$.

On S . By construction $\mathbf{X}_S^\top (\mathbf{Y} - \mathbf{X}_S\check{\boldsymbol{\beta}}_S) = n\lambda \mathbf{z}_S$, so $\check{\mathbf{z}}_S = \mathbf{z}_S$. By Eq. 28.4.1, for $j \in S$, $|\check{\beta}_j - \beta_j| \leq \|(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{X}_S^\top \boldsymbol{\varepsilon}\|_\infty + g < \beta_{\min} \leq |\beta_j|$ on $\mathcal{B}$. So $\check{\beta}_j$ is nonzero with the sign of β_j , and $\check{z}_j = \text{sign}(\check{\beta}_j)$.

Off S . Since $\mathbf{X}\boldsymbol{\beta} = \mathbf{X}_S\boldsymbol{\beta}_S \in \mathcal{C}(\mathbf{X}_S)$, $(\mathbf{I} - \mathbf{M}_S)\mathbf{Y} = (\mathbf{I} - \mathbf{M}_S)\boldsymbol{\varepsilon}$, and

$$\mathbf{Y} - \mathbf{X}_S\check{\boldsymbol{\beta}}_S = \mathbf{Y} - \mathbf{M}_S\mathbf{Y} + n\lambda \mathbf{X}_S(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{z}_S = (\mathbf{I} - \mathbf{M}_S)\boldsymbol{\varepsilon} + n\lambda \mathbf{X}_S(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{z}_S.$$

So for $k \notin S$, $\check{z}_k = a_k + \mathbf{x}_k^\top (\mathbf{I} - \mathbf{M}_S)\boldsymbol{\varepsilon}/(n\lambda)$, with $|a_k| \leq 1 - \eta$ by the irrepresentable condition. On $\mathcal{A}$, $|\check{z}_k| < 1 - \eta + \eta = 1$.

So $\check{\boldsymbol{\beta}}$ and $\check{\mathbf{z}}$ satisfy Eq. 28.3.2, and $\check{\boldsymbol{\beta}}$ is a lasso estimate, because the conditions are sufficient (Theorem 27.4.1(b)). Its support is S , $\mathbf{X}_S$ has full column rank because $C_{\min} > 0$, and $|\check{z}_k| < 1$ off S . By Lemma 28.4.1(b) it is the only lasso estimate.

(b) $\mathbf{x}_k^\top (\mathbf{I} - \mathbf{M}_S)\boldsymbol{\varepsilon}/n$ is normal with mean zero and variance $\sigma^2 \|(\mathbf{I} - \mathbf{M}_S)\mathbf{x}_k\|^2/n^2 \leq \sigma^2 \|\mathbf{x}_k\|^2/n^2 = \sigma^2/n$. The j th entry of $(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \mathbf{X}_S^\top \boldsymbol{\varepsilon}$ is normal with mean zero and variance $\sigma^2 [(\mathbf{X}_S^\top \mathbf{X}_S)^{-1}]_{jj} \leq \sigma^2/(nC_{\min})$, by Theorem 1.7.7 applied to $(\mathbf{X}_S^\top \mathbf{X}_S)^{-1}$, whose largest eigenvalue is $1/(nC_{\min})$ at most. Apply Lemma 28.3.2 with $t = \eta\lambda$ and $t = \beta_{\min} - g$. The events in the lemma use $>$, and the events here use $\geq$, which have the same probability for normal variables with positive variance (and probability zero for those with zero variance).

(c) With the stated λ , the first bound in (b) equals $\delta/2$. With the stated $\beta_{\min}$, the second is at most $\delta/2$.

■

The three hypotheses ask that the active columns be well conditioned ($C_{\min}$), that the inactive ones not be representable by them (η), and that the coefficients stand out from noise and shrinkage ($\beta_{\min}$). Since $g \leq \lambda\sqrt{s/C_{\min}}$, the last asks in the worst case for every nonzero coefficient to exceed a multiple of $\sigma\sqrt{s \log p/n}$. The theorem in this form is due to Wainwright (2009).

28.4.4 The condition is also necessary

Proposition 28.4.3 — Failure of the irrepresentable condition

Let $\mathbf{X}_S$ have full column rank, and suppose that for some $k \notin S$

$$|a_k| = |\mathbf{x}_k^\top \mathbf{X}_S(\mathbf{X}_S^\top \mathbf{X}_S)^{-1} \text{sign}(\boldsymbol{\beta}_S)| > 1.$$

Then the probability that for some $\lambda > 0$ some lasso estimate has $\text{sign}(\hat{\beta}_\lambda) = \text{sign}(\beta)$ is at most $\frac{1}{2}$.

Proof. Suppose a lasso estimate at some $\lambda > 0$ has the signs of β . Its support is S , so by the calculation leading to Eq. 28.4.2, $|a_k + W_k/(n\lambda)| \leq 1$, where $W_k = \mathbf{x}_k^\top (\mathbf{I} - \mathbf{M}_S) \varepsilon$. Since $|a_k| > 1$, this forces $\text{sign}(a_k) W_k/(n\lambda) \leq 1 - |a_k| < 0$, so $\text{sign}(a_k) W_k < 0$. The event in question is therefore contained in $\{\text{sign}(a_k) W_k < 0\}$, which does not depend on λ . W_k is normal with mean zero, so this event has probability $\frac{1}{2}$ if $(\mathbf{I} - \mathbf{M}_S) \mathbf{x}_k \neq \mathbf{0}$, and probability zero otherwise. ■

The argument is due to Zhao and Yu (2006), who showed in addition that the condition with ≤ 1 is necessary for sign consistency. The bound $\frac{1}{2}$ does not improve with more data. Sampling more observations cannot repair a design in which an inactive variable imitates the active ones with coefficients aligned with their signs. In the noiseless limit the lasso *never* recovers the signs (Exercise (C1)).

Example. (An inactive variable that looks active)

Let x_1, x_2 be independent standard normal regressors, let x_3 have correlation r with each of them, and let $x_4, \dots, x_{500}$ be independent noise variables, with $Y = 0.5x_1 + 0.5x_2 + \varepsilon$ and $\sigma = 1$. The population coefficients of x_3 on (x_1, x_2) are (r, r) , so $a_3 = 2r$ (Exercise (A1)). With $r = 0.3$ the condition holds with margin 0.4; with the moderate correlation $r = 0.6$ it fails. Both population designs have $\lambda_{\min}(\Sigma) > 0$, so both are benign for prediction.

Figure 28.4.1(a) shows, for each sample size, the fraction of 200 data sets (fixed design, new errors) for which *some* penalty on a fine grid gives exactly the right signs. When the condition holds, this rises from 0.12 at $n = 50$ to 0.66 at $n = 100$ and 1.000 at $n = 800$. When it fails, it rises only slowly, from 0.03 at $n = 100$ to 0.155 at $n = 800$, and it can never exceed the bound $\frac{1}{2}$ of Proposition 28.4.3, however large n is. The sample irrepresentable quantities at $n = 800$ are 0.66 and 1.21.

Panel (b) shows why. Along the lasso path for one data set with $r = 0.6$ and $n = 800$, the inactive x_3 is the first variable to enter, because its inner product $\mathbf{x}_3^\top \mathbf{X} \beta / n$ with the signal (the mean of the $\mathbf{x}_3^\top \mathbf{Y} / n$ that decides which variable enters first) is 0.62 in this sample (0.6 in the population) and exceeds that of x_1 and x_2 (0.5 each). It never leaves. The lasso finds x_1 and x_2 later, but always together with x_3 .

```
import numpy as np

def soft(z, t):
    """Soft thresholding  $S(z, t) = \text{sign}(z) \max(|z| - t, 0)$ ."""
    return np.sign(z) * np.maximum(np.abs(z) - t, 0.0)

def lasso_cd(X, Y, lam, B=None, tol=1e-9, max_sweeps=2000):

```

28.4.5 Screening instead of selection

A weaker goal, often enough in practice, is **screening**: the selected set should *contain* S , with false variables left for a second stage to remove. It needs only the restricted eigenvalue and a beta-min condition.

Proposition 28.4.4 — Variable screening

Suppose $\lambda \geq 2\lambda_0$, the event $\mathcal{T}$ of Eq. 28.3.5 occurs, $\kappa^2(S) > 0$, and $\beta_{\min} > 3\lambda\sqrt{s}/\kappa^2(S)$. Then every lasso estimate has $\hat{S} \supseteq S$.

Proof. If $j \in S$ and $\hat{\beta}_{\lambda,j} = 0$, then $|\hat{\beta}_{\lambda,j} - \beta_j| = |\beta_j| \geq \beta_{\min}$. By Theorem 28.3.4(b), $|\hat{\beta}_{\lambda,j} - \beta_j| \leq \|\hat{\beta}_\lambda - \beta\| \leq 3\lambda\sqrt{s}/\kappa^2(S) < \beta_{\min}$, a contradiction. ■

In Example (An inactive variable that looks active) with $r = 0.6$, screening succeeds where selection fails: x_1 and x_2 are found, together with x_3 . Second stages build on this. The **thresholded lasso** discards small coefficients and needs no irrepresentable condition (Exercise (B2)). The **adaptive lasso** of Zou (2006) refits with penalty weights $1/|\hat{\beta}_j|$ from a first stage, and **stability selection** (Meinshausen and Bühlmann 2010) keeps the variables selected in most subsamples. All need beta-min conditions; none can find a coefficient below the noise level.

Warning. The lasso's selected set is a random set that depends on small features of the data, especially among correlated regressors. Reporting it as “the important variables” without an assessment of its stability invites overinterpretation. [Section 28.5](#) shows what goes wrong if the selected set is then treated as fixed.

28.4.6 Exercises

28.4.6.1 A. Check your understanding

Exercise A1.

In the population version of [Example \(An inactive variable that looks active\)](#), with $\Sigma_{SS} = \mathbf{I}_2$ and $\Sigma_{3S} = (r, r)$, compute $\Sigma_{3S}\Sigma_{SS}^{-1}\text{sign}(\boldsymbol{\beta}_S)$ for $\boldsymbol{\beta}_S = (0.5, 0.5)$ and for $\boldsymbol{\beta}_S = (0.5, -0.5)$. For which signs does the irrepresentable condition fail?

Solution. $\Sigma_{3S}\Sigma_{SS}^{-1} = (r, r)$. With signs $(1, 1)$ the quantity is $2r$, which exceeds 1 for $r > \frac{1}{2}$. With signs $(1, -1)$ it is 0, so the condition holds with $\eta = 1$. The trouble arises only when x_3 imitates the combination $x_1 + x_2$ that appears in the signal.

28.4.6.2 B. Practice

Exercise B1.

Let $\Sigma = (1-\rho)\mathbf{I} + \rho\mathbf{1}\mathbf{1}^\top$ with $0 \leq \rho < 1$. Show that $\Sigma_{kS}\Sigma_{SS}^{-1}\mathbf{z}_S = \rho(\mathbf{1}^\top\mathbf{z}_S)/\{1+(s-1)\rho\}$ for $k \notin S$, and conclude that the population irrepresentable condition holds for every sign pattern, with margin at least $(1-\rho)/\{1+(s-1)\rho\}$.

Exercise B2.

(*Thresholded lasso.*) Under the assumptions of [Theorem 28.3.4\(b\)](#), let $B = 3\lambda\sqrt{s}/\kappa^2(S)$ and suppose $\beta_{\min} > 2B$. Show that $\{j : |\hat{\beta}_{\lambda,j}| > B\} = S$, and that the signs of the retained coefficients are correct. No irrepresentable condition is needed.

Solution. Every coordinate satisfies $|\hat{\beta}_{\lambda,j} - \beta_j| \leq \|\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}\| \leq B$. For $j \notin S$, $|\hat{\beta}_{\lambda,j}| \leq B$, so j is discarded. For $j \in S$, $|\hat{\beta}_{\lambda,j}| \geq |\beta_j| - B > 2B - B = B$, so j is kept, and $\hat{\beta}_{\lambda,j}$ lies within $B < |\beta_j|$ of β_j , so it has the same sign. The price is the stronger beta-min condition $\beta_{\min} > 6\lambda\sqrt{s}/\kappa^2(S)$ and a threshold that depends on the unknown κ and s .

28.4.6.3 C. Going deeper

Exercise C1.

Let $\sigma = 0$, so $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta}$, and let $\mathbf{X}_S$ have full column rank. Show that if $\max_{k \notin S} |a_k| < 1$, then every λ with $0 < \lambda < \beta_{\min}/\|\hat{\Sigma}_{SS}^{-1}\text{sign}(\boldsymbol{\beta}_S)\|_\infty$ gives a unique lasso estimate with the correct signs, and that if $|a_k| > 1$ for some $k \notin S$, then no $\lambda > 0$ does.

Solution. With $\varepsilon = \mathbf{0}$, the events $\mathcal{A}$ and $\mathcal{B}$ of [Theorem 28.4.2](#) hold whenever $\eta > 0$ and $\beta_{\min} > g$, which is the stated range of λ , with $\eta = 1 - \max_k |a_k|$. Part (a) of the theorem applies, and its proof uses no probability. Conversely, if some lasso estimate had the correct signs, [Eq. 28.4.2](#) with $\varepsilon = \mathbf{0}$ would require $|a_k| \leq 1$ for all $k \notin S$. So with perfect data, the irrepresentable condition (in its weak form) is necessary and, with strict inequality, sufficient.

28.5 Post-selection and debiased inference

This section turns to confidence intervals and tests for a single coefficient β_j when $p > n$. Two tempting approaches fail: least squares intervals for the model the lasso selected, as if it had been fixed in advance, and intervals around the lasso estimate itself, whose shrinkage bias is at least as large as its standard error. The fix is a one-step correction of the lasso, which turns out to be the Frisch–Waugh–Lovell theorem with a lasso in place of a projection.

28.5.1 Why intervals after selection fail

The least squares interval of [Theorem 12.1.1](#) has coverage $1 - \alpha$ for a model fixed before the data are seen. After selection, the interval for β_j is computed only in the samples where x_j was selected, which are those in which its estimated effect happened to be large. Conditional on selection the estimate is biased away from zero, and the interval is centred in the wrong place. This is the winner’s curse of [Chapter 29](#) ([Proposition 29.5.1](#)), and the multiplicity problem of [Chapter 13](#) in another form. With the lasso and $p > n$ it is severe, because the selection is among hundreds or thousands of candidates.

Leeb and Pötscher (2006) proved that this cannot be repaired by estimating the distribution of the post-selection estimator, which depends on the unknown coefficients in a way that no estimator can track uniformly. One can change the target (the selected model’s coefficients, conditional on the selection) or the estimator. This section changes the estimator.

The lasso estimate itself is no better as a centre for an interval. On the event of [Theorem 28.4.2](#), [Eq. 28.4.1](#) shows that it equals least squares on S minus $\lambda \hat{\Sigma}_{SS}^{-1} \text{sign}(\beta_S)$. The shift is of order $\lambda \asymp \sigma \sqrt{\log p/n}$, which is larger than the standard error $\sigma/\sqrt{n}$ of the oracle estimate by the factor $\sqrt{\log p}$. An interval of the usual width centred at the lasso estimate misses the truth more and more often as p grows.

28.5.2 The debiased lasso

Write $\hat{\Sigma} = \mathbf{X}^\top \mathbf{X}/n$, and let $\hat{\Theta}$ be a $p \times p$ matrix computed from $\mathbf{X}$ alone, meant to act like an inverse of $\hat{\Sigma}$ (which does not exist when $p > n$). Its rows are $\hat{\theta}_1^\top, \dots, \hat{\theta}_p^\top$.

Definition 28.5.1 — Debiased lasso

Given a lasso estimate $\hat{\beta}_\lambda$ and $\hat{\Theta}$, the **debiased** (or **desparsified**) lasso is

$$\hat{\mathbf{b}} = \hat{\boldsymbol{\beta}}_\lambda + \frac{1}{n} \hat{\boldsymbol{\Theta}} \mathbf{X}^\top (\mathbf{Y} - \mathbf{X} \hat{\boldsymbol{\beta}}_\lambda). \quad (28.5.1)$$

Its j th entry uses only the row $\hat{\boldsymbol{\theta}}_j$. The quantity $\mu_j = \|\hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j - \mathbf{e}_j\|_\infty$ measures how far $\hat{\boldsymbol{\theta}}_j$ is from being the j th row of an inverse of $\hat{\boldsymbol{\Sigma}}$.

The correction adds to the lasso a multiple of the residual correlations $\mathbf{X}^\top (\mathbf{Y} - \mathbf{X} \hat{\boldsymbol{\beta}}_\lambda)/n$. If $\hat{\boldsymbol{\Sigma}}$ were invertible and $\hat{\boldsymbol{\Theta}} = \hat{\boldsymbol{\Sigma}}^{-1}$, $\hat{\mathbf{b}}$ would be the least squares estimate (Exercise (A1)).

Theorem 28.5.1 — Debiased lasso

In the setting of Section 28.3, let $\hat{\boldsymbol{\Theta}}$ depend on $\mathbf{X}$ only, and let $\hat{\mathbf{b}}$ be the debiased lasso.

- (a) (*Decomposition.*) $\sqrt{n}(\hat{\mathbf{b}} - \boldsymbol{\beta}) = \mathbf{w} + \mathbf{r}$, where $\mathbf{w} = \hat{\boldsymbol{\Theta}} \mathbf{X}^\top \boldsymbol{\varepsilon} / \sqrt{n} \sim N_p(\mathbf{0}, \sigma^2 \hat{\boldsymbol{\Theta}} \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\Theta}}^\top)$ exactly, and $\mathbf{r} = -\sqrt{n}(\hat{\boldsymbol{\Theta}} \hat{\boldsymbol{\Sigma}} - \mathbf{I})(\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta})$.
- (b) (*Remainder.*) $|r_j| \leq \sqrt{n} \mu_j \|\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}\|_1$. If $\lambda \geq 2\lambda_0$, $\phi^2(S) > 0$ and $\mathcal{T}$ occurs, then $|r_j| \leq 4\sqrt{n} \mu_j \lambda s / \phi^2(S)$.
- (c) (*Variance.*) If $\mu_j < 1$, then $\omega_j^2 = \hat{\boldsymbol{\theta}}_j^\top \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j \geq (1 - \mu_j)^2$.
- (d) (*Asymptotic normality.*) Consider a sequence of such problems with $n \rightarrow \infty$, in which $p, s, \mathbf{X}, \boldsymbol{\beta}$ and $\hat{\boldsymbol{\Theta}}$ may change with n and σ is fixed. Suppose $\lambda = 2\lambda_0$ with $\delta = \delta_n \rightarrow 0$ and $\log(1/\delta_n) = O(\log p)$; $\phi^2(S) \geq \phi_0^2 > 0$; $\mu_j \leq C\sqrt{\log p/n}$ for a constant C ; $s \log p / \sqrt{n} \rightarrow 0$; and $\hat{\sigma}/\sigma \rightarrow 1$ in probability. Then

$$T_j = \frac{\sqrt{n}(\hat{b}_j - \beta_j)}{\hat{\sigma} \omega_j} \rightarrow N(0, 1) \quad \text{in distribution,} \quad (28.5.2)$$

and the interval $\hat{b}_j \pm z_{\alpha/2} \hat{\sigma} \omega_j / \sqrt{n}$ has coverage tending to $1 - \alpha$.

Proof.

- (a) Substitute $\mathbf{Y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}$ in Eq. 28.5.1 and write $\boldsymbol{\Delta} = \hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}$:

$$\hat{\mathbf{b}} - \boldsymbol{\beta} = \boldsymbol{\Delta} + \frac{1}{n} \hat{\boldsymbol{\Theta}} \mathbf{X}^\top (\boldsymbol{\varepsilon} - \mathbf{X} \boldsymbol{\Delta}) = \frac{1}{n} \hat{\boldsymbol{\Theta}} \mathbf{X}^\top \boldsymbol{\varepsilon} - (\hat{\boldsymbol{\Theta}} \hat{\boldsymbol{\Sigma}} - \mathbf{I}) \boldsymbol{\Delta}.$$

Multiply by $\sqrt{n}$. Since $\hat{\boldsymbol{\Theta}}$ is a fixed matrix, $\mathbf{w}$ is a linear function of $\boldsymbol{\varepsilon}$, hence normal with mean zero and covariance $\hat{\boldsymbol{\Theta}} \mathbf{X}^\top (\sigma^2 \mathbf{I}) \mathbf{X} \hat{\boldsymbol{\Theta}}^\top / n = \sigma^2 \hat{\boldsymbol{\Theta}} \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\Theta}}^\top$ (Theorem 3.3.1).

- (b) The j th row of $\hat{\boldsymbol{\Theta}} \hat{\boldsymbol{\Sigma}} - \mathbf{I}$ is $(\hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j - \mathbf{e}_j)^\top$, because $\hat{\boldsymbol{\Sigma}}$ is symmetric. By Hölder's inequality $|r_j| \leq \sqrt{n} \mu_j \|\boldsymbol{\Delta}\|_1$. The second bound follows from Theorem 28.3.4(a).
- (c) The columns of $\mathbf{X}$ have $\|\mathbf{x}_j\|^2 = n$, so $\mathbf{e}_j^\top \hat{\boldsymbol{\Sigma}} \mathbf{e}_j = 1$. The j th entry of $\hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j$ differs from 1 by at most μ_j , so $\mathbf{e}_j^\top \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j \geq 1 - \mu_j > 0$. The Cauchy–Schwarz inequality for the nonnegative definite form $\hat{\boldsymbol{\Sigma}}$ (Proposition 1.1.1 applied to $\hat{\boldsymbol{\Sigma}}^{1/2} \mathbf{e}_j$ and $\hat{\boldsymbol{\Sigma}}^{1/2} \hat{\boldsymbol{\theta}}_j$) gives $(1 - \mu_j)^2 \leq (\mathbf{e}_j^\top \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j)^2 \leq (\mathbf{e}_j^\top \hat{\boldsymbol{\Sigma}} \mathbf{e}_j) \omega_j^2 = \omega_j^2$.
- (d) Write $T_j = (\sigma/\hat{\sigma})\{w_j/(\sigma \omega_j) + r_j/(\sigma \omega_j)\}$. By (a), $w_j/(\sigma \omega_j)$ has exactly the $N(0, 1)$ law. For the remainder, $\log(2p/\delta_n) = \log 2 + \log p + \log(1/\delta_n) \leq C' \log p$ for a constant C' and large n , so $\lambda = 2\lambda_0 \leq 2\sigma\sqrt{2C' \log p/n}$. On $\mathcal{T}$, which has

probability at least $1 - \delta_n \rightarrow 1$, part (b) gives

$$\begin{aligned} |r_j| &\leq 4\sqrt{n} \cdot C \sqrt{\frac{\log p}{n}} \cdot 2\sigma \sqrt{\frac{2C' \log p}{n}} \cdot \frac{s}{\phi_0^2} \\ &= \frac{8\sqrt{2C'} C \sigma}{\phi_0^2} \cdot \frac{s \log p}{\sqrt{n}} \rightarrow 0. \end{aligned}$$

By (c) and $\mu_j \rightarrow 0$, $\omega_j \geq \frac{1}{2}$ for large n . Hence $r_j/(\sigma\omega_j) \rightarrow 0$ in probability, and Slutsky's lemma (with $\sigma/\hat{\sigma} \rightarrow 1$) gives Eq. 28.5.2. The coverage statement is $\Pr(|T_j| \leq z_{\alpha/2}) \rightarrow 1 - \alpha$. ■

The theorem separates what the design must deliver (a $\hat{\Theta}$ with small μ_j , and $\phi^2(S)$ bounded below) from what the lasso delivers (an ℓ_1 error of order $s\sqrt{\log p/n}$). The condition $s \log p/\sqrt{n} \rightarrow 0$ is stronger than the $s \log p/n \rightarrow 0$ that suffices for prediction: the remainder must be small compared with the standard error $1/\sqrt{n}$.

28.5.3 Constructing the approximate inverse

The remaining question is how to find a $\hat{\Theta}$ with small μ_j when $\hat{\Sigma}$ is singular. The *node-wise lasso* regresses each column on all the others.

Lemma 28.5.2 — Node-wise lasso

For a fixed j , let $\hat{\gamma}_j \in \mathbb{R}^{p-1}$ be a lasso estimate, with penalty λ_j , for the regression of $\mathbf{x}_j$ on the other columns $\mathbf{X}_{-j}$. Put $\hat{\mathbf{z}}_j = \mathbf{x}_j - \mathbf{X}_{-j}\hat{\gamma}_j$ and $\hat{\tau}_j^2 = \mathbf{x}_j^\top \hat{\mathbf{z}}_j/n$, and let $\hat{\theta}_j$ have entry $1/\hat{\tau}_j^2$ in position j and $-\hat{\gamma}_j/\hat{\tau}_j^2$ elsewhere. Then:

- (a) $\hat{\tau}_j^2 = \|\hat{\mathbf{z}}_j\|^2/n + \lambda_j \|\hat{\gamma}_j\|_1 \geq 0$;
- (b) if $\hat{\tau}_j^2 > 0$, then $(\hat{\Sigma}\hat{\theta}_j)_j = 1$ and $\mu_j = \|\hat{\Sigma}\hat{\theta}_j - \mathbf{e}_j\|_\infty \leq \lambda_j/\hat{\tau}_j^2$;
- (c) the j th debiased estimate is

$$\hat{b}_j = \frac{\hat{\mathbf{z}}_j^\top (\mathbf{Y} - \mathbf{X}_{-j}\hat{\beta}_{\lambda, -j})}{\hat{\mathbf{z}}_j^\top \mathbf{x}_j}. \quad (28.5.3)$$

Proof. The optimality conditions Eq. 28.3.2 for the node-wise regression say that

$$\mathbf{X}_{-j}^\top \hat{\mathbf{z}}_j/n = \lambda_j \hat{\mathbf{k}},$$

where $\hat{\mathbf{k}}$ has entries of size at most 1 and equal to $\text{sign}(\hat{\gamma}_{j,k})$ where $\hat{\gamma}_{j,k} \neq 0$. Hence $\hat{\gamma}_j^\top \mathbf{X}_{-j}^\top \hat{\mathbf{z}}_j/n = \lambda_j \|\hat{\gamma}_j\|_1$, and since $\mathbf{x}_j = \hat{\mathbf{z}}_j + \mathbf{X}_{-j}\hat{\gamma}_j$,

$$\hat{\tau}_j^2 = \frac{\mathbf{x}_j^\top \hat{\mathbf{z}}_j}{n} = \frac{\|\hat{\mathbf{z}}_j\|^2}{n} + \lambda_j \|\hat{\gamma}_j\|_1,$$

which is (a). For (b), $\mathbf{X}\hat{\theta}_j = (\mathbf{x}_j - \mathbf{X}_{-j}\hat{\gamma}_j)/\hat{\tau}_j^2 = \hat{\mathbf{z}}_j/\hat{\tau}_j^2$, so the k th entry of $\hat{\Sigma}\hat{\theta}_j$ is

$\mathbf{x}_k^\top \hat{\mathbf{z}}_j / (n\hat{\tau}_j^2)$. For $k = j$ this is 1 by the definition of $\hat{\tau}_j^2$. For $k \neq j$ it is $\lambda_j \hat{\kappa}_k / \hat{\tau}_j^2$, of size at most $\lambda_j / \hat{\tau}_j^2$. For (c), $\hat{b}_j$ is $\hat{\beta}_{\lambda,j} + \hat{\mathbf{z}}_j^\top (\mathbf{Y} - \mathbf{X}\hat{\boldsymbol{\beta}}_\lambda) / (n\hat{\tau}_j^2)$. Put $n\hat{\tau}_j^2 = \hat{\mathbf{z}}_j^\top \mathbf{x}_j$ and $\mathbf{X}\hat{\boldsymbol{\beta}}_\lambda = \mathbf{x}_j \hat{\beta}_{\lambda,j} + \mathbf{X}_{-j} \hat{\boldsymbol{\beta}}_{\lambda,-j}$; the terms in $\hat{\beta}_{\lambda,j}$ cancel. ■

Part (c) shows what the debiased lasso is. By the Frisch–Waugh–Lovell theorem (Theorem 6.6.2), the least squares coefficient of $\mathbf{x}_j$ comes from regressing $\mathbf{Y}$ on the part of $\mathbf{x}_j$ orthogonal to the other columns, which is zero when $p > n$. The node-wise lasso replaces it by a lasso residual $\hat{\mathbf{z}}_j$, nearly orthogonal to every other column by (b), and removes the other regressors' effect approximately through $\mathbf{X}_{-j} \hat{\boldsymbol{\beta}}_{\lambda,-j}$. Javanmard and Montanari (2014) instead choose $\hat{\boldsymbol{\theta}}_j$ to minimize $\hat{\boldsymbol{\theta}}^\top \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}$ subject to $\|\hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}} - \mathbf{e}_j\|_\infty \leq \mu$.

Remark (Sketch: when the assumptions of part (d) hold). This is a sketch; the full arguments are in van de Geer, Bühlmann, Ritov and Dezeure (2014) and Javanmard and Montanari (2014). Suppose the rows of $\mathbf{X}$ are independent $N_p(\mathbf{0}, \boldsymbol{\Sigma})$, the eigenvalues of $\boldsymbol{\Sigma}$ are bounded away from 0 and ∞ , and row j of $\boldsymbol{\Sigma}^{-1}$ has at most s_j nonzero entries. The population regression of x_j on the others then has s_j nonzero coefficients and residual variance $\tau_j^2 = 1/(\boldsymbol{\Sigma}^{-1})_{jj}$. By the lemma $\mu_j \leq \lambda_j / \hat{\tau}_j^2$ *deterministically*, so with $\lambda_j \asymp \sqrt{\log p/n}$ it remains to show $\hat{\tau}_j^2 \approx \tau_j^2$. This follows from Section 28.3 applied to the node-wise regression, with the random-design bound of Section 28.2, when $s_j \log p/n \rightarrow 0$; the scaled lasso (Sun and Zhang 2012) supplies $\hat{\sigma}$. Then $\omega_j^2 \rightarrow (\boldsymbol{\Sigma}^{-1})_{jj}$, which van de Geer and coauthors show to be the smallest asymptotic variance of a regular estimator.

Warning. The theorem covers one prespecified coefficient, or a fixed finite set. Coefficients chosen *because* they look large bring back the selection problem, and simultaneous intervals need a multiplicity correction such as Bonferroni (Theorem 13.4.1). With moderate n and a truth that is not very sparse, the remainder r_j can be comparable to the noise, and coverage suffers.

28.5.4 A simulation

Example. (Coverage of three intervals)

Take $n = 200$, $p = 400$, a fixed Gaussian design with correlations $0.5^{|j-k|}$, $\sigma = 1$, and $\beta_1 = 1$, $\beta_6 = 0.15$, $\beta_{11} = -1$, $\beta_{16} = 0.15$, all other coefficients zero. The targets are a strong coefficient β_1 , a weak one β_6 , and $\beta_2 = 0$, whose regressor is correlated 0.5 with x_1 . In each of 1000 data sets we fit the lasso with $\lambda = \sigma \sqrt{2 \log p/n} = 0.245$, below $2\lambda_0$ for the reason seen in Example (How tight are the bounds?), and compute three 95% intervals:

- the **naïve** interval: least squares on the selected variables and its t interval, reported only when the target was selected;
- the **debiased** interval $\hat{b}_j \pm 1.96 \hat{\sigma} \omega_j / \sqrt{n}$, with node-wise lasso rows ($\lambda_j = 0.024$) and $\hat{\sigma}^2$ the lasso residual sum of squares divided by n minus the number of selected variables;
- the **oracle** t interval from least squares on the true support plus the target.

Figure 28.5.1: Inference for single coefficients with $n = 200$, $p = 400$, 1000 data sets. (a) Histogram of the standardized debiased estimates of β_1 and the $N(0, 1)$ density. (b) Coverage of nominal 95% intervals: naive least squares after lasso selection (computed only when the target is selected), the debiased lasso, and the oracle.

The results are in [Figure 28.5.1](#). For the null coefficient β_2 , the lasso selected x_2 in a fraction 0.069 of the data sets, and in those the naive interval covered zero only in a fraction 0.174. For the weak coefficient, selected in a fraction 0.329, the naive coverage was 0.903, and for the strong one 0.915. The debiased intervals covered β_1 , β_6 and β_2 in fractions 0.960, 0.946 and 0.940 respectively, close to the oracle's 0.943, 0.956 and 0.958 for the same three coefficients.

On the strong coefficient the lasso's average error is -0.210 , close to $-\lambda$, and the debiased estimate's is 0.014. The standardized estimates T_1 have mean 0.14 and standard deviation 0.95 (panel (a)). Two costs remain.

The debiased intervals are wider than the oracle's (0.393 against 0.288 for β_1): part of this is the price of not knowing the support, and part is tuning. The node-wise penalty $\lambda_j = 0.024$, a tenth of $\sqrt{2 \log p/n}$, keeps the bound $\mu_j \leq \lambda_j / \hat{\tau}_j^2$ of [Lemma 28.5.2](#), and so the remainder, small. But it lets the node-wise fits explain much of each column: $\hat{\tau}_j^2$ (0.28, 0.25 and 0.27 for β_1 , β_6 and β_2) is well below the population value $1/(\Sigma^{-1})_{jj}$, which is $\frac{3}{4}$ for $j = 1$ and $\frac{3}{5}$ otherwise, and that allows a larger ω_j ([Exercise \(B2\)](#)).

The second cost is a remainder bias: 0.049 for β_2 and 0.046 for the weak β_6 , about a third of its value. This is the term $r_j/\sqrt{n}$ of [Theorem 28.5.1](#), at most $\mu_j \|\hat{\beta}_\lambda - \beta\|_1$, with μ_j between 0.088 and 0.099 and an average lasso ℓ_1 error of 0.74. At $n = 200$ that product is not negligible.

28.5.5 Other routes to valid inference

Other approaches answer different questions. **Sample splitting** (Wasserman and Roeder 2009) selects on one half of the data and fits on the other ([Exercise B1](#)). **Selective inference** (Lee, Sun, Sun and Taylor 2016) conditions on the lasso having chosen the reported model, a union of polyhedra in $\mathbf{Y}$. **Simultaneous inference over all models** (Berk, Brown, Buja, Zhang and Zhao 2013) widens the intervals, as Scheffé's method does. These target the coefficients of the *selected* model, which generally differ from β_j . **Double selection** (Belloni, Chernozhukov and Hansen 2014) targets β_j : it keeps the controls that predict the response or x_j and refits least squares, the idea of [Eq. 28.5.3](#).

28.5.6 Exercises

28.5.6.1 A. Check your understanding

Exercise A1.

Suppose $p < n$, $\mathbf{X}$ has full column rank and $\hat{\Theta} = \hat{\Sigma}^{-1}$. Show that the debiased lasso [Eq. 28.5.1](#) equals the least squares estimate, whatever $\hat{\beta}_\lambda$ is, and that $\mu_j = 0$ and $\mathbf{r} = \mathbf{0}$ in [Theorem 28.5.1](#).

Solution. $\hat{\mathbf{b}} = \hat{\beta}_\lambda + (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top (\mathbf{Y} - \mathbf{X} \hat{\beta}_\lambda) = \hat{\beta}_\lambda + \hat{\beta} - \hat{\beta}_\lambda = \hat{\beta}$, where $\hat{\beta} = (\mathbf{X}^\top \mathbf{X})^{-1} \mathbf{X}^\top \mathbf{Y}$. Then $\hat{\Sigma} \hat{\Theta} = \mathbf{I}$, so every $\mu_j = 0$ and $\mathbf{r} = \mathbf{0}$, and part (a) of the theorem reduces to $\sqrt{n}(\hat{\beta} - \beta) \sim N_p(\mathbf{0}, \sigma^2 \hat{\Sigma}^{-1})$ ([Theorem 7.5.1](#)).

Exercise A2.

On the event of [Theorem 28.4.2](#), with $\hat{\Sigma}_{SS} = \mathbf{I}$, show that the interval $\hat{\beta}_{\lambda,j} \pm 1.96 \sigma / \sqrt{n}$ for $j \in S$ covers β_j iff $|\mathbf{x}_j^\top \boldsymbol{\varepsilon} / \sqrt{n} \sigma - \sqrt{n} \lambda \text{sign}(\beta_j) / \sigma| \leq 1.96$. If $\lambda = 2\lambda_0$, what happens to its coverage as $p \rightarrow \infty$?

28.5.6.2 B. Practice

Exercise B1.

(*Sample splitting.*) Split the observations into halves I_1 and I_2 chosen independently of the data. Select a set $\hat{S}$ of columns using only the data in I_1 , and suppose $\mathbf{X}_{I_2, \hat{S}}$ has full column rank and $|\hat{S}| < |I_2|$. Show that if $\hat{S} \supseteq S$, then conditionally on the data in I_1 , the usual t interval for β_j ($j \in \hat{S}$) from the least squares fit of $\mathbf{Y}_{I_2}$ on $\mathbf{X}_{I_2, \hat{S}}$ has exact coverage $1 - \alpha$. What does the fit estimate when $\hat{S}$ misses an active variable?

Solution. The errors in I_2 are independent of those in I_1 , so conditionally on the data in I_1 the set $\hat{S}$ is fixed and $\mathbf{Y}_{I_2} \sim \mathcal{N}(\mathbf{X}_{I_2} \boldsymbol{\beta}, \sigma^2 \mathbf{I})$. If $\hat{S} \supseteq S$, then $\mathbf{X}_{I_2} \boldsymbol{\beta} = \mathbf{X}_{I_2, \hat{S}} \boldsymbol{\beta}_{\hat{S}}$, so the fit on $\mathbf{X}_{I_2, \hat{S}}$ is a correctly specified normal linear model with coefficients $\boldsymbol{\beta}_{\hat{S}}$, and the t interval of [Theorem 12.1.1](#) has exact conditional coverage. Averaging over the data in I_1 , coverage is exact on the event $\hat{S} \supseteq S$. If $\hat{S}$ misses an active variable, the fit estimates the projected coefficients $(\mathbf{X}_{I_2, \hat{S}}^\top \mathbf{X}_{I_2, \hat{S}})^{-1} \mathbf{X}_{I_2, \hat{S}}^\top \mathbf{X}_{I_2} \boldsymbol{\beta}$ ([Proposition 5.5.7](#)), which differ from $\boldsymbol{\beta}_{\hat{S}}$ when the missed variables are correlated with the selected ones, and the residual mean square overestimates σ^2 .

Exercise B2.

In [Lemma 28.5.2](#), show that $\omega_j^2 = \hat{\boldsymbol{\theta}}_j^\top \hat{\boldsymbol{\Sigma}} \hat{\boldsymbol{\theta}}_j = \|\hat{\mathbf{z}}_j\|^2 / (n \hat{\tau}_j^4)$, and hence $\omega_j^2 \leq 1 / \hat{\tau}_j^2$. Interpret: a small $\hat{\tau}_j^2$ (a column that the others explain well) means a large variance for $\hat{b}_j$. Compare with the variance inflation factor ([Definition 26.2.1](#)).

Solution. $\mathbf{X} \hat{\boldsymbol{\theta}}_j = \hat{\mathbf{z}}_j / \hat{\tau}_j^2$, so $\omega_j^2 = \|\mathbf{X} \hat{\boldsymbol{\theta}}_j\|^2 / n = \|\hat{\mathbf{z}}_j\|^2 / (n \hat{\tau}_j^4)$. By [Lemma 28.5.2\(a\)](#), $\|\hat{\mathbf{z}}_j\|^2 / n \leq \hat{\tau}_j^2$, so $\omega_j^2 \leq 1 / \hat{\tau}_j^2$. With least squares in place of the lasso ($p < n$, $\lambda_j = 0$), $\hat{\tau}_j^2 = \|(\mathbf{I} - \mathbf{M}_{(j)}) \mathbf{x}_j\|^2 / n$, and $\omega_j^2 = 1 / \hat{\tau}_j^2$ is the variance factor $n / \{S_{jj}(1 - R_j^2)\}$ of [Eq. 6.6.2](#) for a column with $\|\mathbf{x}_j\|^2 = n$ (and an intercept among the other columns). The node-wise lasso residual plays the role of the FWL residual, and $1 / \hat{\tau}_j^2$ the role of the variance inflation.

28.6 Summary and Notes

28.6.1 Summary

Idea.

1. When $p > n$, least squares interpolates and no single coefficient is estimable. The minimum-norm solution $\mathbf{X}^+ \mathbf{y}$ is the ridgeless limit of ridge and the limit of gradient descent from zero; its error splits into the invisible null-space part of $\boldsymbol{\beta}$ and the variance $\sigma^2 \sum_i d_i^{-2}$ ([Theorem 28.1.1](#)).
2. For isotropic Gaussian regressors its risk is exact ([Proposition 28.1.2](#)). Fitting p of D features gives the double descent curve ([Corollary 28.1.3](#)), whose peak at $p = n$ belongs to the estimator and disappears with a tuned ridge penalty.
3. Sparsity restores identifiability ([Proposition 28.2.1](#)). The compatibility and re-

stricted eigenvalue conditions ask for curvature only on a cone of approximately sparse vectors (Definition 28.2.1); they transfer from populations to samples with a loss of $16s\delta$ (Proposition 28.2.2), and can be small in samples even when they are large in the population.

4. On the event $\|\mathbf{X}^\top \boldsymbol{\varepsilon}/n\|_\infty \leq \lambda_0 = \sigma\sqrt{2\log(2p/\delta)/n}$, which has probability at least $1 - \delta$ (Lemma 28.3.2), every lasso estimate with $\lambda \geq 2\lambda_0$ has its error in the cone and prediction error at most $3\lambda\|\boldsymbol{\beta}\|_1$ without conditions and $9\lambda^2s/\phi^2(S)$ under compatibility (Theorem 28.3.3). Its ℓ_1 and ℓ_2 errors are of order λs and $\lambda\sqrt{s}$ (Theorem 28.3.4).
5. Exact sign recovery holds under the irrepresentable and beta-min conditions (Theorem 28.4.2). Without the irrepresentable condition it has probability at most $\frac{1}{2}$ for every sample size (Proposition 28.4.3); screening needs only the restricted eigenvalue and beta-min conditions (Proposition 28.4.4).
6. Intervals computed after selection under-cover. The debiased lasso adds a one-step correction; its error is exactly normal plus a remainder bounded by $\sqrt{n}\mu_j\|\hat{\boldsymbol{\beta}}_\lambda - \boldsymbol{\beta}\|_1$, which vanishes when $s\log p/\sqrt{n} \rightarrow 0$ (Theorem 28.5.1). With node-wise lasso rows it is the Frisch–Waugh–Lovell estimator with a lasso residual (Lemma 28.5.2).

28.6.2 Notes and sources

Scope. None of the planning sources treats $p > n$ in depth; Agresti (2015, section 11.2) notes it briefly, through a Bayesian prior. Bühlmann and van de Geer (2011), Hastie, Tibshirani and Wainwright (2015) and Wainwright (2019) develop all the topics of the chapter at length.

Interpolation. The term *double descent* is from Belkin, Hsu, Ma and Mandal (2019). Belkin, Hsu and Xu (2020) give exact risk formulas for Gaussian features, including omitted features as in Corollary 28.1.3. Hastie, Montanari, Rosset and Tibshirani (2022) treat general covariances and ridge asymptotically, and Bartlett, Long, Lugosi and Tsigler (2020) characterize benign overfitting.

Design conditions and the lasso. The lasso is due to Tibshirani (1996); Tibshirani (2013) studies uniqueness. Greenshtein and Ritov (2004) introduced persistence, behind the slow rate. The restricted eigenvalue condition and the fast rates are from Bickel, Ritov and Tsybakov (2009), with the Dantzig selector of Candès and Tao (2007); the basic-inequality presentation follows Bühlmann and van de Geer (2011, chapter 6), and van de Geer and Bühlmann (2009) compare the conditions. Donoho and Huo (2001) used mutual coherence, and Cohen, Dahmen and DeVore (2009) the null space property. Raskutti, Wainwright and Yu (2010, 2011) prove the random-design bound and the minimax lower bound. Belloni, Chernozhukov and Wang (2011) and Sun and Zhang (2012) free λ from σ .

Selection and inference. The irrepresentable condition is due to Zhao and Yu (2006) and Meinshausen and Bühlmann (2006), the primal–dual witness proof to Wainwright (2009); Zou (2006) and Meinshausen and Bühlmann (2010) propose the adaptive lasso and stability selection. Leeb and Pötscher (2005, 2006) analyse post-selection distributions and prove that they cannot be estimated uniformly. The debiased lasso is due to Zhang and Zhang (2014), van de Geer, Bühlmann, Ritov and Dezeure (2014) and Javanmard and Montanari (2014). The alternatives are due to Wasserman and Roeder (2009), Meinshausen, Meier and Bühlmann (2009), Lee, Sun, Sun and Taylor (2016), Berk, Brown, Buja, Zhang and Zhao (2013) and Belloni, Chernozhukov and Hansen (2014). Chapter 29 treats selection bias for classical rules, and Chapter 30 extends the lasso to other penalties.

Chapter 29

Model Selection and Prediction

A fitted model is judged by how well it predicts responses it has not seen, and its error on the responses it was fitted to flatters it. For any fitting procedure the flattery is twice the covariance between the fit and the data, $2\sigma^2 p/n$ for least squares whether the model is right or wrong. Correcting for it gives Mallows' C_p and AIC. BIC answers a different question, which model is most probable: it finds a true finite model with probability tending to one, while AIC predicts almost as well as the best candidate when no finite model is true. Cross-validation estimates prediction error with fewer assumptions, and for least squares and ridge it needs no refitting. The search over subsets is unstable, and every estimate and interval computed after it is biased by it, unless the inference is designed to survive the search.

What you need. Chapter 6 (projections, Theorem 6.5.1, and the Frisch–Waugh–Lovell theorem, Theorem 6.6.2), Chapter 7 (the likelihood of the normal model, Theorem 7.3.1), Chapter 9 (adjusted R^2 , Proposition 9.5.3), Chapter 11 (the F test, Theorem 11.1.1), Chapter 13 (Scheffé and Bonferroni, Theorem 13.2.2 and Theorem 13.4.1), Chapter 14 (prediction error and its optimism, Proposition 14.2.7 and Theorem 14.2.6), Chapter 19 (omitted and irrelevant regressors, Theorem 19.1.5) and Chapter 20 (the deletion formulas and PRESS, Theorem 20.3.1). From this part: Chapter 26 (collinearity) and Chapter 27 (ridge regression, thresholding and Stein's lemma, Lemma 27.5.1).

29.0.1 Roadmap

- Prediction error and optimism
- Mallows' C_p , AIC and BIC
- Cross-validation
- All subsets and stepwise search
- Selection bias and honest inference
- Summary and notes

29.1 Prediction error and optimism

Chapter 19 compared a short regression with a long one and found that neither wins everywhere. Leaving out regressors whose coefficients are small buys a drop in variance that can outweigh

the bias it causes, and [Theorem 19.1.5](#) located the break-even point exactly: at the design points the short fit is better iff the noncentrality [Eq. 19.1.1](#) of the omitted block is less than the number of columns omitted. The noncentrality is unknown, so the theorem does not choose a model. It does say what a good choice should aim at, namely the error of the fitted values as predictions, and this chapter builds that into procedures.

The residual mean square describes how well a fit reproduces the data it was fitted to, and every fitting procedure bends towards those data. This section makes the size of that bend exact for any procedure, and turns it into a definition of the degrees of freedom a procedure spends.

29.1.1 In-sample prediction error

Throughout the chapter the data follow

$$\mathbf{Y} = \boldsymbol{\mu} + \boldsymbol{\varepsilon}, \quad \mathbf{E}(\boldsymbol{\varepsilon}) = \mathbf{0}, \quad \text{Cov}(\boldsymbol{\varepsilon}) = \sigma^2 \mathbf{I}_n, \quad (29.1.1)$$

where the mean vector $\boldsymbol{\mu} \in \mathbb{R}^n$ is unrestricted. A candidate linear model $\mathcal{C}(\mathbf{X})$ may or may not contain $\boldsymbol{\mu}$. That is the point of model selection: we want procedures whose properties do not depend on a candidate being right. A **fitting procedure** is any function $\hat{\boldsymbol{\mu}} = \hat{\boldsymbol{\mu}}(\mathbf{Y})$ from $\mathbb{R}^n$ to $\mathbb{R}^n$ with $\mathbf{E}\|\hat{\boldsymbol{\mu}}(\mathbf{Y})\|^2 < \infty$: least squares on a fixed model, least squares on a model chosen from the data, ridge regression, thresholding.

Definition 29.1.1 — Training error, prediction error, optimism

Let $\mathbf{Y}^* = \boldsymbol{\mu} + \boldsymbol{\varepsilon}^*$, where $\boldsymbol{\varepsilon}^*$ is independent of $\boldsymbol{\varepsilon}$ and has the same distribution: new responses at the same design points. For a fitting procedure $\hat{\boldsymbol{\mu}}$:

- (a) the **training error** is $\overline{\text{err}} = n^{-1}\|\mathbf{Y} - \hat{\boldsymbol{\mu}}\|^2$;
- (b) the **in-sample prediction error** is $\text{Err}_{\text{in}} = n^{-1} \mathbf{E}(\|\mathbf{Y}^* - \hat{\boldsymbol{\mu}}\|^2 \mid \mathbf{Y})$;
- (c) the **optimism** is $\text{Err}_{\text{in}} - \overline{\text{err}}$, and its mean $\omega = \mathbf{E}(\text{Err}_{\text{in}} - \overline{\text{err}})$ is the **expected optimism**.

Expanding $\mathbf{Y}^* - \hat{\boldsymbol{\mu}} = \boldsymbol{\varepsilon}^* + (\boldsymbol{\mu} - \hat{\boldsymbol{\mu}})$ and using the independence of $\boldsymbol{\varepsilon}^*$ and $\mathbf{Y}$,

$$\text{Err}_{\text{in}} = \sigma^2 + \frac{1}{n}\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|^2. \quad (29.1.2)$$

So the in-sample prediction error is the irreducible σ^2 plus the average squared error of the fitted values as estimates of the mean. Ranking procedures by $\mathbf{E}(\text{Err}_{\text{in}})$ is the same as ranking them by the risk $\mathbf{E}\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|^2$, which is the criterion of [Theorem 19.1.5\(c\)](#). *In-sample* refers to the design points: the responses are new, the regressor values old. New regressor values are taken up at the end of the section.

29.1.2 The covariance penalty

Theorem 29.1.1 — Optimism is a covariance

Under Eq. 29.1.1, let $\hat{\boldsymbol{\mu}}$ be a fitting procedure.

- (a) The expected optimism is

$$\omega = \frac{2}{n} \sum_{i=1}^n \text{Cov}(\hat{\mu}_i, Y_i).$$

- (b) If $\hat{\boldsymbol{\mu}} = \mathbf{S}\mathbf{Y}$ for a fixed $n \times n$ matrix $\mathbf{S}$, then $\omega = 2\sigma^2 \text{tr}(\mathbf{S})/n$ and $\mathbb{E}\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|^2 = \|(\mathbf{I} - \mathbf{S})\boldsymbol{\mu}\|^2 + \sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top)$.
- (c) For least squares on a model matrix $\mathbf{X}$ of rank p , whether or not $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X})$,

$$\begin{aligned} \mathbb{E}(\overline{\text{err}}) &= \sigma^2 \frac{n-p}{n} + \frac{\|(\mathbf{I} - \mathbf{M})\boldsymbol{\mu}\|^2}{n}, \\ \mathbb{E}(\text{Err}_{\text{in}}) &= \sigma^2 \frac{n+p}{n} + \frac{\|(\mathbf{I} - \mathbf{M})\boldsymbol{\mu}\|^2}{n}, \end{aligned}$$

and $\omega = 2\sigma^2 p/n$.

Proof.

- (a) Write $\mathbf{Y} - \hat{\boldsymbol{\mu}} = (\mathbf{Y} - \boldsymbol{\mu}) - (\hat{\boldsymbol{\mu}} - \boldsymbol{\mu})$. Then

$$\|\mathbf{Y} - \hat{\boldsymbol{\mu}}\|^2 = \|\boldsymbol{\varepsilon}\|^2 + \|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|^2 - 2\boldsymbol{\varepsilon}^\top(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}).$$

Take expectations and compare with Eq. 29.1.2: $n \mathbb{E}(\text{Err}_{\text{in}}) = n\sigma^2 + \mathbb{E}\|\hat{\boldsymbol{\mu}} - \boldsymbol{\mu}\|^2$, so $n\omega = 2\mathbb{E}[\boldsymbol{\varepsilon}^\top(\hat{\boldsymbol{\mu}} - \boldsymbol{\mu})] = 2\sum_i \mathbb{E}[(Y_i - \mu_i)\hat{\mu}_i]$, since $\boldsymbol{\mu}$ is constant and $\mathbb{E}(\boldsymbol{\varepsilon}) = \mathbf{0}$. Because $\mathbb{E}(Y_i - \mu_i) = 0$, the last expectation is $\text{Cov}(\hat{\mu}_i, Y_i)$. The moments exist by the Cauchy–Schwarz inequality.

- (b) $\text{Cov}(\mathbf{S}\mathbf{Y}, \mathbf{Y}) = \sigma^2 \mathbf{S}$, whose diagonal sums to $\sigma^2 \text{tr}(\mathbf{S})$. For the risk, $\mathbf{S}\mathbf{Y} - \boldsymbol{\mu} = \mathbf{S}\boldsymbol{\varepsilon} - (\mathbf{I} - \mathbf{S})\boldsymbol{\mu}$ has mean $-(\mathbf{I} - \mathbf{S})\boldsymbol{\mu}$ and covariance $\sigma^2 \mathbf{S}\mathbf{S}^\top$, and Theorem 2.3.1 with $\mathbf{A} = \mathbf{I}$ gives the sum of the squared mean and the trace.
- (c) Take $\mathbf{S} = \mathbf{M}$, with $\text{tr}(\mathbf{M}) = p$ and $\mathbf{M}\mathbf{M}^\top = \mathbf{M}$ (Proposition 6.3.4). Then $\mathbb{E}(\text{Err}_{\text{in}}) = \sigma^2 + n^{-1}\{\|(\mathbf{I} - \mathbf{M})\boldsymbol{\mu}\|^2 + \sigma^2 p\}$, and subtracting ω gives $\mathbb{E}(\overline{\text{err}})$. ■

Part (c) with $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X})$ is Proposition 14.2.7(a). What is new is that the optimism of least squares does not depend on $\boldsymbol{\mu}$: a wrong model has larger training and prediction errors, but both grow by the same squared bias, so a penalty depending only on p is a sensible correction even for wrong models. Part (a) asks nothing of the procedure but finite second moments: a fit is optimistic to the extent that each fitted value follows its own response.

Idea. The training error of a procedure understates its prediction error by $2/n$ times the total covariance between fitted values and responses. For least squares on p columns the covariance is $\sigma^2 p$, right model or wrong.

Example. (Optimism of a wrong model)

Take $n = 30$ equally spaced points t_i on $[-1, 1]$, a curved mean $\mu_i = 1 + t_i + 1.5t_i^2$, $\sigma = 1$, and fit by least squares a straight line in t together with two columns of pure noise, so $p = 4$. The model is wrong: its squared bias per observation is $\|(\mathbf{I} - \mathbf{M})\boldsymbol{\mu}\|^2/n = 0.2054$. Over 20000 simulated data sets the average optimism is 0.2688, against $2\sigma^2 p/n = 0.2667$ from [Theorem 29.1.1\(c\)](#). Ridge regression ([Theorem 27.2.2](#)) on the same columns with penalty $\lambda = 5$ is a linear smoother with $\text{tr}(\mathbf{S}) = 3.207$; its simulated optimism is 0.2163, against $2 \times 3.207/30 = 0.2138$ from part (b).

```
import numpy as np
rng = np.random.default_rng(2901)
n, sigma, reps = 30, 1.0, 20_000

      :.4f}")
```

29.1.3 Degrees of freedom of a procedure

[Theorem 29.1.1](#) suggests measuring the complexity of any procedure by the covariance it creates.

Definition 29.1.2 — Degrees of freedom

The **degrees of freedom** of a fitting procedure $\hat{\boldsymbol{\mu}}$ under [Eq. 29.1.1](#) is

$$\text{df}(\hat{\boldsymbol{\mu}}) = \frac{1}{\sigma^2} \sum_{i=1}^n \text{Cov}(\hat{\mu}_i, Y_i),$$

so that $\omega = 2\sigma^2 \text{df}(\hat{\boldsymbol{\mu}})/n$.

For least squares on a fixed model $\text{df} = p$, the number of free coefficients, and for a linear smoother $\text{df} = \text{tr}(\mathbf{S})$. For ridge regression with singular values d_j of $\mathbf{X}$ this is $\sum_j d_j^2/(d_j^2 + \lambda)$, the effective degrees of freedom of [Theorem 27.2.2](#), which falls from $\text{rank}(\mathbf{X})$ to 0 as λ grows. If df is known,

$$\widehat{\text{Err}}_{\text{in}} = \overline{\text{err}} + \frac{2\sigma^2}{n} \text{df}(\hat{\boldsymbol{\mu}}) \quad (29.1.3)$$

is an unbiased estimate of $E(\text{Err}_{\text{in}})$ by [Theorem 29.1.1\(a\)](#). [Section 29.2](#) turns this into Mallows' C_p . For a procedure that searches, the covariance is not a count and has to be computed. Under normal errors it is computed by Stein's lemma, [Lemma 27.5.1\(b\)](#), proved in [Section 27.5](#) for the James–Stein theorem: if $\mathbf{Z} \sim N_p(\boldsymbol{\theta}, \sigma^2 \mathbf{I})$ and each g_i is absolutely continuous in z_i with the integrability stated there, then $E[(\mathbf{Z} - \boldsymbol{\theta})^\top \mathbf{g}(\mathbf{Z})] = \sigma^2 E \sum_i \partial g_i(\mathbf{Z})/\partial z_i$.

Proposition 29.1.2 — Degrees of freedom as a divergence

Let $\mathbf{Y} \sim N_n(\boldsymbol{\mu}, \sigma^2 \mathbf{I})$. Suppose that for each i , for almost every value of the other coordinates, $y_i \mapsto \hat{\mu}_i(\mathbf{y})$ is absolutely continuous, and that $E|\partial \hat{\mu}_i/\partial y_i|$ and $E\hat{\mu}_i^2$ are finite. Then

$$\text{df}(\hat{\boldsymbol{\mu}}) = E \sum_{i=1}^n \frac{\partial \hat{\mu}_i}{\partial y_i}(\mathbf{Y}),$$

and $\overline{\text{err}} + 2\sigma^2 n^{-1} \sum_i \partial \hat{\mu}_i/\partial y_i$ is an unbiased estimate of $E(\text{Err}_{\text{in}})$ that does not involve $\boldsymbol{\mu}$.

Proof. Since $E(Y_i - \mu_i) = 0$, $\sum_i \text{Cov}(\hat{\mu}_i, Y_i) = E[(\mathbf{Y} - \boldsymbol{\mu})^\top \hat{\boldsymbol{\mu}}(\mathbf{Y})]$, and each term is integrable by the Cauchy–Schwarz inequality. [Lemma 27.5.1\(b\)](#) with $\mathbf{g} = \hat{\boldsymbol{\mu}}$ turns this into $\sigma^2 E \sum_i \partial \hat{\mu}_i/\partial y_i$. The unbiasedness statement is then [Theorem 29.1.1\(a\)](#). ■

The estimate in the proposition is **Stein's unbiased risk estimate** (Stein 1981). For a linear smoother the divergence is $\text{tr}(\mathbf{S})$, and nothing is new. The interesting cases are adaptive.

Soft thresholding. Take an orthonormal design, $\mathbf{X}^\top \mathbf{X} = \mathbf{I}_p$, and put $\mathbf{Z} = \mathbf{X}^\top \mathbf{Y} \sim N_p(\mathbf{X}^\top \boldsymbol{\mu}, \sigma^2 \mathbf{I})$. For a fit $\hat{\boldsymbol{\mu}} = \mathbf{X} \hat{\boldsymbol{\beta}}(\mathbf{Z})$, $\sum_i \text{Cov}(\hat{\mu}_i, Y_i) = \text{tr} \text{Cov}(\mathbf{X} \hat{\boldsymbol{\beta}}, \mathbf{Y}) = \text{tr} \text{Cov}(\hat{\boldsymbol{\beta}}, \mathbf{X}^\top \mathbf{Y}) = \sum_j \text{Cov}(\hat{\beta}_j, Z_j)$, so the degrees of freedom can be computed coordinate by coordinate in the sequence model $Z_j \sim N(\theta_j, \sigma^2)$. The lasso in this design is soft thresholding, $\hat{\beta}_j = \text{sign}(Z_j)(|Z_j| - \lambda)_+$ ([Theorem 27.4.2](#)). It is Lipschitz, with derivative $1\{|Z_j| > \lambda\}$ except at $\pm\lambda$, so by [Proposition 29.1.2](#) its degrees of freedom are the expected number of nonzero coefficients, as an exercise of [Section 27.4](#) found by direct integration. The shrinkage exactly pays for the search.

Hard thresholding. Subset selection in the same design keeps or drops each coordinate whole, $\hat{\beta}_j = Z_j 1\{|Z_j| > \lambda\}$ ([Theorem 27.4.2](#) again). This jumps by λ at $\pm\lambda$, so Stein's lemma does not apply, and the degrees of freedom exceed the expected count.

Proposition 29.1.3 — Degrees of freedom of hard thresholding

Let $Z \sim N(\theta, \sigma^2)$ and $\lambda > 0$. Then

$$\begin{aligned} \frac{\text{Cov}(Z1\{|Z| > \lambda\}, Z)}{\sigma^2} &= \Pr(|Z| > \lambda) \\ &\quad + \frac{\lambda}{\sigma} \left[\phi\left(\frac{\lambda - \theta}{\sigma}\right) + \phi\left(\frac{\lambda + \theta}{\sigma}\right) \right], \end{aligned}$$

where ϕ is the standard normal density.

Proof. Write $Z = \theta + \sigma W$ with $W \sim N(0, 1)$, and put $a = (\lambda - \theta)/\sigma$, $b = (-\lambda - \theta)/\sigma$, so that $|Z| > \lambda$ iff $W > a$ or $W < b$. The covariance is $E[\sigma W(\theta + \sigma W)1\{W > a \text{ or } W < b\}]$. The truncated moments of the standard normal are $E[W1\{W > a\}] = \phi(a)$, $E[W1\{W < b\}] = -\phi(b)$, $E[W^21\{W > a\}] = 1 - \Phi(a) + a\phi(a)$ and $E[W^21\{W < b\}] = \Phi(b) - b\phi(b)$, each by one integration by parts. Collecting terms,

$$\sigma\theta(\phi(a) - \phi(b)) + \sigma^2(1 - \Phi(a) + \Phi(b) + a\phi(a) - b\phi(b)).$$

Since $\sigma\theta + \sigma^2a = \sigma\lambda$ and $-\sigma\theta - \sigma^2b = \sigma\lambda$, this is $\sigma^2 \Pr(|Z| > \lambda) + \sigma\lambda(\phi(a) + \phi(b))$, and $\phi(b) = \phi((\lambda + \theta)/\sigma)$. ■

The first term is the expected number of coefficients kept. The second is the price of the search: the fit follows Z most closely just where Z decides whether to keep the coordinate. At the threshold $\lambda = \sigma\sqrt{2}$ (which [Section 29.2](#) shows is where C_p and AIC put it) and $\theta = 0$, the expected count is 0.157 but the degrees of freedom are 0.572: the search term 0.415 is more than twice the count. At $\theta = \sigma$ the degrees of freedom are 0.896, and at $\theta = 3\sigma$ they are 1.104, more than one full parameter for a single coordinate.

Example. (Best subset of a given size)

Keep the k largest of $m = 20$ values $|Z_j|$ and set the rest to zero, with $Z_j \sim N(\theta_j, 1)$ independent. For a subset fixed in advance the degrees of freedom would be k . [Figure 29.1.1](#) shows them by simulation. When all $\theta_j = 0$, the best single coordinate already costs 4.91 degrees of freedom, the best five cost 13.94 and the best ten 18.27. When five means equal 6 and the rest are zero, choosing the best five is almost free (5.06), because the five are obvious; choosing a sixth means choosing among fifteen pure-noise coordinates, and the degrees of freedom jump to 9.47. Searching among many candidates of equal merit is expensive, and choosing between clear winners and clear losers is cheap.

```
m, reps_s = 20, 20_000
Zs = rng.normal(size=(reps_s, m))

def subset_df(theta, k):
    """Monte Carlo df of 'keep the k largest |Y_j|' when Y ~ N(theta, I)."""
    Yb = theta + Zs
    keep = np.argsort(-np.abs(Yb), axis=1)[:k]
    fit = np.zeros_like(Yb)
    np.put_along_axis(fit, keep, np.take_along_axis(Yb, keep, axis=1), axis=1)
    return np.mean(np.sum(fit * Zs, axis=1)) # sum_j Cov(fit_j, Y_j)
```

Figure 29.1.1: Degrees of freedom of the best subset of size k among 20 orthonormal coordinates, by simulation (20000 data sets). The dashed line is $df = k$, correct only when the subset is fixed in advance.

```

null = np.zeros(m)
sparse = np.r_[np.full(5, 6.0), np.zeros(m - 5)] # five large means
for k in (1, 5, 10):
    print(f"k = {k:2d}: df null {subset_df(null, k):5.2f}, df sparse {subset_df(
        sparse, k):5.2f}")

```

So a penalty of $2\sigma^2 p/n$ is right for a model chosen in advance and too small for a model chosen by search, a point [Section 29.5](#) returns to.

29.1.4 New regressor values

The in-sample error keeps the design fixed. For a new case with its own regressors the error is larger, and for least squares with k normal regressors and a correct model [Theorem 14.2.6](#) gives it exactly; since $E(s^2) = \sigma^2$, $s^2(1 + 1/n)(n - 2)/(n - k - 2)$ estimates it without bias. Breiman and Spector (1992) found that fixed-design estimates understate the error when the design is random, and recommended five- or ten-fold cross-validation. Cross-validation ([Section 29.3](#)) estimates the random-design error directly.

29.1.5 Exercises

29.1.5.1 A. Check your understanding

Exercise A1.

The procedure $\hat{\mu}(\mathbf{Y}) = \mathbf{Y}$ interpolates the data. Compute its training error, its in-sample prediction error and its degrees of freedom, and check [Theorem 29.1.1\(a\)](#).

29.1.5.2 B. Practice

Exercise B1.

Let $\mathbf{S}_\lambda = \mathbf{X}(\mathbf{X}^\top \mathbf{X} + \lambda \mathbf{I})^{-1} \mathbf{X}^\top$ be the ridge smoother, whose trace $\sum_j d_j^2 / (d_j^2 + \lambda)$ was found in [Theorem 27.2.2](#). Show that $\text{tr}(\mathbf{S}_\lambda \mathbf{S}_\lambda^\top) < \text{tr}(\mathbf{S}_\lambda)$ for every $\lambda > 0$ with $\mathbf{X} \neq \mathbf{0}$, and that for a symmetric smoother $\mathbf{S}$ with eigenvalues in $[0, 1]$, $\text{tr}(\mathbf{S}\mathbf{S}^\top) = \text{tr}(\mathbf{S})$ iff $\mathbf{S}$ is an orthogonal projection.

Solution. A symmetric $\mathbf{S}$ with eigenvalues $s_j \in [0, 1]$ has $\text{tr}(\mathbf{S}\mathbf{S}^\top) = \text{tr}(\mathbf{S}^2) = \sum_j s_j^2 \leq \sum_j s_j = \text{tr}(\mathbf{S})$, with equality iff every $s_j \in \{0, 1\}$, that is, iff $\mathbf{S}$ is idempotent, an orthogonal projection ([Theorem 6.3.3](#)). The ridge smoother is symmetric with eigenvalues $d_j^2 / (d_j^2 + \lambda)$, which lie in $(0, 1)$ for $d_j > 0$, and at least one d_j is positive. So the variance term of [Theorem 29.1.1\(b\)](#), $\sigma^2 \text{tr}(\mathbf{S}\mathbf{S}^\top)$, is strictly smaller than the optimism term $\sigma^2 \text{tr}(\mathbf{S})$.

Exercise B2.

Arrange n observations on a circle, and let $\hat{\mu}_i$ be the average of $Y_{i-q}, \dots, Y_{i+q}$ (indices modulo n , $2q + 1 \leq n$). Find the degrees of freedom and the expected optimism, and explain why a wider window is “simpler”.

29.1.5.3 C. Going deeper

Exercise C1.

In the sequence model $Z_j \sim N(\theta_j, \sigma^2)$, $j = 1, \dots, p$, independent, soft thresholding at λ has Stein’s unbiased risk estimate

$$\text{SURE}(\lambda) = \sum_{j=1}^p \min(Z_j^2, \lambda^2) - p\sigma^2 + 2\sigma^2 \#\{j : |Z_j| > \lambda\}$$

by [Proposition 29.1.2](#), because $Z_j - \hat{\theta}_j$ is Z_j when $|Z_j| \leq \lambda$ and $\pm\lambda$ otherwise. Let $0 = a_0 \leq a_1 \leq \dots \leq a_p$ be 0 and the ordered $|Z_j|$. Show that SURE is nondecreasing on each interval $[a_k, a_{k+1})$, so it is minimized over $\lambda \geq 0$ at one of $a_0, \dots, a_p$. Compute $\text{SURE}(0)$, and explain why the minimized value is biased downwards. (Minimizing SURE is the SureShrink rule of Donoho and Johnstone 1995.)

Solution. On $[a_k, a_{k+1})$ exactly $p - k$ of the $|Z_j|$ exceed λ (for distinct values), so $\text{SURE}(\lambda) = \sum_{|Z_j| \leq a_k} Z_j^2 + (p - k)\lambda^2 - p\sigma^2 + 2\sigma^2(p - k)$, which is nondecreasing in λ and smallest at a_k . At $\lambda = 0$ nothing is shrunk and $\text{SURE}(0) = p\sigma^2$, the exact risk of $\mathbf{Z}$. Each $\text{SURE}(a_k)$ is unbiased for its own risk, so their minimum has expectation at most the smallest risk: the optimism of a minimized estimate studied in [Section 29.5](#).

Exercise C2.

In [Example \(Best subset of a given size\)](#) with all $\theta_j = 0$ and $k = 1$, show that the degrees of freedom equal $E \max_j Z_j^2$ (with $\sigma = 1$). Deduce that they are at least 1, and

use $E \max_j Z_j^2 \geq (E \max_j |Z_j|)^2$ to explain why they grow without bound as $m \rightarrow \infty$.

29.2 Mallows' Cp, AIC and BIC

A **selection criterion** assigns a number to each candidate model and picks the smallest. C_p estimates the prediction error of [Section 29.1](#), AIC a likelihood-based discrepancy, and BIC the posterior probability of the model. The first two nearly always agree; the third answers a different question, and the difference shows up in large samples.

29.2.1 Candidates

The candidates are a finite collection of models $\mathcal{C}(\mathbf{X}_k)$, $k \in \mathcal{K}$, with $\text{rank}(\mathbf{X}_k) = p_k$, each fitted by least squares: $\hat{\boldsymbol{\mu}}_k = \mathbf{M}_k \mathbf{Y}$, with residual sum of squares $\text{SSE}_k = \|(\mathbf{I} - \mathbf{M}_k) \mathbf{Y}\|^2$. Typically $\mathbf{X}_k$ consists of the intercept and a subset of the columns of a full model matrix $\mathbf{X}_F$ of rank $P < n$, and $s^2 = \text{SSE}_F / (n - P)$ is the usual variance estimate from the full model. The data follow [Eq. 29.1.1](#). By [Theorem 29.1.1\(c\)](#) the scaled risk of candidate k is

$$J_k = \frac{E \|\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu}\|^2}{\sigma^2} = p_k + \gamma_k, \quad \gamma_k = \frac{\|(\mathbf{I} - \mathbf{M}_k) \boldsymbol{\mu}\|^2}{\sigma^2}, \quad (29.2.1)$$

variance plus squared bias. The bias term γ_k is the noncentrality [Eq. 19.1.1](#) of the test of candidate k against any correct larger model.

29.2.2 Mallows' Cp

Definition 29.2.1 — Mallows' C_p

The C_p statistic of candidate k is

$$C_k = \frac{\text{SSE}_k}{s^2} - n + 2p_k.$$

With σ^2 in place of s^2 , $\sigma^2(C_k + n)/n$ is the covariance-penalty estimate [Eq. 29.1.3](#) of the in-sample prediction error of candidate k . The scaling makes C_k comparable with p_k .

Proposition 29.2.1 — Properties of C_p

- (a) Under [Eq. 29.1.1](#), $C_k^\sigma = \text{SSE}_k / \sigma^2 - n + 2p_k$ is unbiased for J_k .
- (b) Assume normal errors, $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X}_F)$, $\mathcal{C}(\mathbf{X}_k) \subseteq \mathcal{C}(\mathbf{X}_F)$ and $n - P > 2$. Then

$$E(C_k) = J_k + \frac{2(P - p_k + \gamma_k)}{n - P - 2}.$$

- (c) Let $F_k = [(\text{SSE}_k - \text{SSE}_F) / (P - p_k)] / s^2$ be the F statistic for testing candidate k

against the full model ($p_k < P$). Then

$$C_k = (P - p_k)(F_k - 1) + p_k.$$

In particular $C_F = P$, and $C_k \leq p_k$ iff $F_k \leq 1$.

Proof.

- (a) By Theorem 29.1.1(c), $E(\text{SSE}_k) = \sigma^2(n - p_k) + \|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2 = \sigma^2(n - p_k + \gamma_k)$.
 (b) Write $\text{SSE}_k = \text{SSE}_F + (\text{SSE}_k - \text{SSE}_F)$. By Theorem 11.1.1(a), applied to $\mathcal{C}(\mathbf{X}_k) \subseteq \mathcal{C}(\mathbf{X}_F)$, the two terms are independent, $\text{SSE}_F/\sigma^2 \sim \chi^2(n - P)$, and $(\text{SSE}_k - \text{SSE}_F)/\sigma^2$ is noncentral χ^2 with $P - p_k$ degrees of freedom and noncentrality $\|(\mathbf{M}_F - \mathbf{M}_k)\boldsymbol{\mu}\|^2/\sigma^2 = \gamma_k$, so its mean is $P - p_k + \gamma_k$. By Lemma 14.1.3, $E(\sigma^2/s^2) = (n - P)/(n - P - 2)$. Hence

$$\begin{aligned} E\left(\frac{\text{SSE}_k}{s^2}\right) &= (n - P) + (P - p_k + \gamma_k) \frac{n - P}{n - P - 2} \\ &= n - p_k + \gamma_k + \frac{2(P - p_k + \gamma_k)}{n - P - 2}, \end{aligned}$$

and subtracting $n - 2p_k$ gives the result.

- (c) By the definition of F_k , $\text{SSE}_k/s^2 = (n - P) + (P - p_k)F_k$. Subtract $n - 2p_k$. ■

By (b), estimating σ^2 costs little unless the full model uses up most of the data. Mallows (1973) proposed plotting C_k against p_k : points near the line $C_p = p$ have small bias, and the lowest point estimates the best predictor. By (c), adding q columns changes C_p by $2q - (\text{SSE}_{\text{small}} - \text{SSE}_{\text{big}})/s^2$, so C_p prefers the larger model iff the F statistic of the added columns, with the full-model s^2 , exceeds 2.

29.2.3 AIC

If g is the true density and f a model density, the **Kullback–Leibler divergence** $\int g \log(g/f) \geq 0$ is zero iff $f = g$ (Kullback and Leibler 1951), and up to a term free of f it is $E_g[-\log f(\mathbf{Y}^*)]$ for a new data set $\mathbf{Y}^* \sim g$. A fitted model $f(\cdot; \hat{\boldsymbol{\theta}})$ is therefore judged by the **discrepancy**

$$\Delta = E_{\mathbf{Y}^*}[-2 \log f(\mathbf{Y}^*; \hat{\boldsymbol{\theta}}(\mathbf{Y}))],$$

with $\mathbf{Y}^*$ independent of $\mathbf{Y}$. The maximized log-likelihood evaluates the same function at the data themselves, and is optimistic in the same way as the training error.

Definition 29.2.2 — AIC and BIC

For a model with d_k free parameters and maximized log-likelihood ℓ_k ,

$$\text{AIC}_k = -2\ell_k + 2d_k, \quad \text{BIC}_k = -2\ell_k + d_k \log n.$$

In the normal linear model with unknown variance, $d_k = p_k + 1$ and $-2\ell_k = n \log(2\pi \text{SSE}_k/n) + n$ (Theorem 7.3.1), so up to a constant common to all candidates,

$$\text{AIC}_k = n \log \frac{\text{SSE}_k}{n} + 2(p_k + 1), \quad \text{BIC}_k = n \log \frac{\text{SSE}_k}{n} + (p_k + 1) \log n. \quad (29.2.2)$$

Akaike (1973, 1974) showed that $2d$ is the leading term of the optimism of -2ℓ for a correct model fitted by maximum likelihood, in large samples. In the normal linear model the optimism can be computed exactly, without asymptotics.

Theorem 29.2.2 — The expected discrepancy of a normal linear model

Let $\mathbf{Y} \sim N_n(\boldsymbol{\mu}, \sigma^2 \mathbf{I})$ with $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X}_k)$ and $n > p_k + 2$, and let $\hat{\sigma}_k^2 = \text{SSE}_k/n$. For the fitted density $N_n(\hat{\boldsymbol{\mu}}_k, \hat{\sigma}_k^2 \mathbf{I})$,

$$E(\Delta_k) = E[n \log(2\pi \hat{\sigma}_k^2)] + \frac{n(n + p_k)}{n - p_k - 2}.$$

Consequently

$$\text{AICc}_k = -2\ell_k + 2(p_k + 1) + \frac{2(p_k + 1)(p_k + 2)}{n - p_k - 2} \quad (29.2.3)$$

is an unbiased estimate of $E(\Delta_k)$.

Proof. For a new data set $\mathbf{Y}^* = \boldsymbol{\mu} + \boldsymbol{\varepsilon}^*$, $-2 \log f(\mathbf{Y}^*) = n \log(2\pi \hat{\sigma}_k^2) + \|\mathbf{Y}^* - \hat{\boldsymbol{\mu}}_k\|^2 / \hat{\sigma}_k^2$, and as in Eq. 29.1.2 $E(\|\mathbf{Y}^* - \hat{\boldsymbol{\mu}}_k\|^2 \mid \mathbf{Y}) = n\sigma^2 + \|\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu}\|^2$. So

$$\Delta_k = n \log(2\pi \hat{\sigma}_k^2) + \frac{n\sigma^2 + \|\mathbf{M}_k \boldsymbol{\varepsilon}\|^2}{\hat{\sigma}_k^2},$$

using $\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu} = \mathbf{M}_k \boldsymbol{\varepsilon}$ when $\boldsymbol{\mu} \in \mathcal{C}(\mathbf{X}_k)$. Now $\|\mathbf{M}_k \boldsymbol{\varepsilon}\|^2 / \sigma^2 \sim \chi^2(p_k)$ and $n\hat{\sigma}_k^2 / \sigma^2 = \|(\mathbf{I} - \mathbf{M}_k) \boldsymbol{\varepsilon}\|^2 / \sigma^2 \sim \chi^2(n - p_k)$ are independent (Theorem 7.5.1), and $E(\sigma^2 / \hat{\sigma}_k^2) = n / (n - p_k - 2)$ by Lemma 14.1.3. Hence the second term has mean $n(n + p_k) / (n - p_k - 2)$. For the second statement, $-2\ell_k = n \log(2\pi \hat{\sigma}_k^2) + n$, and the identity $n(n + p) = (n - p - 2)(n + 2(p + 1)) + 2(p + 1)(p + 2)$ shows that $n(n + p) / (n - p - 2) = n + 2(p + 1) + 2(p + 1)(p + 2) / (n - p - 2)$. ■

The corrected criterion AICc is due to Sugiura (1978) and Hurvich and Tsai (1989). Its extra term vanishes as $n \rightarrow \infty$ with p_k fixed, which recovers AIC. It matters when p_k is not small compared with n . With $n = 20$ and $p_k = 5$, AIC charges $2(p_k + 1) = 12$, while the exact charge in the proof is $2(p_k + 1)n / (n - p_k - 2) = 18.46$. A simulation of 100000 data sets gives a mean discrepancy of 68.11, equal to the theorem's value to two decimals. AIC underestimates it by 6.46, and the underestimate favours the larger models.

```
import numpy as np
rng = np.random.default_rng(2902)
n_c, p_c, reps_c = 20, 5, 100_000
Xc = np.column_stack([np.ones(n_c), rng.normal(size=(n_c, p_c - 1))])
mu_c = Xc @ np.linspace(1, 2, p_c) # the model is correct
H = Xc @ np.linalg.solve(Xc.T @ Xc, Xc.T)
```

```

Yc = mu_c + rng.normal(size=(reps_c, n_c))
fit_c = Yc @ H
s2ml = np.mean((Yc - fit_c) ** 2, axis=1)          # ML variance estimate
# discrepancy: expected -2 log-likelihood of an independent copy Y*, at the fitted
# values
disc = n_c * np.log(2 * np.pi * s2ml) + (n_c + np.sum((fit_c - mu_c) ** 2, axis=1))
      / s2ml
target = np.mean(n_c * np.log(2 * np.pi * s2ml)) + n_c * (n_c + p_c) / (n_c - p_c -
2)
print(f"E(discrepancy) {disc.mean():.2f}, formula {target:.2f}")
print(f"penalty in AIC {2 * (p_c + 1)}, in AICc {2 * (p_c + 1) * n_c / (n_c - p_c -
2):.2f}")

```

For a wrong candidate the penalty is no longer free of μ , and $2d_k$ is an approximation, justified when the candidate is close to the truth (Konishi and Kitagawa 2008 discuss corrections). In practice AIC and C_p rank candidates almost identically (Exercise (B1)).

29.2.4 BIC

Suppose the candidates carry prior probabilities π_k , and the parameters θ_k of model k a prior density $\pi(\theta_k | k)$. The posterior probability of model k is proportional to $\pi_k m_k(\mathbf{y})$, where

$$m_k(\mathbf{y}) = \int f_k(\mathbf{y} | \theta_k) \pi(\theta_k | k) d\theta_k$$

is the **marginal likelihood** of the model. For the conjugate normal prior of Theorem 7.6.2 the integral has a closed form. BIC is an approximation that needs no particular prior.

Remark (Sketch: where $\log n$ comes from). This is a heuristic derivation; Schwarz (1978) proved the result for exponential families, and Kass and Raftery (1995) give conditions and error terms. Let $\hat{\theta}$ maximize $\ell(\theta) = \log f_k(\mathbf{y} | \theta)$, and let $\mathbf{J}_n = -\nabla^2 \ell(\hat{\theta})$ be the observed information, which for independent observations grows like n : $\mathbf{J}_n = n\tilde{\mathbf{J}}$ with $\tilde{\mathbf{J}}$ of order one. Expanding ℓ to second order about $\hat{\theta}$ (Laplace's method, Tierney and Kadane 1986),

$$\begin{aligned}
m_k(\mathbf{y}) &\approx f_k(\mathbf{y} | \hat{\theta}) \pi(\hat{\theta} | k) \int e^{-(\theta - \hat{\theta})^\top \mathbf{J}_n (\theta - \hat{\theta})/2} d\theta \\
&= f_k(\mathbf{y} | \hat{\theta}) \pi(\hat{\theta} | k) (2\pi)^{d_k/2} \det(\mathbf{J}_n)^{-1/2}.
\end{aligned}$$

Since $\log \det \mathbf{J}_n = d_k \log n + \log \det \tilde{\mathbf{J}}$,

$$-2 \log m_k(\mathbf{y}) = -2\ell_k + d_k \log n + O(1),$$

where the $O(1)$ collects the prior density at $\hat{\theta}$, $\det \tilde{\mathbf{J}}$ and 2π , none of which grows with n . So BIC_k approximates $-2 \log m_k$, and with equal prior probabilities the model with the smallest BIC is approximately the most probable.

The error is of order one, so $\exp(-\text{BIC}_k/2)$ is a crude estimate of a posterior probability, but the rate is right: each parameter costs $\log n$. For a “unit information” prior the error is of order $n^{-1/2}$ (Kass and Wasserman 1995).

29.2.5 Three criteria, one data set, one threshold

Adjusted R^2 of [Chapter 9](#) is sometimes used as a criterion too.

Proposition 29.2.3 — Adjusted R^2 as a criterion

Maximizing $\bar{R}^2$ over candidates that contain the intercept is minimizing $s_k^2 = \text{SSE}_k/(n - p_k)$, and for two nested candidates the larger has the larger $\bar{R}^2$ iff its added columns have $F > 1$.

Proof. These are [Proposition 9.5.3\(d\)](#) and (c). ■

The threshold 1 is lower than any of the others, so $\bar{R}^2$ chooses the largest models. Since $E(s_k^2) = \sigma^2(1 + \gamma_k/(n - p_k))$ ([Theorem 19.1.2\(c\)](#)), minimizing s_k^2 aims at the smallest *bias*, not the smallest prediction error.

For two nested candidates, each criterion is a test with its own critical value. Let the larger model add q columns, have residual degrees of freedom ν , and let $F = [(\text{SSE}_{\text{small}} - \text{SSE}_{\text{big}})/q]/(\text{SSE}_{\text{big}}/\nu)$, so that $\text{SSE}_{\text{small}}/\text{SSE}_{\text{big}} = 1 + qF/\nu$. The larger model is preferred by

criterion	when	threshold for F , approximately
adjusted R^2	$F > 1$ (Proposition 29.2.3)	1
C_p	$F > 2$, with s^2 from the full model	2
AIC	$n \log(1 + qF/\nu) > 2q$	2
BIC	$n \log(1 + qF/\nu) > q \log n$	$\log n$
F test at level α	$F > F_\alpha(q, \nu)$	$F_\alpha(q, \nu)$

The approximations use $\log(1 + x) \approx x$ and $\nu \approx n$. With $n = 50$, $q = 1$ and $\nu = 47$, the exact thresholds are 1.92 for AIC and 3.82 for BIC ($\log n = 3.91$), against $F_{0.05}(1, 47) = 4.05$. As tests of one column, AIC acts at level 0.17 and BIC at level 0.056, close to the conventional 5% at this sample size. BIC's level falls as n grows, and AIC's does not.

Example. (Violent crime in the states)

Return to the 50 states of [Chapter 6](#) (the District of Columbia left out) and take as response the logarithm of the violent crime rate in 2009. The candidate regressors are the percentages of adults with a high-school diploma, of people below the poverty line, of single-parent households, of white residents and of urban residents, so there are $2^5 = 32$ candidates, all with an intercept. The full model has $P = 6$ and $s^2 = 0.1035$. The eight candidates with the smallest C_p are

regressors	p	C_p	ΔAIC	ΔBIC	$\bar{R}^2$
single, urban	3	2.20	0.00	0.42	0.471

Figure 29.2.1: C_p against the number of columns for the 32 candidate models for log violent crime in the 50 states. The dashed line is $C_p = p$. The three labelled models are the choices of BIC, of C_p and AIC, and of adjusted R^2 .

poverty, single, urban	4	2.47	0.09	2.42	0.480
single	2	3.54	1.49	0.00	0.445
high school, single, urban	4	3.94	1.72	4.05	0.463
high school, poverty, single, urban	5	4.01	1.57	5.82	0.474
single, white, urban	4	4.04	1.82	4.16	0.462
poverty, single, white, urban	5	4.47	2.09	6.34	0.468
high school, single	3	5.48	3.42	3.85	0.434

where Δ is the difference from the smallest value over all 32 candidates. C_p and AIC choose single parenthood and urbanization; BIC drops urbanization; $\bar{R}^2$ adds poverty. The first three rows are within two units of each other on every scale, and none of the criteria separates them convincingly. Figure 29.2.1 is Mallows' plot. Every candidate without single parenthood lies far above the line $C_p = p$: it is badly biased.

```
import itertools
import numpy as np
```

```

import statsmodels.api as sm
data = sm.datasets.statcrime.load_pandas().data.drop(index="District of Columbia")
names = ["hs_grad", "poverty", "single", "white", "urban"]
y = np.log(data["violent"].to_numpy())
n = len(y)

def sse(cols):
    X = np.column_stack([np.ones(n)] + [data[c].to_numpy() for c in cols])
    b, *_ = np.linalg.lstsq(X, y, rcond=None)
    return np.sum((y - X @ b) ** 2), X.shape[1]

sse_full, P = sse(names)
s2 = sse_full / (n - P)                                # sigma^2 estimate from the

```

29.2.6 Consistency and efficiency

The thresholds explain the large-sample behaviour. The F statistic of an irrelevant column stays of order one, so a growing threshold such as $\log n$ eventually excludes it and a fixed one does not; that of a relevant column grows like n .

Proposition 29.2.4 — AIC and BIC in large samples

Let the candidate set $\mathcal{K}$ be finite and fixed, and consider a sequence of designs and means with $n \rightarrow \infty$. Let the errors be independent and identically distributed with mean zero and variance σ^2 , and let $\sup_n \|\mu\|^2/n < \infty$. Call k *correct* if $\mu \in \mathcal{C}(\mathbf{X}_k)$. Assume that there is a correct k_0 such that every other correct candidate has $p_k > p_{k_0}$, and that $\liminf_n \|(\mathbf{I} - \mathbf{M}_k)\mu\|^2/n > 0$ for every candidate that is not correct. Select $\hat{k}$ by minimizing $\text{IC}_k = n \log(\text{SSE}_k/n) + c_n p_k$.

- (a) If $c_n \rightarrow \infty$ and $c_n/n \rightarrow 0$, then $\Pr(\hat{k} = k_0) \rightarrow 1$. In particular BIC ($c_n = \log n$) is consistent.
- (b) If $c_n = c$ is constant, the errors are normal, and k is a correct candidate with $\mathcal{C}(\mathbf{X}_{k_0}) \subset \mathcal{C}(\mathbf{X}_k)$ and $q = p_k - p_{k_0}$, then $\Pr(\text{IC}_k < \text{IC}_{k_0}) \rightarrow \Pr\{\chi^2(q) > cq\} > 0$. In particular AIC ($c = 2$) is not consistent when such a candidate is available.
- (c) (*Efficiency, stated with a sketch.*) Suppose instead that no candidate is correct,

and that the candidate sets grow with n so that the smallest risk over candidates tends to infinity. Then, under moment conditions on the errors and a condition limiting the number of candidates, with σ^2 known or consistently estimated in C_p , and for AIC with the largest candidate dimension $o(n)$, the loss $\|\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu}\|^2$ of the C_p or AIC choice divided by $\min_k \|\hat{\boldsymbol{\mu}}_k - \boldsymbol{\mu}\|^2$ tends to one in probability (Shibata 1981; Li 1987). A criterion with $c_n \rightarrow \infty$ does not have this property in general.

Proof. Throughout, $\text{SSE}_k = \|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2 + 2\boldsymbol{\mu}^\top (\mathbf{I} - \mathbf{M}_k)\boldsymbol{\varepsilon} + \|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\varepsilon}\|^2$. The last term is $\|\boldsymbol{\varepsilon}\|^2 - \|\mathbf{M}_k\boldsymbol{\varepsilon}\|^2$, where $\|\boldsymbol{\varepsilon}\|^2/n \rightarrow \sigma^2$ in probability by the weak law of large numbers and $\mathbb{E}\|\mathbf{M}_k\boldsymbol{\varepsilon}\|^2 = \sigma^2 p_k$, so $\|\mathbf{M}_k\boldsymbol{\varepsilon}\|^2 = O_p(1)$ by Markov's inequality. The middle term has mean zero and variance $4\sigma^2\|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2 = O(n)$, so it is $O_p(\sqrt{n})$ by Chebyshev's inequality.

- (a) It suffices to show $\Pr(\text{IC}_k > \text{IC}_{k_0}) \rightarrow 1$ for each $k \neq k_0$, since $\mathcal{K}$ is finite. For k_0 , $\text{SSE}_{k_0} = \|\boldsymbol{\varepsilon}\|^2 - \|\mathbf{M}_{k_0}\boldsymbol{\varepsilon}\|^2$, so $\text{SSE}_{k_0}/n \rightarrow \sigma^2$.

A correct $k \neq k_0$. Then $|\text{SSE}_k - \text{SSE}_{k_0}| \leq \|\mathbf{M}_k\boldsymbol{\varepsilon}\|^2 + \|\mathbf{M}_{k_0}\boldsymbol{\varepsilon}\|^2 = O_p(1)$, and $n \log(\text{SSE}_k/\text{SSE}_{k_0}) = n \log(1 + (\text{SSE}_k - \text{SSE}_{k_0})/\text{SSE}_{k_0}) = O_p(1)$, because the ratio inside the logarithm is $O_p(1/n)$. Hence $\text{IC}_k - \text{IC}_{k_0} = O_p(1) + c_n(p_k - p_{k_0})$, which tends to $+\infty$ in probability since $p_k > p_{k_0}$ and $c_n \rightarrow \infty$.

A candidate that is not correct. Let $0 < 2b < \liminf_n \|(\mathbf{I} - \mathbf{M}_k)\boldsymbol{\mu}\|^2/n$. By the expansion, $\text{SSE}_k/n \geq \sigma^2 + b$ with probability tending to one, so $\log(\text{SSE}_k/\text{SSE}_{k_0}) \geq \delta$ with probability tending to one, where $\delta = \frac{1}{2} \log(1 + b/\sigma^2) > 0$. Then $\text{IC}_k - \text{IC}_{k_0} \geq n\delta - c_n|p_k - p_{k_0}|$, which tends to $+\infty$ because $c_n/n \rightarrow 0$.

- (b) Here $D = \text{SSE}_{k_0} - \text{SSE}_k = \|(\mathbf{M}_k - \mathbf{M}_{k_0})\boldsymbol{\varepsilon}\|^2$, and $D/\sigma^2 \sim \chi^2(q)$ exactly for every n (Theorem 4.3.2). With $\text{SSE}_k/n \rightarrow \sigma^2$, Slutsky's theorem gives $nD/\text{SSE}_k \rightarrow \chi^2(q)$ in distribution, and $n \log(1 + D/\text{SSE}_k) - nD/\text{SSE}_k \rightarrow 0$ in probability because $D/\text{SSE}_k = O_p(1/n)$ and $|\log(1 + x) - x| \leq x^2$ for $x \geq 0$. So $n \log(\text{SSE}_{k_0}/\text{SSE}_k) \rightarrow \chi^2(q)$ in distribution. Now $\text{IC}_k < \text{IC}_{k_0}$ iff $n \log(\text{SSE}_{k_0}/\text{SSE}_k) > cq$, and cq is a continuity point of the limit.

- (c) *Sketch.* By Proposition 29.2.1(a), C_k^σ is unbiased for the scaled risk of each candidate, and $C_k^\sigma - J_k$ and the loss minus the risk are sums of centred quadratic and linear forms in $\boldsymbol{\varepsilon}$. The conditions make these fluctuations small compared with the risks, uniformly over the candidates, so minimizing C_k is asymptotically the same as minimizing the loss. Li (1987) gives such conditions for C_p , cross-validation and generalized cross-validation: finite moments of order $4m$ for the errors and $\sum_k (nR_k)^{-m} \rightarrow 0$ for some m , where R_k is the risk of candidate k per observation. AIC differs from C_p by terms of order p_k^2/n , which are negligible when the candidate dimensions are $o(n)$ (Shibata 1981). A growing penalty c_n biases the choice towards candidates whose risk is larger by a factor that does not tend to one, as Figure 29.2.2(b) shows. ■

For AIC the limits in (b) are 0.157, 0.135 and 0.075 for $q = 1, 2, 5$: one extra column is kept about one time in six however large the sample. Nishii (1984) proved (a) and (b) for the normal linear model.

Example. (Consistency against efficiency)

Panel (a) of Figure 29.2.2 uses six independent normal regressors, three of them with

Figure 29.2.2: (a) Probability of selecting the true subset among 64, when a finite true model exists; dashed: AIC's limit 0.598. (b) Loss of the selected model relative to the best candidate, when no candidate is true. 1000 simulated data sets per point in (a), 400 in (b).

slopes 1, 0.5 and 0.25 and three with slope zero, and all 64 subsets as candidates. With $n = 50$ the true subset is found by AIC with probability 0.28 and by BIC with probability 0.24, because the smallest slope is hard to detect. With $n = 3200$ BIC finds it with probability 0.99, while AIC stays at 0.60. That is the limit $\Pr\{\chi^2(1) \leq 2\}^3 = 0.598$, because in large samples AIC keeps each irrelevant regressor independently when its squared t statistic exceeds about 2.

In panel (b) the truth has 1000 regressors with slopes $2/j$, all nonzero, and the candidates are the nested models containing the first k regressors, $k \leq n/4$. No candidate is correct. The ratio of the loss of the chosen model to the smallest loss among the candidates falls for AIC, from 1.18 at $n = 100$ to 1.07 at $n = 3200$, while for BIC it stays between 1.3 and 1.8 at every sample size.

```
import itertools
import numpy as np
rng = np.random.default_rng(2903)
beta = np.array([1.0, 0.5, 0.25, 0.0, 0.0, 0.0]) # three relevant, three
        irrelevant
true_set = (0, 1, 2)
subsets = [s for k in range(7) for s in itertools.combinations(range(6), k)]

def choose(X, y, penalty):
    """All-subsets choice by  $n \log(\text{SSE}/n) + \text{penalty} * (\text{number of columns})$ ."""
    n = len(y)
    best, arg = np.inf, None
    for s in subsets:
        Xs = np.column_stack([np.ones(n), X[:, list(s)]])
        b, *_ = np.linalg.lstsq(Xs, y, rcond=None)
        crit = n * np.log(np.sum((y - Xs @ b) ** 2) / n) + penalty * Xs.shape[1]
        if crit < best:
            best, arg = crit, s
    return arg
```

```

def hit_rates(n, reps):
    X = rng.normal(size=(n, 6))                # the design, fixed for
    this n
    hits = np.zeros(2)
    for _ in range(reps):
        y = 1 + X @ beta + rng.normal(size=n)
        hits += [choose(X, y, 2.0) == true_set, choose(X, y, np.log(n)) == true_set]
    return hits / reps

for n in (50, 200, 800):
    aic, bic = hit_rates(n, 100)
    print(f"n = {n:4d}: AIC finds the true subset {aic:.2f} of the time, BIC {bic:.2f}")

```

The two properties cannot be combined: Yang (2005) showed that no rule can be consistent and also attain the best rate of prediction risk. The choice between AIC and BIC is a choice of goal: prediction (AIC, C_p , cross-validation) or identifying a small true set of regressors (BIC).

29.2.7 Selection in an orthonormal design

When the columns are orthonormal the search disappears, and the criteria can be compared exactly.

Proposition 29.2.5 — Selection as hard thresholding

Let $\mathbf{X}$ have orthonormal columns, $\mathbf{X}^\top \mathbf{X} = \mathbf{I}_m$, put $\mathbf{Z} = \mathbf{X}^\top \mathbf{Y}$, and let σ^2 be known. Among all subsets S of the columns, $\text{SSE}_S/\sigma^2 + c^2|S|$ is minimized (uniquely, with probability one) by $S = \{j : |Z_j| > c\sigma\}$. The selected fit has coefficients $Z_j 1\{|Z_j| > c\sigma\}$.

Proof. The projection onto the columns in S is $\sum_{j \in S} \mathbf{x}_j \mathbf{x}_j^\top$, so $\text{SSE}_S = \|\mathbf{Y}\|^2 - \sum_{j \in S} Z_j^2$ and the criterion is $\|\mathbf{Y}\|^2/\sigma^2 + \sum_{j \in S} (c^2 - Z_j^2/\sigma^2)$. A column lowers it iff $Z_j^2 > c^2\sigma^2$, and ties have probability zero. ■

With known σ^2 , C_p and AIC take $c = \sqrt{2}$ and BIC takes $c = \sqrt{\log n}$. Testing each coefficient at level 5% and keeping the significant ones (the **pretest estimator** of Bancroft 1944) takes $c = 1.96$. This is the hard thresholding of [Theorem 27.4.2](#), and each coordinate can be studied alone. With $\sigma = 1$ and $Z \sim N(\theta, 1)$, the risk of $Z 1\{|Z| > c\}$ is

$$\begin{aligned}
 R(\theta; c) &= \theta^2 D + 1 - D + (c - \theta)\phi(c - \theta) + (c + \theta)\phi(c + \theta), \\
 D &= \Phi(c - \theta) - \Phi(-c - \theta),
 \end{aligned}
 \tag{29.2.4}$$

where D is the probability that the coordinate is dropped ([Exercise \(B2\)](#)). Least squares has risk 1, and dropping the coordinate always has risk θ^2 .

[Figure 29.2.3](#) shows the trade. At $\theta = 0$ the risks are 0.572 for $c = \sqrt{2}$, 0.279 for the pretest and 0.075 for BIC with $n = 1000$. (At zero the risk equals the degrees of freedom of [Proposition 29.1.3](#): both are $E[Z^2 1\{|Z| > c\}]$.) The curves cross 1 at $\theta = 0.78, 0.84$ and 0.92 and peak

Figure 29.2.3: Risk of hard thresholding $Z1\{|Z| > c\}$, $Z \sim N(\theta, 1)$, for the thresholds of C_p and AIC, a 5% pretest and BIC with $n = 1000$. Least squares has risk 1 (dashed); always dropping the coordinate has risk θ^2 (grey).

at 1.651, 2.464 and 3.956, at $\theta = 1.88$, 2.16 and 2.59. A larger threshold gains more at zero and loses more at moderate θ , and no threshold, least squares included, is uniformly best. This is [Theorem 19.1.5](#) again: dropping a coordinate helps iff $\theta^2 < 1$, and the data cannot tell which side of the boundary they are on. Shrinkage avoids the bump: the James–Stein estimator of [Theorem 27.5.2](#) beats least squares everywhere when $m \geq 3$.

```
import numpy as np
from scipy.stats import norm

def hard_risk(theta, c):
    """E(Z 1{|Z| > c} - theta)^2 for Z ~ N(theta, 1)."""
    D = norm.cdf(c - theta) - norm.cdf(-c - theta) # Pr(|Z| <= c): coordinate
    dropped
    return theta**2 * D + 1 - D + (c - theta) * norm.pdf(c - theta) + (c + theta) *
    norm.pdf(c + theta)

thetas = np.linspace(0, 6, 601)
for label, c in [("C_p / AIC", np.sqrt(2)), ("5% pretest", 1.96), ("BIC, n = 1000",
    np.sqrt(np.log(1000)))]:
    r = hard_risk(thetas, c)
    print(f"{label:14s} c = {c:.3f}: risk at 0 = {r[0]:.3f}, "
        f"maximum {r.max():.3f} at theta = {thetas[r.argmax():.2f}")
```

29.2.8 Exercises

29.2.8.1 A. Check your understanding

Exercise A1.

In [Example \(Violent crime in the states\)](#) the model with single parenthood and urbanization has $\text{SSE} = 4.782$. Compute its C_p from s^2 , n and p , and the F statistic for testing it against the full model.

Solution. $C_p = 4.782/0.1035 - 50 + 6 = 46.20 - 44 = 2.20$. By [Proposition 29.2.1\(c\)](#), $2.20 = 3(F - 1) + 3$, so $F = 0.73$: the three regressors left out together have an F statistic below one.

29.2.8.2 B. Practice**Exercise B1.**

Let $\hat{\sigma}^2$ be any fixed positive number and write $\text{SSE}_k/n = \hat{\sigma}^2(1 + \delta_k)$. Show that

$$\text{AIC}_k - \text{AIC}_j = \frac{\text{SSE}_k - \text{SSE}_j}{\hat{\sigma}^2} + 2(p_k - p_j) + n O(\delta_k^2 + \delta_j^2),$$

and conclude that with $\hat{\sigma}^2 = s^2$ AIC and C_p differences agree when every candidate's residual mean square is close to s^2 .

Exercise B2.

Derive [Eq. 29.2.4](#). (Split the risk according to whether the coordinate is kept, and use $\int_a^b w^2 \phi(w) dw = \Phi(b) - \Phi(a) - b\phi(b) + a\phi(a)$.)

Solution. Let $Z = \theta + W$. When the coordinate is dropped ($|Z| \leq c$, probability D) the loss is θ^2 ; when kept it is W^2 . So $R = \theta^2 D + E[W^2 1\{|\theta + W| > c\}]$. The event $|\theta + W| \leq c$ is $-c - \theta \leq W \leq c - \theta$, so $E[W^2 1\{|\theta + W| > c\}] = 1 - \int_{-c-\theta}^{c-\theta} w^2 \phi(w) dw = 1 - D + (c - \theta)\phi(c - \theta) + (c + \theta)\phi(c + \theta)$, using $\phi(-x) = \phi(x)$.

Exercise B3.

Show that AIC prefers the larger of two nested candidates iff $F > (\nu/q)(e^{2q/n} - 1)$, and BIC iff $F > (\nu/q)(n^{q/n} - 1)$. Find the limits of both thresholds as $n \rightarrow \infty$ with q and $n - \nu$ fixed.

29.2.8.3 C. Going deeper**Exercise C1.**

In panel (a) of [Example \(Consistency against efficiency\)](#), suppose the three regressors with zero slopes are orthogonal to each other and to the relevant ones. Show that for large n AIC selects the true subset iff each of them has squared t statistic below about 2, and deduce the limit $\Pr\{\chi^2(1) \leq 2\}^3$.

Solution. Every candidate that omits a relevant regressor loses with probability tending to one (Proposition 29.2.4, proof of (a), second case, which holds for any c_n with $c_n/n \rightarrow 0$). Among candidates containing the relevant block, orthogonality makes $\text{SSE}_{k_0 \cup A} = \text{SSE}_{k_0} - \sum_{j \in A} \|\mathbf{M}_{\{j\}} \boldsymbol{\epsilon}\|^2$, and $n \log(\text{SSE}_{k_0}/\text{SSE}_{k_0 \cup A}) = \sum_{j \in A} T_j^2 + o_p(1)$ with $T_j^2 \rightarrow \chi^2(1)$ independent. AIC adds A iff this exceeds $2|A|$, so it chooses $A = \{j : T_j^2 > 2\}$ up to $o_p(1)$, and chooses $A = \emptyset$ with probability tending to $\prod_j \Pr(T_j^2 \leq 2) = \Pr\{\chi^2(1) \leq 2\}^3$.

29.3 Cross-validation

The criteria of Section 29.2 correct the training error by a formula that rests on assumptions. Cross-validation instead predicts cases that the fit has not seen. It needs neither σ^2 nor degrees of freedom, and applies to any procedure, including one that selects a model. Its price is computation, a bias that is easy to describe, and a variance that is not.

29.3.1 K-fold and leave-one-out

Definition 29.3.1 — Cross-validation

Let the cases $(\mathbf{x}_{(i)}, y_i)$, $i = 1, \dots, n$, be divided into K disjoint **folds** $I_1, \dots, I_K$. For each k , let $\hat{f}^{(-k)}$ be the prediction rule obtained by applying the procedure to the cases outside I_k . The **K -fold cross-validation** estimate of prediction error is

$$\text{CV}_K = \frac{1}{n} \sum_{k=1}^K \sum_{i \in I_k} (y_i - \hat{f}^{(-k)}(\mathbf{x}_{(i)}))^2.$$

With $K = n$, each fold is a single case, and CV_n is **leave-one-out** cross-validation. With $K = 2$ and one fold used only for fitting, the estimate is a **holdout** or **validation-set** estimate.

The idea is old (Stone 1974; Geisser 1975; Allen 1974 for least squares). What cross-validation estimates is clearest when the cases are a random sample.

Proposition 29.3.1 — What K-fold cross-validation estimates

Let the cases be independent draws of $(\mathbf{X}, Y)$, let the folds be fixed in advance with equal sizes n/K , and let $\text{Err}(m) = \mathbb{E}(Y_0 - \hat{f}_m(\mathbf{X}_0))^2$ be the expected squared error of the procedure fitted to m cases, for an independent new case $(\mathbf{X}_0, Y_0)$. Then

$$\mathbb{E}(\text{CV}_K) = \text{Err}(n - n/K).$$

Proof. For $i \in I_k$, the rule $\hat{f}^{(-k)}$ is the procedure applied to $n - n/K$ independent cases, and case i is independent of them and has the same distribution as $(\mathbf{X}_0, Y_0)$. So each term of the double sum has expectation $\text{Err}(n - n/K)$. ■

Figure 29.3.1: (a) Mean and standard deviation of CV_K over 4000 training sets ($n = 40$, ten regressors), with the expected error at sample size $n - n/K$ (crosses) and at n (dashed). (b) CV_{10} against the prediction error of the model actually fitted.

The expectation is over training sets as well as new cases. Cross-validation therefore estimates the expected error of the *procedure* at a slightly smaller sample size, not the error of the particular fit computed from all n cases. For least squares with k normal regressors and a correct model, [Theorem 14.2.6](#) gives $\text{Err}(m) = \sigma^2(1 + 1/m)(m - 2)/(m - k - 2)$, so the bias of CV_K can be computed exactly.

Example. (Bias and spread of K-fold cross-validation)

Take $n = 40$ cases with $k = 10$ independent standard normal regressors, an intercept, slopes 0.5 and $\sigma = 1$, and fit by least squares. The target is $\text{Err}(40) = 1.391$. Over 4000 training sets, the averages of CV_K for $K = 2, 5, 10, 40$ are 2.378, 1.551, 1.461 and 1.408, against $\text{Err}(n - n/K)$ of 2.363, 1.547, 1.456 and 1.406 from [Proposition 29.3.1](#). Fitting to half the data inflates the error by 70% here, because ten slopes are estimated from twenty cases. Their standard deviations across training sets are 1.062, 0.477, 0.411 and 0.378. For this stable procedure leave-one-out has both the smallest bias and the smallest variance.

The error of the fitted model itself, $\sigma^2 + \|\hat{\beta} - \beta\|^2$ for a new standard normal case, varies too: its mean is 1.395 and its standard deviation 0.203. Panel (b) of [Figure 29.3.1](#) plots CV_{10} against it. The correlation is -0.005 (-0.014 for leave-one-out). Cross-validation reports how well least squares does on average with forty such cases, not how well this fit will do.

```
import numpy as np
rng = np.random.default_rng(2905)
n_s, k_s, sigma = 40, 10, 1.0
beta = np.r_[1.0, np.full(k_s, 0.5)]  # intercept and ten
    slopes

def err_theory(m):
    """Expected error of a least squares fit to m cases (Chapter 14, normal
    regressors)."""
```

```

    return sigma**2 * (1 + 1 / m) * (m - 2) / (m - k_s - 2)

def cv_kfold(X, y, K):
    folds = np.arange(len(y)) % K                                # equal folds (cases
    are exchangeable)
    sq = np.empty(len(y))
    for f in range(K):
        tr, te = folds != f, folds == f
        b, *_ = np.linalg.lstsq(X[tr], y[tr], rcond=None)
        sq[te] = (y[te] - X[te] @ b) ** 2
    return sq.mean()

Ks = [2, 5, 10, n_s]

def simulate(reps):
    cv = np.empty((reps, len(Ks)))
    err_cond = np.empty(reps)                                     # error of the fit at
    hand
    for r in range(reps):
        Xr = np.column_stack([np.ones(n_s), rng.normal(size=(n_s, k_s))])
        yr = Xr @ beta + sigma * rng.normal(size=n_s)
        b, *_ = np.linalg.lstsq(Xr, yr, rcond=None)
        err_cond[r] = sigma**2 + np.sum((b - beta) ** 2)           # new case  $X_0 \sim N(0, I)$ 
        cv[r] = [cv_kfold(Xr, yr, K) for K in Ks]
    return cv, err_cond

cv, err_cond = simulate(300)                                     # the book's figures
    use 4000
for j, K in enumerate(Ks):
    print(f"K = {K:2d}: mean {cv[:, j].mean():.3f} (theory {err_theory(n_s - n_s //
    K):.3f}), sd {cv[:, j].std():.3f}")
print(f"error of the fit at hand: mean {err_cond.mean():.3f} (theory {err_theory(n_s
):.3f})")
print("correlation of CV_10 with it:", np.corrcoef(cv[:, 2], err_cond)[0, 1])

```

Bates, Hastie and Tibshirani (2024) study this phenomenon for linear models. The spread falling with K is typical of least squares, whose fits change little when a few cases are removed; for procedures that jump, such as subset selection, leave-one-out can be the more variable choice (Breiman and Spector 1992). Five or ten folds are the usual compromise.

29.3.2 The leverage shortcut

Leave-one-out looks expensive: n refits. For least squares and for ridge regression it costs one fit. The reason is a small fixed-point argument.

Theorem 29.3.2 — Leave-one-out without refitting

Let Ω be a $p \times p$ nonnegative definite matrix, let $\hat{\beta}$ minimize $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \mathbf{b}^\top \Omega \mathbf{b}$, and let $\hat{\beta}_{(i)}$ minimize the same criterion with case i removed. Assume that $\mathbf{A}_{(i)} = \mathbf{X}_{(i)}^\top \mathbf{X}_{(i)} + \Omega$

is nonsingular for every i , where $\mathbf{X}_{(i)}$ is $\mathbf{X}$ without row i . Let $\mathbf{S} = \mathbf{X}(\mathbf{X}^\top \mathbf{X} + \mathbf{\Omega})^{-1} \mathbf{X}^\top$ and $\hat{\mathbf{y}} = \mathbf{S}\mathbf{y}$. Then:

- (a) $s_{ii} < 1$ for every i ;
- (b) $y_i - \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)} = (y_i - \hat{y}_i)/(1 - s_{ii})$;
- (c) consequently

$$\text{CV}_n = \frac{1}{n} \sum_{i=1}^n \left(\frac{y_i - \hat{y}_i}{1 - s_{ii}} \right)^2. \quad (29.3.1)$$

For least squares ($\mathbf{\Omega} = \mathbf{0}$) this is [Theorem 20.3.1\(d\)](#), and $\text{CV}_n = \text{PRESS}/n$ with PRESS as in [Eq. 20.3.1](#).

Proof.

- (a) Write $\mathbf{x} = \mathbf{x}_{(i)}$ and $\mathbf{A} = \mathbf{A}_{(i)}$, which is positive definite because it is nonnegative definite and nonsingular. Then $\mathbf{X}^\top \mathbf{X} + \mathbf{\Omega} = \mathbf{A} + \mathbf{x}\mathbf{x}^\top$, and $(\mathbf{A} + \mathbf{x}\mathbf{x}^\top)^{-1} \mathbf{x} = \mathbf{x}(1 + a)^{-1}$ with $a = \mathbf{x}^\top \mathbf{A}^{-1} \mathbf{x} \geq 0$. Hence $(\mathbf{A} + \mathbf{x}\mathbf{x}^\top)^{-1} \mathbf{x} = \mathbf{A}^{-1} \mathbf{x} / (1 + a)$ and $s_{ii} = \mathbf{x}^\top (\mathbf{A} + \mathbf{x}\mathbf{x}^\top)^{-1} \mathbf{x} = a / (1 + a) < 1$.
- (b) Let $\tilde{y}_i = \mathbf{x}_{(i)}^\top \hat{\boldsymbol{\beta}}_{(i)}$, the leave-one-out prediction, and let $\tilde{\mathbf{y}}$ be $\mathbf{y}$ with y_i replaced by $\tilde{y}_i$. For any $\mathbf{b}$, the full criterion evaluated at $\tilde{\mathbf{y}}$ is the leave-one-out criterion plus $(\tilde{y}_i - \mathbf{x}_{(i)}^\top \mathbf{b})^2 \geq 0$. At $\mathbf{b} = \hat{\boldsymbol{\beta}}_{(i)}$ the extra term is zero and the leave-one-out criterion is at its minimum. So $\hat{\boldsymbol{\beta}}_{(i)}$ minimizes the full criterion for the data $\tilde{\mathbf{y}}$, and since that minimizer is unique ($\mathbf{X}^\top \mathbf{X} + \mathbf{\Omega} = \mathbf{A} + \mathbf{x}\mathbf{x}^\top$ is positive definite), $\mathbf{X} \hat{\boldsymbol{\beta}}_{(i)} = \mathbf{S} \tilde{\mathbf{y}}$. Its i th entry reads

$$\tilde{y}_i = (\mathbf{S} \tilde{\mathbf{y}})_i = (\mathbf{S} \mathbf{y})_i - s_{ii}(y_i - \tilde{y}_i) = \hat{y}_i - s_{ii}(y_i - \tilde{y}_i).$$

Rearranging, $(1 - s_{ii})(y_i - \tilde{y}_i) = y_i - \hat{y}_i$, and (a) allows division by $1 - s_{ii}$.

- (c) follows from (b), and for $\mathbf{\Omega} = \mathbf{0}$, $s_{ii} = h_{ii}$ and (b) is [Theorem 20.3.1\(d\)](#). ■

The argument uses only that deleting a case gives the same answer as replacing its response by its own prediction. It covers the ridge estimators of [Chapter 27](#) and the smoothers of [Chapter 43](#) ([Theorem 43.5.2](#)), but not the lasso or subset selection, where deleting a case can change which coefficients are nonzero.

[Section 27.2](#) already used the leave-one-out shortcut and GCV to choose the ridge λ ; the theorem proves the shortcut for every quadratic penalty. Replacing each s_{ii} by its average $\text{tr}(\mathbf{S})/n$ gives a criterion that needs only the trace.

Definition 29.3.2 — Generalized cross-validation

For a linear smoother $\hat{\mathbf{y}} = \mathbf{S}\mathbf{y}$ with $\text{tr}(\mathbf{S}) < n$,

$$\text{GCV} = \frac{n^{-1} \|\mathbf{y} - \hat{\mathbf{y}}\|^2}{(1 - \text{tr}(\mathbf{S})/n)^2}.$$

Craven and Wahba (1979) introduced GCV for smoothing splines and Golub, Heath and Wahba (1979) for ridge regression, where it is leave-one-out after a rotation that equalizes the diagonal of $\mathbf{S}$. Since $(1 - x)^{-2} = 1 + 2x + O(x^2)$, $\text{GCV} \approx \overline{\text{err}}(1 + 2\text{df}/n)$, the covariance penalty Eq. 29.1.3 with σ^2 replaced by $\overline{\text{err}}$. For least squares $\text{GCV} = ns^2/(n - p)$, and for a correct model ($\mu \in \mathcal{C}(\mathbf{X})$), by Proposition 20.3.2, $E(\text{PRESS})/n \geq \sigma^2 n/(n - p) = E(\text{GCV})$: high-leverage cases inflate leave-one-out.

For the state regression of Example (Violent crime in the states) with all five regressors, $\text{PRESS}/n = 0.1426$ and $\text{GCV} = 0.1176$. For ridge regression on the standardized regressors with $\lambda = 5$ (intercept unpenalized), $\text{tr}(\mathbf{S}) = 4.870$, and the shortcut gives $\text{CV}_n = 0.1309$, equal to the brute-force value from fifty refits to rounding error, against $\text{GCV} = 0.1140$.

```
import numpy as np
import statsmodels.api as sm
data = sm.datasets.statecrime.load_pandas().data.drop(index="District of Columbia")
names = ["hs_grad", "poverty", "single", "white", "urban"]
y = np.log(data["violent"].to_numpy())
Zs = data[names].to_numpy()
Zs = (Zs - Zs.mean(axis=0)) / Zs.std(axis=0) # standardized regressors
X = np.column_stack([np.ones(len(y)), Zs])
n, p = X.shape
Omega = np.diag([0.0] + [1.0] * (p - 1)) # ridge penalty,
# intercept left free

def ridge_fit(X, y, lam):
    return np.linalg.solve(X.T @ X + lam * Omega, X.T @ y)

lam = 5.0
S = X @ np.linalg.solve(X.T @ X + lam * Omega, X.T) # the smoother matrix
resid = y - S @ y
loo_short = resid / (1 - np.diag(S)) # the shortcut
loo_brute = np.array([y[i] - X[i] @ ridge_fit(np.delete(X, i, 0), np.delete(y, i),
    lam)
    for i in range(n)]) # n refits
print("largest discrepancy:", np.max(np.abs(loo_short - loo_brute)))
cv_loo = np.mean(loo_short**2)
gcv = np.mean(resid**2) / (1 - np.trace(S) / n) ** 2
print(f"CV_n = {cv_loo:.5f}, GCV = {gcv:.5f}, tr(S) = {np.trace(S):.3f}")
```

Remark (Sketch: leave-one-out behaves like AIC). If every leverage is close to p/n , then $(1 - h_{ii})^{-2} \approx 1 + 2p/n$ and $\text{CV}_n \approx (\text{SSE}/n)(1 + 2p/n)$, so $n \log \text{CV}_n \approx n \log(\text{SSE}/n) + 2p$, the AIC of Eq. 29.2.2 up to a constant. Stone (1977) made this equivalence precise. Leave-one-out therefore shares AIC's large-sample behaviour: efficient when no candidate is correct (Li 1987), not consistent when one is. Shao (1993) showed that consistency requires leaving out a fraction of the cases that tends to one, the opposite of what prediction suggests; K -fold with fixed K is not consistent either.

29.3.3 Choosing a model by cross-validation

To choose among candidates, take the smallest CV_K . The fold errors $\text{CV}^{(k)}$ give a rough standard error $\text{sd}(\text{CV}^{(1)}, \dots, \text{CV}^{(K)})/\sqrt{K}$, which treats the folds as independent although their

Figure 29.3.2: Ten-fold cross-validation error of the best subset of each size for log violent crime in the 50 states, with one-standard-error bars. Dashed: the minimum plus one standard error.

training sets overlap; no unbiased estimate of the variance of CV_K exists (Bengio and Grandvalet 2004). The **one-standard-error rule** (Breiman, Friedman, Olshen and Stone 1984) takes the simplest candidate within one standard error of the minimum, trading a little estimated error for a smaller model.

Example. (Cross-validating the state regressions)

For each size from 0 to 5, take the best subset of the state regressors by residual sum of squares and estimate its prediction error by ten-fold cross-validation, with one random split into folds of five states. Figure 29.3.2 shows the result. The minimum, 0.1136 with standard error 0.0198, is at two regressors (single parenthood and urbanization), the choice of C_p and AIC. Single parenthood alone has 0.1162, well within one standard error, so the one-standard-error rule chooses it, the choice of BIC. The full model has 0.1351 and the intercept alone 0.1993. Leave-one-out over all 32 candidates gives 0.1129 for single parenthood and urbanization and 0.1130 for single parenthood alone, a tie, and 0.1184 for poverty with single parenthood and urbanization.

```
import itertools
import numpy as np
import statsmodels.api as sm
data = sm.datasets.statelcrime.load_pandas().data.drop(index="District of Columbia")
names = ["hs_grad", "poverty", "single", "white", "urban"]
y = np.log(data["violent"].to_numpy())
n = len(y)

def design(cols):
    return np.column_stack([np.ones(n)] + [data[c].to_numpy() for c in cols])

def sse(cols):
    X = design(cols)
    b, *_ = np.linalg.lstsq(X, y, rcond=None)
    return np.sum((y - X @ b) ** 2)
```

```

# best subset of each size, by residual sum of squares
best = [min(itertools.combinations(names, k), key=sse) for k in range(len(names) +
1)]

rng = np.random.default_rng(2906)
K = 10
folds = rng.permutation(np.arange(n) % K)           # a random split into 10
            folds of 5
cv, se = [], []
for cols in best:
    X = design(cols)
    fold_err = []
    for f in range(K):
        tr, te = folds != f, folds == f
        b, *_ = np.linalg.lstsq(X[tr], y[tr], rcond=None)
        fold_err.append(np.mean((y[te] - X[te] @ b) ** 2))
    cv.append(np.mean(fold_err))
    se.append(np.std(fold_err, ddof=1) / np.sqrt(K))    # the usual (optimistic)
            standard error
cv, se = np.array(cv), np.array(se)
k_min = int(np.argmin(cv))
k_1se = int(np.min(np.nonzero(cv <= cv[k_min] + se[k_min])[0]))
for k, cols in enumerate(best):
    print(f"{k} regressors {cols}: CV {cv[k]:.4f} (se {se[k]:.4f})")
print("minimum CV at size", k_min, "; one-standard-error rule chooses size", k_1se)

```

The example has a flaw: the best subset of each size was found from all fifty states, and only its fitting was cross-validated.

29.3.4 Cross-validating the whole procedure

Cross-validation estimates the error of whatever is repeated inside the folds. Every decision that looked at the responses, such as screening regressors, choosing a subset, choosing λ or deleting outliers, must be repeated inside each fold. Otherwise the held-out cases have already influenced the fit that predicts them.

Example. (Screening, then cross-validating)

Take $n = 50$ cases, 200 candidate regressors and a response that is independent of all of them, with $\sigma = 1$. The procedure keeps the 5 regressors most correlated with the response and fits least squares on them. Every procedure has expected prediction error at least $\sigma^2 = 1$ here. Over 200 data sets:

- ten-fold cross-validation of the least squares fit, after screening on all the data, averages 0.720, and is below 1 in a fraction 0.93 of the data sets;
- ten-fold cross-validation that repeats the screening inside every fold averages 1.427;
- the actual prediction error of the screened and fitted model averages 1.372.

The wrong version reports that noise predicts the response. The right one is slightly pessimistic, because it uses 45 cases instead of 50 ([Proposition 29.3.1](#)).

```

import numpy as np
rng = np.random.default_rng(2907)
n, m, keep, K = 50, 200, 5, 10

def screen(X, y):
    """Indices of the `keep` columns most correlated with y."""
    Xc, yc = X - X.mean(axis=0), y - y.mean()
    corr = np.abs(Xc.T @ yc) / np.sqrt(np.sum(Xc**2, axis=0) * (yc @ yc))
    return np.argsort(-corr)[:keep]

def fit(X, y):
    A = np.column_stack([np.ones(len(y)), X])
    return np.linalg.lstsq(A, y, rcond=None)[0]

def predict(b, X):
    return b[0] + X @ b[1:]

def one_data_set():
    X = rng.normal(size=(n, m))
    y = rng.normal(size=n)                                # unrelated to every
                                                            # column
    folds = rng.permutation(np.arange(n) % K)
    cols = screen(X, y)                                    # screening on ALL the
                                                            # data
    wrong = right = 0.0
    for f in range(K):
        tr, te = folds != f, folds == f
        b = fit(X[tr][:, cols], y[tr])                    # wrong: screening done
                                                            # outside
        wrong += np.sum((y[te] - predict(b, X[te][:, cols])) ** 2)
        cols_f = screen(X[tr], y[tr])                     # right: screen again
                                                            # in the fold
        b = fit(X[tr][:, cols_f], y[tr])
        right += np.sum((y[te] - predict(b, X[te][:, cols_f])) ** 2)
    b = fit(X[:, cols], y)
    truth = 1 + b[0] ** 2 + np.sum(b[1:] ** 2)             # error on a new case
    return wrong / n, right / n, truth

res = np.array([one_data_set() for _ in range(200)])
print("average CV, screening outside the folds:", res[:, 0].mean().round(3))
print("average CV, screening inside the folds: ", res[:, 1].mean().round(3))
print("average true error of the fitted model: ", res[:, 2].mean().round(3))

```

When cross-validation is used both to choose among candidates and to report the error of the choice, the same problem appears in a milder form. The smallest of many cross-validation estimates is biased downwards as an estimate of the error of the model it picks (Section 29.5). The remedy is **nested cross-validation**: an outer loop holds out folds for assessment, and inside each outer training set an inner cross-validation makes the choice (Varma and Simon 2006). The outer estimate then describes the whole procedure, choice included, at sample size $n - n/K$.

29.3.5 Exercises

29.3.5.1 A. Check your understanding

Exercise A1.

In [Example \(Bias and spread of K-fold cross-validation\)](#), compute $\text{Err}(20)$ from [Theorem 14.2.6](#) and confirm the value quoted for $K = 2$. Why is a holdout estimate that fits on half the data especially biased when the number of regressors is large?

Solution. $\text{Err}(20) = (1 + 1/20)(18/8) = 1.05 \times 2.25 = 2.3625$. The factor $(m - 2)/(m - k - 2)$ blows up as the training size m approaches $k + 2$. With ten regressors, halving m from 40 to 20 moves it from $38/28$ to $18/8$.

29.3.5.2 B. Practice

Exercise B1.

For the intercept-only model, show that the leave-one-out residual is $n(y_i - \bar{y})/(n - 1)$ and that $\text{CV}_n = ns^2/(n - 1)$, where s^2 is the sample variance. Check this against [Theorem 29.3.2](#).

Solution. Without case i the mean is $\bar{y}_{(i)} = (n\bar{y} - y_i)/(n - 1)$, so $y_i - \bar{y}_{(i)} = (ny_i - n\bar{y})/(n - 1)$. Squaring and averaging, $\text{CV}_n = n^{-1}\{n/(n - 1)\}^2 \sum_i (y_i - \bar{y})^2 = n \sum_i (y_i - \bar{y})^2 / (n - 1)^2 = ns^2/(n - 1)$. In [Theorem 29.3.2](#), $s_{ii} = h_{ii} = 1/n$ and $1/(1 - 1/n) = n/(n - 1)$.

Exercise B2.

In [Theorem 29.3.2](#), suppose $\mathbf{X}$ has full column rank. Show that $s_{ii} \leq h_{ii}$, where h_{ii} is the least squares leverage, so that the shortcut inflates ridge residuals less than least squares residuals.

Solution. $\mathbf{X}^\top \mathbf{X} + \mathbf{\Omega} - \mathbf{X}^\top \mathbf{X} = \mathbf{\Omega}$ is nonnegative definite, so $(\mathbf{X}^\top \mathbf{X} + \mathbf{\Omega})^{-1} \leq (\mathbf{X}^\top \mathbf{X})^{-1}$ in the nonnegative definite ordering (for positive definite $\mathbf{A} \geq \mathbf{B}$, $\mathbf{B}^{-1} - \mathbf{A}^{-1} = \mathbf{B}^{-1/2}(\mathbf{I} - \mathbf{C}^{-1})\mathbf{B}^{-1/2}$ with $\mathbf{C} = \mathbf{B}^{-1/2}\mathbf{A}\mathbf{B}^{-1/2} \geq \mathbf{I}$). Evaluating both quadratic forms at $\mathbf{x}_{(i)}$ gives $s_{ii} \leq h_{ii}$.

29.3.5.3 C. Going deeper

Exercise C1.

Generalize [Proposition 29.3.1](#) to folds of unequal sizes $n_1, \dots, n_K$, and to leave-one-out for a design that is fixed rather than random. In the fixed-design case, what does $E(\text{CV}_n)$ equal for least squares, and how does it compare with the in-sample prediction error of [Theorem 29.1.1](#)?

Exercise C2.

Suppose $\max_i |h_{ii} - p/n| \leq \epsilon p/n$. Show that

$$\frac{\text{SSE}}{n} \left(1 - \frac{p}{n}(1 + \epsilon)\right)^{-2} \geq \text{CV}_n \geq \frac{\text{SSE}}{n} \left(1 - \frac{p}{n}(1 - \epsilon)\right)^{-2},$$

and deduce that $n \log \text{CV}_n = n \log(\text{SSE}/n) + 2p + O(p\epsilon + p^2/n)$. Which designs satisfy the hypothesis with small ϵ ?

29.4 All subsets and stepwise search

With m candidate regressors and the intercept always in, there are 2^m subsets. This section describes exhaustive search, branch and bound and the stepwise shortcuts, and shows that the subset they find depends on small features of the data, far more than the fitted values do.

29.4.1 Searching all subsets

The search splits into two stages, because every criterion based on the residual sum of squares agrees within a size.

Proposition 29.4.1 — One size, one ranking

Among candidates with the same number of columns p , the orderings by C_p , AIC, AICc, BIC, R^2 , $\bar{R}^2$ and SSE coincide.

Proof. For fixed p , n and s^2 , each of C_p , $n \log(\text{SSE}/n)$ plus a penalty depending on p , $1 - \text{SSE}/\text{SST}$ and $1 - (n-1)\text{SSE}/\{(n-p)\text{SST}\}$ is a monotone function of SSE, increasing for the criteria to be minimized and decreasing for the two R^2 . ■

So it suffices to find, for each size, the subset with the smallest residual sum of squares, and then compare the $m + 1$ winners with the criterion. Cross-validation does not reduce in this way, since its value is not a function of SSE and p ; in practice it is applied to the size winners, as in [Example \(Cross-validating the state regressions\)](#).

Visiting all 2^m subsets is cheap per subset. Sweeping on one pivot ([Definition 10.2.1](#)) adds or removes a column in $O(m^2)$ operations, and a Gray-code order, in which consecutive subsets differ in one column, gives every residual sum of squares with one sweep (Schatzoff, Tsao and Fienberg 1968). That makes m up to about 20 routine. Beyond that the number of subsets is the obstacle: finding the best subset of a given size is NP-hard in general (Natarajan 1995).

29.4.2 Branch and bound

The key fact is that removing columns never reduces the residual sum of squares: if $\mathcal{C}(\mathbf{X}_A) \subseteq \mathcal{C}(\mathbf{X}_B)$, then $\text{SSE}_A - \text{SSE}_B = \|(\mathbf{M}_B - \mathbf{M}_A)\mathbf{y}\|^2 \geq 0$ by [Theorem 6.5.1](#). A subset whose residual sum of squares is already too large therefore cannot have a good subset below it.

Organize the subsets as a tree. The root is the full set $\{1, \dots, m\}$. A node is a subset S together with the index ℓ of the last column deleted to reach it ($\ell = 0$ at the root), and its children delete one more column $j \in S$ with $j > \ell$. Deleting in increasing order of index reaches every subset along exactly one path. The descendants of (S, ℓ) are the subsets $T \subseteq S$ that contain $F = \{j \in S : j \leq \ell\}$, the columns that can no longer be deleted.

Proposition 29.4.2 — Branch and bound for C_p

Let c^* be the smallest C_p found so far. If a node (S, ℓ) satisfies

$$\frac{\text{SSE}_S}{s^2} - n + 2(|F| + 1) \geq c^*,$$

then no descendant of the node has $C_p < c^*$, and the node need not be expanded. A depth-first search that evaluates every expanded node and skips such nodes' descendants returns a subset of minimal C_p .

Proof. A descendant T contains F and is contained in S , so $\text{SSE}_T \geq \text{SSE}_S$ and $|T| \geq |F|$, with the intercept counted separately. Hence its $C_p = \text{SSE}_T/s^2 - n + 2(|T| + 1)$ is at least the left side of the display. The search only skips subsets that cannot beat a value already attained, so the minimum it reports is the minimum over all subsets. ■

The same bound works for AIC, BIC or the best subset of each size. Furnival and Wilson (1974) combined bounds of this kind with an efficient order of sweeps in the “leaps and bounds” algorithm, which handles 30 to 40 regressors. Bertsimas, King and Mazumder (2016) solved much larger problems by mixed-integer optimization, with a certificate of optimality.

Example. (How much branch and bound saves)

Take $n = 100$ cases and $m = 15$ independent normal regressors, five with nonzero slopes (1, -0.8, 0.6, 0.4, 0.3) and ten with zero slopes. Exhaustive search evaluates 32768 subsets. The branch and bound of [Proposition 29.4.2](#) finds the same C_p -best subset, with 6 regressors (the four largest slopes and two irrelevant columns), after 1110 evaluations, a fraction 0.034 of the work.

            for j in S:
                if j > last:
                    visit(tuple(k for k in S if k != j), j)

    visit(tuple(range(m)), -1)
    return best[1], best[0], count[0]

S_bb, cp_bb, fits = branch_and_bound()
print("branch and bound:", S_bb, round(cp_bb, 3), "after", fits, "fits of", 2**m)

```

29.4.3 Stepwise search

Stepwise methods give up the guarantee of finding the best subset in exchange for examining only $O(m^2)$ of them.

Definition 29.4.1 — Stepwise selection

Let the current subset be S , with p_S columns including the intercept.

- (a) **Forward selection** starts from the intercept alone. At each step it adds the column $j \notin S$ that most reduces SSE, provided its **F -to-enter** $F_j = (\text{SSE}_S - \text{SSE}_{S+j}) / \{\text{SSE}_{S+j} / (n - p_S - 1)\}$ exceeds a threshold F_{in} , and stops otherwise.
- (b) **Backward elimination** starts from the full model. At each step it removes the column $j \in S$ with the smallest **F -to-remove** $F_j = (\text{SSE}_{S-j} - \text{SSE}_S) / \{\text{SSE}_S / (n - p_S)\}$, provided this is below a threshold F_{out} , and stops otherwise.
- (c) **Stepwise regression** (Efroymson 1960) alternates: after each forward step it removes any column whose F -to-remove has fallen below F_{out} , with $F_{\text{out}} \leq F_{\text{in}}$.

The thresholds may be replaced by a criterion: add or remove the column that lowers AIC (or C_p , or BIC) most, and stop when no move lowers it.

The single step of forward selection can be described in several equivalent ways, all of them versions of the Frisch–Waugh–Lovell theorem.

Proposition 29.4.3 — What a stepwise step maximizes

Let $\tilde{\mathbf{y}} = (\mathbf{I} - \mathbf{M}_S)\mathbf{y}$ and $\tilde{\mathbf{x}}_j = (\mathbf{I} - \mathbf{M}_S)\mathbf{x}_j \neq \mathbf{0}$, and let $r_j = \tilde{\mathbf{y}}^\top \tilde{\mathbf{x}}_j / (\|\tilde{\mathbf{y}}\| \|\tilde{\mathbf{x}}_j\|)$ be the partial correlation of $\mathbf{y}$ and $\mathbf{x}_j$ given the columns of S (Definition 14.5.1).

- (a) $\text{SSE}_S - \text{SSE}_{S+j} = r_j^2 \text{SSE}_S$ and $F_j = (n - p_S - 1) r_j^2 / (1 - r_j^2)$. So the column that most reduces SSE is the one with the largest r_j^2 , the largest F -to-enter, and the smallest C_p , AIC or BIC of the enlarged model.
- (b) For $j \in S$, $\text{SSE}_{S-j} - \text{SSE}_S = t_j^2 s_S^2$, where t_j is the t statistic of $\mathbf{x}_j$ in the model S and $s_S^2 = \text{SSE}_S / (n - p_S)$. So backward elimination removes the column with the smallest $|t_j|$, and its F -to-remove is t_j^2 .

Proof.

- (a) By Theorem 6.6.2(b), the residual vector of the model $S + j$ is the residual of the regression of $\tilde{\mathbf{y}}$ on $\tilde{\mathbf{x}}_j$, so $\text{SSE}_{S+j} = \|\tilde{\mathbf{y}}\|^2 - (\tilde{\mathbf{x}}_j^\top \tilde{\mathbf{y}})^2 / \|\tilde{\mathbf{x}}_j\|^2 = (1 - r_j^2) \text{SSE}_S$. Then $F_j = (n - p_S - 1) r_j^2 / (1 - r_j^2)$ is increasing in r_j^2 . At a fixed size the criteria rank by SSE (Proposition 29.4.1).
- (b) Apply (a) to the model $S - j$ and the column $\mathbf{x}_j$: the increase is $(\tilde{\mathbf{x}}_j^\top \tilde{\mathbf{y}})^2 / \|\tilde{\mathbf{x}}_j\|^2$ with residuals now taken on $S - j$. By Theorem 6.6.2(a) this is $\hat{\beta}_j^2 \|\tilde{\mathbf{x}}_j\|^2$, and by Eq. 6.6.2 $\text{Var}(\hat{\beta}_j) = \sigma^2 / \|\tilde{\mathbf{x}}_j\|^2$, so the increase is $\hat{\beta}_j^2 s_S^2 / \widehat{\text{Var}}(\hat{\beta}_j) = t_j^2 s_S^2$. ■

Criterion-based stopping is therefore threshold-based stopping with a particular threshold: forward selection by AIC adds a column iff its F -to-enter exceeds about 2, and by BIC iff it exceeds about $\log n$ (the table in Section 29.2). The traditional thresholds $F_{\text{in}} = F_{\text{out}} = 4$ correspond to BIC at $n \approx 55$.

For the state data, forward selection by AIC adds single parenthood and then urbanization and stops. Backward elimination by AIC removes white, high school, poverty (in that order) and stops at the same two regressors, which are also the all-subsets AIC choice. Forward

and backward computed the criterion for 13 and 15 subsets, against 32 for exhaustive search. Agreement is common but not guaranteed.

Example. (A pair that forward selection cannot find)

Take $n = 60$ cases of three regressors, $\mathbf{x}_1$ and $\mathbf{x}_2$ with sample correlation 0.96 and $\mathbf{x}_3$ independent of both, and let $\mathbf{y} = 3(\mathbf{x}_1 - \mathbf{x}_2) + 0.4\mathbf{x}_3 + \boldsymbol{\varepsilon}$. The signal lies mostly in the difference $\mathbf{x}_1 - \mathbf{x}_2$, a direction in which the regressors vary little. The sample correlations of $\mathbf{y}$ with $\mathbf{x}_1$, $\mathbf{x}_2$ and $\mathbf{x}_3$ are -0.02 , -0.19 and 0.41 . Forward selection enters $\mathbf{x}_3$ first and then $\mathbf{x}_2$, reaching $R^2 = 0.19$. The best pair is $\{\mathbf{x}_1, \mathbf{x}_2\}$, with $R^2 = 0.39$. Neither of its members looks useful alone, so a procedure that adds one column at a time never sees it. Backward elimination starts from a model that contains the pair and can keep it, but it has blind spots of its own ([Exercise \(C1\)](#)) and cannot start when $m \geq n$.

```
import itertools
import numpy as np
rng = np.random.default_rng(2909)
n2 = 60
z = rng.normal(size=(n2, 3))
x1 = z[:, 0]
x2 = 0.95 * z[:, 0] + np.sqrt(1 - 0.95**2) * z[:, 1]      # corr(x1, x2) about 0.95
x3 = z[:, 2]
Xf = np.column_stack([x1, x2, x3])
yf = 3 * (x1 - x2) + 0.4 * x3 + rng.normal(size=n2)      # the signal is in x1 - x2

def rss(cols):
    A = np.column_stack([np.ones(n2)] + [Xf[:, j] for j in cols])
    b, *_ = np.linalg.lstsq(A, yf, rcond=None)
    return np.sum((yf - A @ b) ** 2)

first = min(range(3), key=lambda j: rss([j]))
second = min((j for j in range(3) if j != first), key=lambda j: rss([first, j]))
best_pair = min(itertools.combinations(range(3), 2), key=rss)
print("forward chooses", sorted([first, second]), "RSS", round(rss([first, second]),
1))
print("best pair", list(best_pair), "RSS", round(rss(best_pair), 1))
```

Collinear regressors are exactly where this happens: a contrast between them can be highly predictive while each member is not ([Chapter 26](#) describes such directions through the eigenvectors of $\mathbf{X}^\top \mathbf{X}$).

29.4.4 Comparing the procedures

Example. (Selection procedures in a simulation)

Take $n = 60$ cases of eight normal regressors with all pairwise correlations 0.5, $\sigma = 1$, an intercept, and three nonzero slopes, either weak (1, 0.5, 0.25) or strong (1, 0.8, 0.6). Each procedure is scored by its loss at the design points, $\|\mathbf{X}(\hat{\boldsymbol{\beta}} - \boldsymbol{\beta})\|^2 / \sigma^2$, with the intercept's expected contribution 1 included. Over 2000 data sets:

Weak slopes:

procedure	loss	Pr(true)	size
least squares, all eight	8.98	0.00	8.00
true subset (oracle)	3.97	1.00	3.00
all subsets, AIC	7.81	0.18	3.42
all subsets, BIC	7.33	0.18	2.52
all subsets, leave-one-out	7.76	0.19	3.34
forward, AIC	7.70	0.19	3.34
backward, AIC	7.89	0.17	3.50

Strong slopes:

procedure	loss	Pr(true)	size
least squares, all eight	9.02	0.00	8.00
true subset (oracle)	4.06	1.00	3.00
all subsets, AIC	7.27	0.37	3.93
all subsets, BIC	6.17	0.70	3.20
all subsets, leave-one-out	7.17	0.39	3.85
forward, AIC	7.16	0.39	3.86
backward, AIC	7.35	0.35	3.98

Every selection rule beats least squares on all eight regressors, whose expected loss is 9 ([Theorem 29.1.1\(c\)](#)), but none comes close to the oracle's 4. The search method hardly matters: forward selection by AIC returned the all-subsets AIC choice in a fraction 0.95 of the weak data sets and 0.96 of the strong ones. The criterion matters more: with strong effects BIC finds the true subset in a fraction 0.70 of data sets and has the smallest loss, while with a weak third slope every rule usually misses it, BIC keeping 2.52 regressors on average.

The simulation illustrates [Proposition 29.2.4](#) in a finite sample: where a small true model exists and its effects are large, BIC wins; with many small effects the comparison tilts towards AIC and cross-validation.

29.4.5 Instability

A procedure is **unstable** if small changes in the data change its output a great deal. Subset selection is a discontinuous function of the data: a column is in or out. Breiman (1996b) showed that this instability inflates the variance of the predictions that follow, and that averaging over perturbed data sets can reduce it.

Example. (Bootstrapping the state regressions)

Resample the 50 states with replacement (the case bootstrap of [Section 23.1](#)) 1000 times and repeat the all-subsets AIC and BIC choices on each resample. AIC chooses 27 different subsets of the 32 and BIC 25. The AIC choice for the original data, single parenthood and urbanization, is chosen in a fraction 0.15 of resamples, and the most

Figure 29.4.1: Fraction of 1000 bootstrap resamples of the 50 states in which each regressor is in the subset chosen by AIC or BIC (log violent crime, all 32 subsets).

frequent AIC choice, poverty with single parenthood and urbanization, in 0.20. The BIC choice, single parenthood alone, is its most frequent choice, at 0.31. Figure 29.4.1 shows how often each regressor is included. Even single parenthood, whose t statistic in the chosen model is about 5.5, is left out by AIC in a fifth of the resamples. It is correlated -0.70 with the percentage of white residents, and the two can stand in for each other.

```
import itertools
from collections import Counter
import numpy as np
import statsmodels.api as sm
data = sm.datasets.statelcrime.load_pandas().data.drop(index="District of Columbia")
names = ["hs_grad", "poverty", "single", "white", "urban"]
y_all = np.log(data["violent"].to_numpy())
Z_all = data[names].to_numpy()
n = len(y_all)
subsets = [S for k in range(6) for S in itertools.combinations(range(5), k)]

def select(Z, y, penalty):
    def crit(S):
        X = np.column_stack([np.ones(len(y)), Z[:, list(S)]])
        b, *_ = np.linalg.lstsq(X, y, rcond=None)
        return n * np.log(np.sum((y - X @ b) ** 2) / n) + penalty * (len(S) + 2)
    return min(subsets, key=crit)

rng = np.random.default_rng(2911)
B = 200  # the book's figure
        uses 1000
chosen = {"AIC": Counter(), "BIC": Counter()}
for _ in range(B):
    idx = rng.integers(0, n, size=n)  # resample whole
    states
    chosen["AIC"][select(Z_all[idx], y_all[idx], 2.0)] += 1
    chosen["BIC"][select(Z_all[idx], y_all[idx], np.log(n))] += 1
for crit, counts in chosen.items():
```

```
print(crit, "distinct models:", len(counts))
for S, c in counts.most_common(3):
    print("    ", [names[j] for j in S], c / B)
```

Instability is a property of the question as much as of the method. The three models favoured by the criteria and the bootstrap (single parenthood alone, with urbanization, and with poverty and urbanization) predict almost equally well (their leave-one-out errors in [Example \(Cross-validating the state regressions\)](#) lie between 0.1129 and 0.1184), so any rule that must name one will name different ones for similar data. The remedies are to report the uncertainty, as in the figure, or to stop requiring a single model: average over bootstrap resamples (bagging, Breiman 1996a) or over models weighted by posterior probability (Hoeting, Madigan, Raftery and Volinsky 1999), or shrink instead of selecting ([Chapter 27](#)).

29.4.6 Exercises

29.4.6.1 A. Check your understanding

Exercise A1.

How many subsets must exhaustive search examine for $m = 20$ and $m = 40$ candidate regressors? At a million subsets per second, how long does each take?

29.4.6.2 B. Practice

Exercise B1.

Show that in the tree of [Proposition 29.4.2](#) every subset of $\{1, \dots, m\}$ is reached along exactly one path from the root, and that the descendants of (S, ℓ) are exactly the subsets T with $F \subseteq T \subseteq S$.

Solution. A subset T with complement $\{j_1 < \dots < j_r\}$ in $\{1, \dots, m\}$ is reached by deleting $j_1, \dots, j_r$ in increasing order, and every path deletes in increasing order, so this is the only path. A descendant of (S, ℓ) deletes further columns of S with indices above ℓ , so it contains $F = \{j \in S : j \leq \ell\}$; conversely any T with $F \subseteq T \subseteq S$ is reached from (S, ℓ) by deleting the columns of $S \setminus T$, all of which exceed ℓ , in increasing order.

Exercise B2.

In stepwise regression, show that the column just entered has F -to-remove equal to its F -to-enter. Deduce that it cannot be removed at the next step if $F_{\text{out}} \leq F_{\text{in}}$, and explain what can happen if $F_{\text{out}} > F_{\text{in}}$.

Solution. After j enters, the model is $S + j$ with $p_S + 1$ columns, and its F -to-remove is $(\text{SSE}_S - \text{SSE}_{S+j}) / \{\text{SSE}_{S+j} / (n - p_S - 1)\}$, which is the F -to-enter of j at the previous step. It exceeded $F_{\text{in}} \geq F_{\text{out}}$, so j stays. If $F_{\text{out}} > F_{\text{in}}$, a column with $F_{\text{in}} < F_j < F_{\text{out}}$ is added and immediately removed, returning to S , where it is added again: the procedure cycles.

Exercise B3.

Show that a column's F -to-remove in backward elimination is the square of its t statistic, and that backward elimination with $F_{\text{out}} = t_{\alpha/2}^2(\nu)$ is the rule “drop the least significant coefficient while any is not significant at level α ”. Why do the p -values of the surviving coefficients not have their nominal meaning?

29.4.6.3 C. Going deeper**Exercise C1.**

In [Example \(A pair that forward selection cannot find\)](#), show that the best subset of size one is $\{\mathbf{x}_3\}$ and the best of size two is $\{\mathbf{x}_1, \mathbf{x}_2\}$, so the best subsets of consecutive sizes need not be nested. Why does this not contradict [Theorem 6.5.1](#)?

Solution. Among single columns the residual sum of squares is smallest for the largest squared correlation with $\mathbf{y}$, and 0.41^2 is far above 0.19^2 and 0.02^2 . The best pair was computed in the example. [Theorem 6.5.1](#) compares a subset with its own supersets, so $\text{SSE}_{\{3\}} \geq \text{SSE}_{\{1,3\}}$ and $\text{SSE}_{\{3\}} \geq \text{SSE}_{\{2,3\}}$; it says nothing about $\{1, 2\}$, which does not contain $\{3\}$. Because best subsets need not be nested, a search that only adds columns (forward) or only removes them (backward) can miss the best subset of some size.

29.5 Selection bias and honest inference

Everything in Part III assumed that the model was fixed before the data were seen. After a search, the reported model, its coefficients, its error estimate and its test statistics are the ones that looked best, and each is biased: effects look larger, errors smaller, and intervals cover less often than they claim. This section proves the direction of the bias, measures it, and describes three remedies.

29.5.1 The winner's curse

Proposition 29.5.1 — What selection does to estimates and intervals

- (a) (*Selected maxima are biased upwards.*) Let $Z_1, \dots, Z_m$ have finite means $\theta_1, \dots, \theta_m$, and let $\hat{J}$ be an index at which $Z_{\hat{J}} = \max_j Z_j$. Then

$$E(Z_{\hat{J}}) \geq \max_j \theta_j \geq E(\theta_{\hat{J}}),$$

so $E(Z_{\hat{J}} - \theta_{\hat{J}}) \geq 0$. If the Z_j are independent $N(\theta, 1)$ with a common mean and $m \geq 2$, the bias is $E \max_j Z_j - \theta > 0$.

- (b) (*Selected minima of risk estimates are optimistic.*) Let $\hat{R}_k$ be an unbiased estimate

of R_k for each candidate k in a finite set, and let $\hat{k}$ minimize $\hat{R}_k$. Then

$$E(\hat{R}_{\hat{k}}) \leq \min_k R_k \leq E(R_{\hat{k}}).$$

- (c) (*Selected intervals under-cover.*) Let $Z \sim N(\theta, 1)$, and report the interval $Z \pm z_{\alpha/2}$ only when $|Z| > c$. If $c \geq z_{\alpha/2}$, the probability that the reported interval covers θ , given that it is reported, is 0 at $\theta = 0$. It tends to $1 - \alpha$ as $|\theta| \rightarrow \infty$.

Proof.

- (a) $\max_j Z_j \geq Z_i$ for every i , so $E \max_j Z_j \geq \theta_i$ for every i , which is the first inequality. The second holds pointwise: $\theta_j \leq \max_j \theta_j$. In the normal case, $\max_j Z_j - \theta = \max_j (Z_j - \theta)$ has the distribution of the largest of $m \geq 2$ independent standard normals, which exceeds $Z_1 - \theta$ with positive probability and is never smaller, so its mean exceeds $E(Z_1 - \theta) = 0$.
- (b) $\hat{R}_{\hat{k}} \leq \hat{R}_k$ for every k ; take expectations to get $E \hat{R}_{\hat{k}} \leq R_k$ for every k . The second inequality holds pointwise.
- (c) At $\theta = 0$ the interval covers iff $|Z| \leq z_{\alpha/2}$, which is incompatible with $|Z| > c \geq z_{\alpha/2}$. As $|\theta| \rightarrow \infty$, $\Pr(|Z| > c) \rightarrow 1$, so the conditional coverage tends to the unconditional $\Pr(|Z - \theta| \leq z_{\alpha/2}) = 1 - \alpha$.

■

Part (a) is the **winner's curse**: the largest of ten unbiased estimates of equal means overstates its mean by 1.539 standard errors on average, and the coefficient and t statistic of a regressor that “won” a screening are biased in the same way. Part (b) applies to every criterion of this chapter, since C_p and cross-validation are unbiased for each fixed candidate ([Proposition 29.2.1\(a\)](#) and [Proposition 29.3.1](#)); the search degrees of freedom of [Section 29.1](#) measure the same effect.

Example. (Freedman's paradox)

Freedman (1983) described the following procedure, which many analyses follow in some form. Fit $n = 100$ cases on 50 regressors, none of which is related to the response. Keep those with p -value below 0.25, refit on the survivors, and report. In one simulated data set 15 regressors survive the first pass, 7 of them are significant at 5% in the refit, and the overall F test of the refit has p -value 0.0030. Over 2000 data sets, an average of 12.3 regressors survive and 5.6 are significant, and the overall F test rejects at 5% in a fraction 0.94 of them. Pure noise produces a model that every standard test endorses.

```
import numpy as np
from scipy import stats
rng = np.random.default_rng(2913)
n, m = 100, 50

def ols(X, y):
    """Coefficients, t statistics (slopes), overall F p-value; X without intercept.
    """
    A = np.column_stack([np.ones(len(y)), X])
    b, *_ = np.linalg.lstsq(A, y, rcond=None)
    e = y - A @ b
```

```

df = len(y) - A.shape[1]
s2 = e @ e / df
t = b / np.sqrt(s2 * np.diag(np.linalg.inv(A.T @ A)))
ssr = np.sum((A @ b - y.mean()) ** 2)
F = (ssr / X.shape[1]) / s2
return t[1:], df, stats.f.sf(F, X.shape[1], df)

def screen_and_refit():
    X = rng.normal(size=(n, m))
    y = rng.normal(size=n)
    t, df, _ = ols(X, y)
    keep = np.abs(t) > stats.t.ppf(1 - 0.25 / 2, df)
    t2, df2, p_F = ols(X[:, keep], y)
    survivors
    return keep.sum(), np.sum(np.abs(t2) > stats.t.ppf(0.975, df2)), p_F

kept, signif, p_F = screen_and_refit()
print(f"one data set: {kept} kept, {signif} significant at 5%, overall F p-value {
    p_F:.4f}")
runs = np.array([screen_and_refit() for _ in range(500)])
print("over 500 data sets: mean kept", runs[:, 0].mean(), " mean significant", runs
   [:, 1].mean(),
    " Pr(F significant)", np.mean(runs[:, 2] < 0.05))

```

29.5.2 Coverage after selection

The failure in [Proposition 29.5.1\(c\)](#) concerns intervals reported only after selection. A subtler failure affects intervals for a coefficient that is always reported, when the *model* around it was chosen from the data.

Example. (Coverage after a pretest)

Take two standardized regressors with correlation r , known σ , and the question: what is β_1 ? The analyst first tests $\beta_2 = 0$ at level 5%. If the test rejects, she reports the usual 95% interval for β_1 from the model with both regressors; otherwise, the interval from the model with $\mathbf{x}_1$ alone. Each interval is correct for its own model. Panel (b) of [Figure 29.5.1](#) shows the coverage of the reported interval as a function of $\delta = \beta_2 / \text{sd}(\hat{\beta}_2)$, the standardized size of the coefficient being tested. When $\delta = 0$ the short model is correct and coverage is close to nominal. When δ is large the test always keeps $\mathbf{x}_2$ and coverage is nominal. In between, the test often drops $\mathbf{x}_2$ although the short slope is biased by $r\beta_2$ ([Theorem 19.1.2](#)), and the coverage falls to a minimum of 0.873 (at $\delta = 2.2$) for $r = 0.5$, 0.599 (at $\delta = 1.8$) for $r = 0.8$ and 0.234 (at $\delta = 1.2$) for $r = 0.95$.

Panel (a) is the one-dimensional case of [Proposition 29.5.1\(c\)](#) with $c = 1.96$: the conditional coverage is 0 at $\theta = 0$, 0.844 at $\theta = 1$, 0.951 at $\theta = 2$ and 0.971 at $\theta = 3$, where it slightly over-covers.

```

z = stats.norm.ppf(0.975)

def conditional_coverage(theta, c=z):

```

Figure 29.5.1: (a) Coverage of $Z \pm 1.96$, $Z \sim N(\theta, 1)$, given that it is reported only when $|Z| > 1.96$. (b) Coverage for β_1 of the usual 95% interval from the model chosen by a 5% test of $\beta_2 = 0$, for three correlations between the regressors (200000 simulations per point).

```

"""Pr(|Z - theta| <= z | |Z| > c) for Z ~ N(theta, 1): the reported interval."""
lo, hi = theta - z, theta + z
inside_sel = (stats.norm.cdf(max(hi, c) - theta) - stats.norm.cdf(max(lo, c) -
theta)) \
    + (stats.norm.cdf(min(hi, -c) - theta) - stats.norm.cdf(min(lo, -c) - theta)
)
return inside_sel / (stats.norm.sf(c - theta) + stats.norm.cdf(-c - theta))

def pretest_coverage(delta, r, reps=200_000):
    """Coverage of the usual 95% interval for beta_1 after a 5% pretest of beta_2 =
    0.
    Two standardized regressors with correlation r, sigma known; delta = beta_2 / sd
    (beta_2 hat)."""
    sd2 = 1 / np.sqrt(1 - r**2) # sd of either long-
    model slope
    C = np.array([[1, -r], [-r, 1]]) / (1 - r**2) # covariance of (b1, b2)
    in the long model
    b = rng.normal(size=(reps, 2)) @ np.linalg.cholesky(C).T + [0.0, delta * sd2]
    keep = np.abs(b[:, 1] / sd2) > z # the pretest keeps x2
    b1_short = b[:, 0] + r * b[:, 1] # short slope (sd 1)
    cover_long = np.abs(b[:, 0]) <= z * sd2 # true beta_1 = 0
    cover_short = np.abs(b1_short) <= z
    return np.mean(np.where(keep, cover_long, cover_short))

for r, d_min in ((0.5, 2.2), (0.8, 1.8), (0.95, 1.2)): # the minimizing
    delta of the figure
    print(f"r = {r}: coverage at delta = 0, {d_min}, 5:",
        ", ".join(f"{pretest_coverage(d, r, 50_000):.3f}" for d in (0.0, d_min,
        5.0)))

```

The coverage depends on the unknown δ , and it is worst where the data are least able to tell whether $\mathbf{x}_2$ belongs. No simple correction repairs this: Leeb and Pötscher (2005, 2006) showed that the distribution of a post-selection estimator cannot be estimated consistently, uniformly in

the parameters, so bootstrapping the whole procedure does not rescue the naive interval either.

29.5.3 Honest inference, I: splitting the sample

The simplest remedy separates the two uses of the data. Choose the model on one part of the sample, and compute intervals from the other part, as if the model had been fixed in advance, which, for that part, it was (Cox 1975).

Proposition 29.5.2 — Sample splitting

Let $\mathbf{Y} = (\mathbf{Y}_1^\top, \mathbf{Y}_2^\top)^\top$, where $\mathbf{Y}_2 \sim N_{n_2}(\boldsymbol{\mu}_2, \sigma^2 \mathbf{I})$ is independent of $\mathbf{Y}_1$, and let $\mathbf{X}_2$ be the fixed design of the second part. Let $\hat{M}$ be any rule that chooses a set of columns from $\mathbf{Y}_1$ (and the design), with values in the set of M for which $\mathbf{X}_{2,M}$ has full column rank $p_M < n_2$. For each such M , let $\boldsymbol{\beta}_M = (\mathbf{X}_{2,M}^\top \mathbf{X}_{2,M})^{-1} \mathbf{X}_{2,M}^\top \boldsymbol{\mu}_2$, and let $I_{M,j}$ be the usual level $1 - \alpha$ t interval for the j th coefficient from the least squares fit of $\mathbf{Y}_2$ on $\mathbf{X}_{2,M}$. Then, given $\mathbf{Y}_1$, $I_{\hat{M},j}$ covers $\beta_{\hat{M},j}$ with probability at least $1 - \alpha$, with equality if $\boldsymbol{\mu}_2 \in \mathcal{C}(\mathbf{X}_{2,\hat{M}})$. The same holds unconditionally.

Proof. Given $\mathbf{Y}_1$, the model $M = \hat{M}$ is fixed and $\mathbf{Y}_2$ still has its distribution, by independence. For fixed M , write $\mathbf{M}_M$ for the projection onto $\mathcal{C}(\mathbf{X}_{2,M})$ and $w = [(\mathbf{X}_{2,M}^\top \mathbf{X}_{2,M})^{-1}]_{jj}$. The estimate $\hat{\beta}_{M,j}$ is normal with mean $\beta_{M,j}$ and variance $\sigma^2 w$, so $Z = (\hat{\beta}_{M,j} - \beta_{M,j})/(\sigma\sqrt{w}) \sim N(0, 1)$. The residual sum of squares $\|(\mathbf{I} - \mathbf{M}_M)\mathbf{Y}_2\|^2$ is a function of $(\mathbf{I} - \mathbf{M}_M)\mathbf{Y}_2$, which is uncorrelated with $\mathbf{M}_M\mathbf{Y}_2$ and hence independent of it (Theorem 3.4.1), and $W = \|(\mathbf{I} - \mathbf{M}_M)\mathbf{Y}_2\|^2/\sigma^2 \sim \chi^2(\nu, \gamma)$ with $\nu = n_2 - p_M$ and $\gamma = \|(\mathbf{I} - \mathbf{M}_M)\boldsymbol{\mu}_2\|^2/\sigma^2$ (Theorem 4.3.2(a)). The interval covers iff $|Z| \leq t_{\alpha/2}(\nu)\sqrt{W/\nu}$, iff $W > \nu Z^2/t_{\alpha/2}(\nu)^2$. Conditioning on Z and using Proposition 4.1.3, this probability is nondecreasing in γ , and at $\gamma = 0$ it is $1 - \alpha$ by the definition of the t distribution. Averaging over $\mathbf{Y}_1$ gives the unconditional statement. ■

The target $\beta_{M,j}$ is the coefficient of $\mathbf{x}_j$ in the best approximation to the mean by the chosen columns, which is what the fitted coefficient estimates, right model or wrong. The costs: selection sees only part of the data, the intervals are wider, and the result depends on the random split. Wasserman and Roeder (2009) and Rinaldo, Wasserman and G'Sell (2019) develop the idea for high-dimensional and assumption-lean settings.

29.5.4 Honest inference, II: covering every model

The second remedy keeps all the data and widens the intervals until they cover the coefficients of every model that could have been chosen, simultaneously. Then it does not matter which one was.

Proposition 29.5.3 — Simultaneous inference over submodels

Assume the normal model Eq. 7.3.1 with $\text{rank}(\mathbf{X}) = P < n$, let s^2 be the full-model

estimate with $\nu = n - P$, and let $\mathcal{M}$ be a collection of column subsets M with $\mathbf{X}_M$ of full column rank. For $M \in \mathcal{M}$ and $j \in M$ let $\mathbf{v}_{M,j} = \mathbf{X}_M(\mathbf{X}_M^\top \mathbf{X}_M)^{-1} \mathbf{e}_j$, where $\mathbf{e}_j$ picks out the coefficient of $\mathbf{x}_j$, and

$$\beta_{M,j} = \mathbf{v}_{M,j}^\top \mathbf{X} \boldsymbol{\beta}, \quad \hat{\beta}_{M,j} = \mathbf{v}_{M,j}^\top \mathbf{Y},$$

and for $K > 0$ let

$$I_{M,j}(K) = [\hat{\beta}_{M,j} \pm K s \|\mathbf{v}_{M,j}\|].$$

Let N be the number of pairs (M, j) and q the dimension of the span of the $\mathbf{v}_{M,j}$.

- (a) With $K = \sqrt{q F_\alpha(q, \nu)}$, $\Pr(\beta_{M,j} \in I_{M,j}(K) \text{ for all } M \in \mathcal{M}, j \in M) \geq 1 - \alpha$.
- (b) The same holds with $K = t_{\alpha/(2N)}(\nu)$.
- (c) If K has the property in (a), then for every selection rule $\hat{M}$ with values in $\mathcal{M}$, a function of $\mathbf{Y}$ that may also depend on the unknown $\boldsymbol{\beta}$ and σ , $\Pr(\beta_{\hat{M},j} \in I_{\hat{M},j}(K) \text{ for all } j \in \hat{M}) \geq 1 - \alpha$.
- (d) The smallest K with the property in (c) for every such rule, including rules that depend on the unknown parameters (the convention of Berk, Brown, Buja, Zhang and Zhao 2013), is K_{PoSI} , the $1 - \alpha$ quantile of $\max_{M,j} |\mathbf{v}_{M,j}^\top (\mathbf{Y} - \mathbf{X} \boldsymbol{\beta})| / (s \|\mathbf{v}_{M,j}\|)$, whose distribution does not depend on $\boldsymbol{\beta}$ or σ .

Proof. In each case $\hat{\beta}_{M,j} - \beta_{M,j} = \mathbf{v}_{M,j}^\top (\mathbf{Y} - \mathbf{X} \boldsymbol{\beta})$ with $\mathbf{v}_{M,j} \in \mathcal{C}(\mathbf{X})$. (a) Let $\mathcal{V}$ be the span of the $\mathbf{v}_{M,j}$, a subspace of $\mathcal{C}(\mathbf{X})$ of dimension q . By Theorem 13.2.2(a), with probability exactly $1 - \alpha$, $|\mathbf{v}^\top (\mathbf{Y} - \mathbf{X} \boldsymbol{\beta})| \leq \sqrt{q F_\alpha(q, \nu)} s \|\mathbf{v}\|$ for every $\mathbf{v} \in \mathcal{V}$, in particular for every $\mathbf{v}_{M,j}$. (b) Each $(\hat{\beta}_{M,j} - \beta_{M,j}) / (s \|\mathbf{v}_{M,j}\|)$ has the $t(\nu)$ distribution, because $\mathbf{v}_{M,j}^\top \mathbf{Y}$ is independent of s^2 when $\mathbf{v}_{M,j} \in \mathcal{C}(\mathbf{X})$ (Theorem 7.5.1). Apply Theorem 13.4.1(b) with $\alpha_{M,j} = \alpha/N$. (c) The event in (c) contains the simultaneous event of (a). (d) The simultaneous event of (a) is $\{\max_{M,j} T_{M,j} \leq K\}$ with $T_{M,j} = |\mathbf{v}_{M,j}^\top (\mathbf{Y} - \mathbf{X} \boldsymbol{\beta})| / (s \|\mathbf{v}_{M,j}\|)$. Its distribution is free of $\boldsymbol{\beta}$ and σ because $\mathbf{Y} - \mathbf{X} \boldsymbol{\beta} = \sigma \mathbf{z}$ with $\mathbf{z} \sim N_n(\mathbf{0}, \mathbf{I})$ and $s = \sigma \|(\mathbf{I} - \mathbf{M})\mathbf{z}\| / \sqrt{\nu}$. So K_{PoSI} has the property in (a) and hence in (c). If $K < K_{\text{PoSI}}$, take the rule that selects a model containing a pair at which $T_{M,j}$ is largest, a rule that uses $\boldsymbol{\beta}$ and so is allowed in (c); its coverage is $\Pr(\max T_{M,j} \leq K) < 1 - \alpha$. ■

This is the PoSI (post-selection inference) approach of Berk, Brown, Buja, Zhang and Zhao (2013): model selection treated as a multiple-comparison problem of Chapter 13. The Scheffé bound never exceeds $\sqrt{P F_\alpha(P, \nu)}$, however many models are searched, and the price is paid whether or not the search was aggressive.

Example. (Honest intervals for the state regressions)

For the state data, with the intercept always in, the 32 candidate models contain $N = 80$ slope coefficients. Every $\mathbf{v}_{M,j}$ is orthogonal to $\mathbf{1}$, so they span at most $q = 5$ dimensions, and $\nu = 44$. The multipliers are 2.015 for the naive t interval, 3.12 for PoSI (by simulation), 3.484 for Scheffé and 3.684 for Bonferroni. In the model chosen by AIC, single parenthood and urbanization, the t statistics computed with the full-model s are 5.46 and 1.83. Single parenthood clears every multiplier. Urbanization clears none, not

even the naive one: AIC kept it because its squared t exceeds about 2 (the threshold of Section 29.2), which is a decision about prediction, not evidence of an effect.

```
import itertools
import statsmodels.api as sm
rng = np.random.default_rng(2914)
data = sm.datasets.statcrime.load_pandas().data.drop(index="District of Columbia")
names = ["hs_grad", "poverty", "single", "white", "urban"]
ys = np.log(data["violent"].to_numpy())
Xs = np.column_stack([np.ones(len(ys)), data[names].to_numpy()])
ns, P = Xs.shape
nu = ns - P

# unit vectors u with coefficient of x_j in submodel M = (u' y) / ||v||, for
# every M and j in M
U = []
for k in range(1, 6):
    for M in itertools.combinations(range(1, 6), k):
        XM = Xs[:, [0, *M]]
        V = XM @ np.linalg.inv(XM.T @ XM)
        # column i is v for
        # coefficient i
        for i in range(1, len(M) + 1):
            U.append(V[:, i] / np.linalg.norm(V[:, i]))
U = np.array(U)
# 80 unit vectors, all
# in C(X) minus 1
Qb, _ = np.linalg.qr(Xs)
Qb = Qb[:, 1:]
# orthonormal basis of
# C(X) orthogonal to 1
W = U @ Qb
# coordinates of the u'
# s in that basis
sims = 100_000
Zp = rng.normal(size=(sims, P - 1))
s = np.sqrt(rng.chisquare(nu, size=sims) / nu)
K_posi = np.quantile(np.max(np.abs(Zp @ W.T), axis=1) / s, 0.95)
K_t = stats.t.ppf(0.975, nu)
K_bonf = stats.t.ppf(1 - 0.025 / len(U), nu)
K_sch = np.sqrt((P - 1) * stats.f.ppf(0.95, P - 1, nu))
print(f"{len(U)} coefficients; multipliers: t {K_t:.3f}, PoSI {K_posi:.3f}, "
      f"Bonferroni {K_bonf:.3f}, Scheffe {K_sch:.3f}")
```

Example. (Three ways to report after forward selection)

Take $n = 100$ cases of ten normal regressors with pairwise correlations 0.5, $\sigma = 1$, choose a model by forward selection with AIC, and report 95% intervals for the chosen coefficients, with the projection coefficients $\beta_{\hat{M},j}$ as targets. Over 3000 data sets, the fraction of reported intervals that cover their targets is:

	naive	split in half	Scheffé
no signal: coverage	0.440	0.946	1.000
no signal: mean half-width	0.228	0.351	0.516
three slopes of 0.3: coverage	0.868	0.956	1.000
three slopes of 0.3: mean half-width	0.248	0.379	0.559

With no signal, fewer than half of the naive intervals cover: a coefficient is reported only because its estimate was large. Splitting restores the nominal level at the cost of intervals about one and a half times as wide. The Scheffé intervals, with multiplier $\sqrt{10F_{0.05}(10, 89)} = 4.403$, are valid for every model and every rule, and here they are very conservative, because forward selection explores only a small part of the 5120 coefficients they protect.

29.5.5 Honest inference, III: conditioning on the selection

The third remedy uses all the data and asks for coverage *given* that the model was selected. In the one-dimensional setting of [Proposition 29.5.1\(c\)](#) this can be done exactly.

Example. (A selective interval)

Let $Z \sim N(\theta, 1)$ be reported only when $|Z| > 1.96$, and suppose $Z = 2.5$ is observed. Given selection, Z has the normal distribution truncated to $|z| > 1.96$. Let F_θ be its distribution function. Then $F_\theta(Z)$ is uniform on $(0, 1)$ given selection, whatever θ , and $F_\theta(z)$ decreases in θ ([Exercise C1](#)). So $\{\theta : 0.025 \leq F_\theta(2.5) \leq 0.975\}$ is an interval with conditional coverage exactly 95% for every θ . Numerically it is $[-0.42, 4.33]$, against the naive $[0.54, 4.46]$. An estimate just past the threshold is weak evidence once the threshold is taken into account, and the selective interval includes zero.

```
from scipy.optimize import brentq

def trunc_cdf(x, theta, c=z):
    """Distribution function at x of N(theta, 1) conditioned on |Z| > c."""
    den = stats.norm.sf(c - theta) + stats.norm.cdf(-c - theta)
    if x <= -c:
        num = stats.norm.cdf(x - theta)
    elif x < c:
        num = stats.norm.cdf(-c - theta)
    else:
        num = stats.norm.cdf(-c - theta) + stats.norm.cdf(x - theta) - stats.norm.
        cdf(c - theta)
    return num / den

z_obs = 2.5
lower = brentq(lambda th: trunc_cdf(z_obs, th) - 0.975, -10, z_obs)
upper = brentq(lambda th: trunc_cdf(z_obs, th) - 0.025, -10, 10)
print(f"naive interval [{z_obs - z:.2f}, {z_obs + z:.2f}], selective interval [{
    lower:.2f}, {upper:.2f}]")
```

Lee, Sun, Sun and Taylor (2016) extended the construction to selection events that are polyhedra $\{\mathbf{AY} \leq \mathbf{b}\}$, which covers the lasso at a fixed penalty, forward stepwise selection (Tibshirani, Taylor, Lockhart and Tibshirani 2016) and thresholding: a linear function of $\mathbf{Y}$, given the selection and the part of $\mathbf{Y}$ orthogonal to it, is a truncated normal. The intervals can be very long near the selection boundary. Selecting on part of the data but using all of it for inference

(“data carving”, Fithian, Sun and Taylor 2014) shortens them. In high dimensions the debiased lasso of [Theorem 28.5.1](#) gives intervals for the full model’s coefficients instead.

None of the three routes is free. The cheapest honest inference is still to fix the model before seeing the data, and to use selection for prediction, where its errors can be measured.

29.5.6 Exercises

29.5.6.1 A. Check your understanding

Exercise A1.

In [Proposition 29.5.1\(c\)](#), take $c = 1.5 < z_{0.025}$. Compute the conditional coverage at $\theta = 0$.

29.5.6.2 B. Practice

Exercise B1.

In the orthonormal design of [Proposition 29.2.5](#) with $\sigma = 1$ and a zero coefficient, show that $E(|Z_j| \mid |Z_j| > c) = \phi(c)/(1 - \Phi(c))$. Evaluate it for $c = \sqrt{2}$ and $c = 1.96$, and interpret it as the average size of a selected null coefficient.

Solution. By symmetry $E(|Z| \mid |Z| > c) = E(Z \mid Z > c) = \int_c^\infty z\phi(z) dz / (1 - \Phi(c)) = \phi(c)/(1 - \Phi(c))$. For $c = \sqrt{2}$ this is $0.1468/0.0786 = 1.87$; for $c = 1.96$ it is $0.0584/0.0250 = 2.34$. A coefficient that is truly zero, once selected, is reported with an estimate of about two standard errors on average: the winner’s curse of [Proposition 29.5.1\(a\)](#), in its purest form.

Exercise B2.

Verify that the 32 candidate models of [Example \(Honest intervals for the state regressions\)](#) contain 80 slope coefficients, and that every $\mathbf{v}_{M,j}$ for a slope is orthogonal to $\mathbf{1}$. Why does this let Scheffé’s bound use $q = 5$ instead of 6?

Solution. Each of the 5 regressors appears in $2^4 = 16$ of the models, so there are $5 \times 16 = 80$ pairs. The vector $\mathbf{v}_{M,j} = \mathbf{X}_M(\mathbf{X}_M^\top \mathbf{X}_M)^{-1} \mathbf{e}_j$ satisfies $\mathbf{X}_M^\top \mathbf{v}_{M,j} = \mathbf{e}_j$, and the intercept column of $\mathbf{X}_M$ is $\mathbf{1}$, with $\mathbf{e}_j$ zero in that position, so $\mathbf{1}^\top \mathbf{v}_{M,j} = 0$. All the $\mathbf{v}_{M,j}$ lie in $\mathcal{C}(\mathbf{X}) \cap \mathbf{1}^\perp$, of dimension 5, and [Theorem 13.2.2\(a\)](#) needs only a subspace containing them.

29.5.6.3 C. Going deeper

Exercise C1.

Let F_θ be the distribution function of $N(\theta, 1)$ truncated to a set A of positive probability. Show that for $\theta_1 < \theta_2$ the density ratio $f_{\theta_2}(z)/f_{\theta_1}(z)$ is increasing in $z \in A$, and deduce that $F_{\theta_2}(z) \leq F_{\theta_1}(z)$ for every z . Why does this make the set in [Example \(A selective](#)

interval) an interval?

Solution. On A , $f_\theta(z) = \phi(z - \theta) / \Pr_\theta(A) = \phi(z) e^{\theta z - \theta^2/2} / \Pr_\theta(A)$, so the ratio is a positive constant times $e^{(\theta_2 - \theta_1)z}$, increasing in z . Put $g = f_{\theta_2} / f_{\theta_1}$ on A . If $g(z) \leq 1$ then $g \leq 1$ on $A \cap (-\infty, z]$, so $F_{\theta_2}(z) \leq F_{\theta_1}(z)$. If $g(z) > 1$ then $g > 1$ on $A \cap [z, \infty)$, so $1 - F_{\theta_2}(z) \geq 1 - F_{\theta_1}(z)$. Either way $F_{\theta_2}(z) \leq F_{\theta_1}(z)$. For fixed z , $\theta \mapsto F_\theta(z)$ is therefore nonincreasing (and continuous), so $\{\theta : 0.025 \leq F_\theta(z) \leq 0.975\}$ is an interval.

Exercise C2.

In [Example \(Coverage after a pretest\)](#), let $\hat{\beta}_1^S$ be the short slope and $\hat{\beta}_2$ the long-model estimate of β_2 . Use [Lemma 19.1.1](#) to show that the two are independent, and write the coverage of the reported interval as

$$\Pr(|T_2| \leq z) \Pr(|\hat{\beta}_1^S - \beta_1| \leq z \text{sd}(\hat{\beta}_1^S)) + \Pr(|T_2| > z, |\hat{\beta}_1 - \beta_1| \leq z \text{sd}(\hat{\beta}_1)),$$

where $T_2 = \hat{\beta}_2 / \text{sd}(\hat{\beta}_2)$. Explain why only the first term depends on the bias $r\beta_2$ of the short slope in this simple way.

29.6 Summary and Notes

29.6.1 Summary

Idea.

1. The training error of any fitting procedure understates its in-sample prediction error by $2n^{-1} \sum_i \text{Cov}(\hat{\mu}_i, Y_i)$ on average. For least squares on p columns this is $2\sigma^2 p/n$, whether or not the model is correct, and for a linear smoother $2\sigma^2 \text{tr}(\mathbf{S})/n$ ([Theorem 29.1.1](#)).
2. The degrees of freedom of a procedure are $\sigma^{-2} \sum_i \text{Cov}(\hat{\mu}_i, Y_i)$ ([Definition 29.1.2](#)). Under normality they equal the expected divergence of the fit, by Stein's lemma ([Lemma 27.5.1](#), [Proposition 29.1.2](#)). Soft thresholding costs its expected number of nonzero coefficients, hard thresholding and subset search cost more ([Proposition 29.1.3](#) and [Example \(Best subset of a given size\)](#)).
3. Mallows' C_p is an unbiased estimate of the scaled risk of each candidate, and it prefers a larger model iff the added columns have $F > 2$ ([Definition 29.2.1](#) and [Proposition 29.2.1](#)). AIC estimates a Kullback–Leibler discrepancy, and AICc estimates it without bias in the normal linear model ([Definition 29.2.2](#) and [Theorem 29.2.2](#)). BIC approximates a log marginal likelihood, with penalty $\log n$ per parameter.
4. Criteria with a growing penalty such as BIC find a true finite model with probability tending to one. AIC keeps each irrelevant column with probability about $\Pr\{\chi^2(1) > 2\}$ however large n is, but it is efficient for prediction when no candidate is true ([Proposition 29.2.4](#)).
5. In an orthonormal design selection is hard thresholding, and no threshold dominates another ([Proposition 29.2.5](#) and [Eq. 29.2.4](#)).

6. K -fold cross-validation estimates the expected error of the procedure fitted to $n - n/K$ cases, not the error of the model at hand ([Proposition 29.3.1](#)). For quadratic penalties, leave-one-out needs no refitting, and GCV replaces the leverages by their average ([Theorem 29.3.2](#) and [Definition 29.3.2](#)). Every data-driven step must be repeated inside the folds ([Example \(Screening, then cross-validating\)](#)).
7. Criteria that depend on SSE agree within a size ([Proposition 29.4.1](#)). Branch and bound finds the best subset exactly with far fewer fits ([Proposition 29.4.2](#)). Stepwise steps maximize partial correlations ([Proposition 29.4.3](#)) and can miss the best subset, and the chosen subset is unstable ([Example \(Bootstrapping the state regressions\)](#)).
8. After selection, estimates are biased away from zero, minimized error estimates are optimistic, and naive intervals under-cover ([Proposition 29.5.1](#)). Sample splitting ([Proposition 29.5.2](#)), simultaneous intervals over all submodels ([Proposition 29.5.3](#)) and conditional intervals ([Example \(A selective interval\)](#)) restore validity at different prices.

29.6.2 Notes and sources

Coverage. The chapter covers Seber and Lee (2003, chapter 12), Christensen (2020, chapter 14), Sen and Srivastava (1990, chapter 11) and Fahrmeir, Kneib, Lang and Marx (2021, section 3.4) with its own arguments and examples. The comparison of short and long regressions behind selection is [Theorem 19.1.5](#). Shrinkage, the high-dimensional case, and penalized and boosted fits are in [Chapter 27](#), [Chapter 28](#) and [Chapter 30](#); bagging and random forests are outside the book's scope.

Optimism and degrees of freedom. The covariance form of the optimism is due to Efron (1986, 2004), and the covariance definition of degrees of freedom, with the observation that selection adds to them, to Ye (1998). Stein (1981) proved the identity behind [Proposition 29.1.2](#) and the unbiased risk estimate. Zou, Hastie and Tibshirani (2007) showed that the number of nonzero lasso coefficients is unbiased for its degrees of freedom, and Tibshirani (2015) studied the search degrees of freedom of best subset selection, of which [Proposition 29.1.3](#) is the orthonormal case. Breiman (1992) estimated the prediction error of a selected model by resampling residuals, and Breiman and Spector (1992) compared fixed and random designs and leave-one-out with five- and ten-fold cross-validation.

Criteria. C_p and its plot are due to Mallows (1973), AIC to Akaike (1973, 1974), and AICc to Sugiura (1978) and Hurvich and Tsai (1989), whose derivation [Theorem 29.2.2](#) follows. BIC is from Schwarz (1978); Kass and Raftery (1995) and Kass and Wasserman (1995) discuss its accuracy. Consistency for penalties with $c_n \rightarrow \infty$, $c_n/n \rightarrow 0$ is due to Nishii (1984), efficiency to Shibata (1981) and Li (1987), and their incompatibility to Yang (2005). Konishi and Kitagawa (2008) treat information criteria at book length. The pretest estimator goes back to Bancroft (1944).

Cross-validation. Cross-validation is due to Stone (1974) and Geisser (1975), PRESS to Allen (1974), the equivalence with AIC to Stone (1977), and the need for large validation sets for consistency to Shao (1993); Shao (1997) unifies these results. GCV is from Craven and Wahba (1979) and Golub, Heath and Wahba (1979), and the one-standard-error rule from Breiman, Friedman, Olshen and Stone (1984). Bengio and Grandvalet (2004) and Bates, Hastie and Tibshirani (2024) analyse its variance and its target. Varma and Simon (2006) and Hastie, Tibshirani and Friedman (2009, section 7.10) discuss cross-validation after screening.

Search. Enumeration by sweeps is due to Schatzoff, Tsao and Fienberg (1968), branch and bound to Furnival and Wilson (1974), and stepwise regression to Efroymson (1960). Miller (2002) is the standard monograph on subset selection. Natarajan (1995) proved NP-hardness, Bertsimas, King and Mazumder (2016) used mixed-integer optimization, and Hastie, Tibshirani and Tibshirani (2020) compare best subset, forward stepwise and the lasso. Breiman (1996b) analysed instability, Breiman (1996a) proposed bagging, Hoeting, Madigan, Raftery and Volinsky (1999) review model averaging, and Meinshausen and Bühlmann (2010) introduced stability selection.

Inference after selection. The screening paradox is Freedman’s (1983). Leeb and Pötscher (2005, 2006) showed that post-selection distributions cannot be estimated uniformly. Sample splitting goes back to Cox (1975), with modern versions by Wasserman and Roeder (2009) and Rinaldo, Wasserman and G’Sell (2019). [Proposition 29.5.3](#) is the PoSI approach of Berk, Brown, Buja, Zhang and Zhao (2013). Exact conditional inference is due to Lee, Sun, Sun and Taylor (2016) and Tibshirani, Taylor, Lockhart and Tibshirani (2016), and data carving to Fithian, Sun and Taylor (2014).

Chapter 30

Regularization and Boosting

Ridge regression and the lasso are two members of one family: least squares plus a penalty on the coefficients. This chapter studies the family as a whole: when a minimizer exists and is unique, how to recognize one, what prior it corresponds to, and what is gained by giving up convexity. Two penalties then carry structure the lasso cannot see: the elastic net keeps correlated regressors together, and the group lasso selects whole factors. The second half turns to boosting, which fits a regression by many small steps along one coordinate at a time. Run to the end, it reproduces least squares; stopped early, it is a shrinkage estimator whose path, with small steps, is almost the lasso path. The number of steps plays the part of the penalty.

What you need. [Chapter 1](#) (the singular value decomposition, [Theorem 1.8.1](#), and the Cauchy–Schwarz inequality, [Proposition 1.1.1](#)), [Chapter 6](#) (least squares as projection, [Theorem 6.4.1](#), and the minimum-norm solution, [Proposition 6.10.1](#)), [Chapter 7](#) (the conjugate posterior, [Theorem 7.6.2](#) and [Proposition 7.6.3](#)), and indicator coding of factors ([Section 8.5](#), [Definition 8.5.1](#)). From this part: [Chapter 27](#) (ridge regression, [Theorem 27.2.2](#), and the lasso, [Definition 27.4.1](#) and [Theorem 27.4.2](#)) and [Chapter 29](#) (covariance penalties, [Theorem 29.1.1](#), and cross-validation). [Chapter 28](#) is needed only for remarks.

30.1 Penalized least squares in general

Ridge regression and the lasso of [Chapter 27](#) raise the same questions: is there a minimizer, is it unique, and how do we recognize one? This section answers them for a general, mainly convex, penalty, reads a penalty as a prior, and ends with penalties that give up convexity on purpose. Throughout, $\mathbf{X}$ is $n \times p$ of any rank, and p may exceed n .

30.1.1 The criterion

Definition 30.1.1 — Penalized least squares

A **penalty** is a function $P : \mathbb{R}^p \rightarrow [0, \infty)$. For $\lambda \geq 0$, the **penalized least squares criterion** is

$$Q_\lambda(\mathbf{b}) = \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda P(\mathbf{b}), \quad (30.1.1)$$

and a **penalized least squares estimate** is any minimizer $\hat{\boldsymbol{\beta}}_\lambda$ of Q_λ . The penalty is **convex** if $P(\alpha\mathbf{b} + (1 - \alpha)\mathbf{c}) \leq \alpha P(\mathbf{b}) + (1 - \alpha)P(\mathbf{c})$ for all $\mathbf{b}, \mathbf{c}$ and $\alpha \in (0, 1)$, and **strictly convex** if the inequality is strict whenever $\mathbf{b} \neq \mathbf{c}$. The penalization is **partial** if $\mathbf{b} = (\mathbf{b}_1^\top, \mathbf{b}_2^\top)^\top$ and P depends on $\mathbf{b}_2$ alone; the coefficients in $\mathbf{b}_1$ are then **unpenalized**.

Other scalings (no $\frac{1}{2}$, or a divisor n) multiply λ by a constant; results are quoted here in the scaling of Eq. 30.1.1. Ridge ($P = \frac{1}{2}\|\mathbf{b}\|^2$, Theorem 27.2.2) and the lasso ($P = \|\mathbf{b}\|_1$, Definition 27.4.1) are convex; the best-subset penalty $\#\{j : b_j \neq 0\}$ of Chapter 29 and the bridge penalties $\sum_j |b_j|^q$, $q < 1$, are not. Sections 30.2 and 30.3 add penalties with structure.

Intercept and scaling. An intercept is not penalized. Minimizing over it first gives $b_0 = \bar{y} - \bar{\mathbf{x}}^\top \mathbf{b}$ and leaves Eq. 30.1.1 with $\mathbf{y}$ and the columns of $\mathbf{X}$ centred (Exercise (B2)), the partialling-out of Theorem 6.6.2, so we centre and drop it. A penalty that treats coordinates alike is not equivariant under rescaling a column, so the columns are also scaled to a common length, a choice that is part of the model.

30.1.2 Existence and uniqueness

For least squares a minimizer always exists and its fit is unique (Theorem 6.4.1). For penalized criteria:

Theorem 30.1.1 — Existence and uniqueness of penalized estimates

Let P be continuous and $\lambda \geq 0$.

- (a) If $Q_\lambda(\mathbf{b}) \rightarrow \infty$ as $\|\mathbf{b}\| \rightarrow \infty$, a minimizer exists. This holds in each of three cases:
 - (i) $\mathbf{X}$ has full column rank; (ii) $\lambda > 0$ and $P(\mathbf{b}) \geq c\|\mathbf{b}\|$ for some $c > 0$; (iii) the penalization is partial, $\mathbf{X} = [\mathbf{X}_1, \mathbf{X}_2]$ with $\mathbf{X}_1$ of full column rank, $\lambda > 0$, and $P(\mathbf{b}) \geq c\|\mathbf{b}_2\|$ for some $c > 0$.
- (b) If P is convex, the set of minimizers is convex, and all minimizers have the same fitted vector $\mathbf{X}\hat{\boldsymbol{\beta}}_\lambda$. If in addition $\lambda > 0$, they all have the same penalty $P(\hat{\boldsymbol{\beta}}_\lambda)$.
- (c) If P is convex and either $\mathbf{X}$ has full column rank, or $\lambda > 0$ and P is strictly convex, the minimizer is unique.

Proof.

- (a) Let $\mathcal{S} = \{\mathbf{b} : Q_\lambda(\mathbf{b}) \leq Q_\lambda(\mathbf{0})\}$. It is closed because Q_λ is continuous, and bounded because $Q_\lambda \rightarrow \infty$, so Q_λ attains its minimum on $\mathcal{S}$. Any point outside $\mathcal{S}$ has a larger value than $\mathbf{0}$, so this minimum is a global minimizer. In case (i), the smallest singular value s of $\mathbf{X}$ is positive (Theorem 1.8.1), so $\|\mathbf{y} - \mathbf{X}\mathbf{b}\| \geq s\|\mathbf{b}\| - \|\mathbf{y}\|$, which tends to infinity. In case (ii), $Q_\lambda(\mathbf{b}) \geq \lambda c\|\mathbf{b}\|$. In case (iii), suppose $\|\mathbf{b}^{(k)}\| \rightarrow \infty$ along a sequence on which Q_λ stays bounded. Then $\lambda c\|\mathbf{b}_2^{(k)}\|$ is bounded, so $\|\mathbf{b}_1^{(k)}\| \rightarrow \infty$. With $s_1 > 0$ the smallest singular value of $\mathbf{X}_1$, $\|\mathbf{y} - \mathbf{X}\mathbf{b}^{(k)}\| \geq s_1\|\mathbf{b}_1^{(k)}\| - \|\mathbf{y}\| - \|\mathbf{X}_2\mathbf{b}_2^{(k)}\| \rightarrow \infty$, a contradiction.
- (b) If P is convex, so is Q_λ , as a sum of convex functions, and the set of minimizers of a convex function is convex. Let $\mathbf{b}$ and $\mathbf{c}$ be minimizers with value q , and put $\mathbf{m} = \frac{1}{2}(\mathbf{b} + \mathbf{c})$. With $\mathbf{u} = \mathbf{y} - \mathbf{X}\mathbf{b}$ and $\mathbf{v} = \mathbf{y} - \mathbf{X}\mathbf{c}$, the parallelogram identity gives

$$\|\mathbf{y} - \mathbf{X}\mathbf{m}\|^2 = \left\|\frac{1}{2}(\mathbf{u} + \mathbf{v})\right\|^2 = \frac{1}{2}\|\mathbf{u}\|^2 + \frac{1}{2}\|\mathbf{v}\|^2 - \frac{1}{4}\|\mathbf{X}(\mathbf{b} - \mathbf{c})\|^2.$$

Together with $P(\mathbf{m}) \leq \frac{1}{2}P(\mathbf{b}) + \frac{1}{2}P(\mathbf{c})$ this yields $q \leq Q_\lambda(\mathbf{m}) \leq q - \frac{1}{8}\|\mathbf{X}(\mathbf{b} - \mathbf{c})\|^2$. Hence $\mathbf{X}\mathbf{b} = \mathbf{X}\mathbf{c}$. The two minimizers then have equal residual sums of squares, so when $\lambda > 0$ their penalties are equal too.

- (c) If $\mathbf{X}$ has full column rank, $\mathbf{X}\mathbf{b} = \mathbf{X}\mathbf{c}$ forces $\mathbf{b} = \mathbf{c}$. If P is strictly convex and $\mathbf{b} \neq \mathbf{c}$, the inequality for $P(\mathbf{m})$ in (b) is strict and $Q_\lambda(\mathbf{m}) < q$, which is impossible. ■

Norms satisfy (a)(ii), so the lasso, group lasso and elastic net always have minimizers. By (b), when $p > n$ the lasso's minimizers, possibly many, share their fit and ℓ_1 norm (they are unique in general position; Tibshirani, 2013).

30.1.3 Optimality conditions

The corner of $|b|$ at zero, which makes the lasso set coefficients to zero, calls for a substitute for the gradient.

Definition 30.1.2 — Subgradient

Let P be convex. A vector $\mathbf{s}$ is a **subgradient** of P at $\mathbf{b}$ if $P(\mathbf{c}) \geq P(\mathbf{b}) + \mathbf{s}^\top(\mathbf{c} - \mathbf{b})$ for every $\mathbf{c} \in \mathbb{R}^p$. The set of all subgradients at $\mathbf{b}$ is the **subdifferential** $\partial P(\mathbf{b})$.

Where P is differentiable, $\partial P(\mathbf{b}) = \{\nabla P(\mathbf{b})\}$. For $P(b) = |b|$ on $\mathbb{R}$, the subdifferential is $\{\text{sign}(b)\}$ if $b \neq 0$ and $[-1, 1]$ at 0.

Lemma 30.1.2 — Optimality condition

Let P be convex and $\lambda > 0$. A vector $\hat{\mathbf{\beta}}$ minimizes Q_λ iff

$$\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\hat{\mathbf{\beta}}) \in \lambda \partial P(\hat{\mathbf{\beta}}). \quad (30.1.2)$$

In that case $Q_\lambda(\mathbf{b}) - Q_\lambda(\hat{\mathbf{\beta}}) \geq \frac{1}{2}\|\mathbf{X}(\mathbf{b} - \hat{\mathbf{\beta}})\|^2$ for every $\mathbf{b}$.

Proof. Write $\mathbf{r} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}$ and $\mathbf{d} = \mathbf{b} - \hat{\boldsymbol{\beta}}$. Expanding the square,

$$Q_\lambda(\mathbf{b}) - Q_\lambda(\hat{\boldsymbol{\beta}}) = -\mathbf{d}^\top \mathbf{X}^\top \mathbf{r} + \frac{1}{2} \|\mathbf{X}\mathbf{d}\|^2 + \lambda(P(\mathbf{b}) - P(\hat{\boldsymbol{\beta}})). \quad (30.1.3)$$

If $\mathbf{X}^\top \mathbf{r} = \lambda \mathbf{s}$ with $\mathbf{s} \in \partial P(\hat{\boldsymbol{\beta}})$, then $\lambda(P(\mathbf{b}) - P(\hat{\boldsymbol{\beta}})) \geq \lambda \mathbf{s}^\top \mathbf{d} = \mathbf{d}^\top \mathbf{X}^\top \mathbf{r}$, and [Eq. 30.1.3](#) gives the stated lower bound, which is nonnegative. Conversely, let $\hat{\boldsymbol{\beta}}$ be a minimizer and fix $\mathbf{b}$. For $0 < \tau < 1$, convexity gives $P(\hat{\boldsymbol{\beta}} + \tau \mathbf{d}) - P(\hat{\boldsymbol{\beta}}) \leq \tau(P(\mathbf{b}) - P(\hat{\boldsymbol{\beta}}))$. Apply [Eq. 30.1.3](#) to $\hat{\boldsymbol{\beta}} + \tau \mathbf{d}$ in place of $\mathbf{b}$:

$$\begin{aligned} 0 &\leq Q_\lambda(\hat{\boldsymbol{\beta}} + \tau \mathbf{d}) - Q_\lambda(\hat{\boldsymbol{\beta}}) \\ &\leq -\tau \mathbf{d}^\top \mathbf{X}^\top \mathbf{r} + \frac{\tau^2}{2} \|\mathbf{X}\mathbf{d}\|^2 + \lambda \tau (P(\mathbf{b}) - P(\hat{\boldsymbol{\beta}})). \end{aligned}$$

Divide by τ and let $\tau \rightarrow 0$. The result is $\lambda(P(\mathbf{b}) - P(\hat{\boldsymbol{\beta}})) \geq \mathbf{d}^\top \mathbf{X}^\top \mathbf{r}$ for every $\mathbf{b}$, which says that $\mathbf{X}^\top \mathbf{r} / \lambda \in \partial P(\hat{\boldsymbol{\beta}})$. ■

Condition [Eq. 30.1.2](#) is the **Karush–Kuhn–Tucker** (KKT) condition; with $\lambda = 0$ it is the normal equations. Most penalties below are sums of Euclidean norms of blocks.

Lemma 30.1.3 — Subdifferential of a sum of block norms

Let $G_1, \dots, G_K$ partition $\{1, \dots, p\}$, let $w_1, \dots, w_K > 0$, and let $P(\mathbf{b}) = \sum_k w_k \|\mathbf{b}_{G_k}\|$, where $\mathbf{b}_{G_k}$ is the subvector of $\mathbf{b}$ with coordinates in G_k . Then $\mathbf{s} \in \partial P(\mathbf{b})$ iff, for every k ,

$$\mathbf{s}_{G_k} = w_k \frac{\mathbf{b}_{G_k}}{\|\mathbf{b}_{G_k}\|} \quad \text{if } \mathbf{b}_{G_k} \neq \mathbf{0}, \quad \|\mathbf{s}_{G_k}\| \leq w_k \quad \text{if } \mathbf{b}_{G_k} = \mathbf{0}.$$

With singleton blocks and unit weights, $P = \|\cdot\|_1$, and $\mathbf{s} \in \partial \|\mathbf{b}\|_1$ iff $s_j = \text{sign}(b_j)$ when $b_j \neq 0$ and $|s_j| \leq 1$ when $b_j = 0$.

Proof. First, $\mathbf{s} \in \partial P(\mathbf{b})$ iff $\mathbf{s}_{G_k} \in \partial(w_k \|\cdot\|)(\mathbf{b}_{G_k})$ for every k . Summing the blockwise inequalities gives one direction. For the other, apply the subgradient inequality to a $\mathbf{c}$ that differs from $\mathbf{b}$ only in block k . So it suffices to describe the subdifferential of $f(\mathbf{u}) = w\|\mathbf{u}\|$ on $\mathbb{R}^d$. We show that $\mathbf{s} \in \partial f(\mathbf{u})$ iff $\|\mathbf{s}\| \leq w$ and $\mathbf{s}^\top \mathbf{u} = w\|\mathbf{u}\|$.

If these two conditions hold, then for every $\mathbf{v}$, by Cauchy–Schwarz ([Proposition 1.1.1](#)), $f(\mathbf{v}) = w\|\mathbf{v}\| \geq \mathbf{s}^\top \mathbf{v} = f(\mathbf{u}) + \mathbf{s}^\top (\mathbf{v} - \mathbf{u})$. Conversely, let $\mathbf{s} \in \partial f(\mathbf{u})$. Taking $\mathbf{v} = \mathbf{0}$ and $\mathbf{v} = 2\mathbf{u}$ gives $\mathbf{s}^\top \mathbf{u} \geq w\|\mathbf{u}\|$ and $\mathbf{s}^\top \mathbf{u} \leq w\|\mathbf{u}\|$. Then $w\|\mathbf{u} + \tau \mathbf{v}\| \geq w\|\mathbf{u}\| + \tau \mathbf{s}^\top \mathbf{v}$ for all $\tau > 0$. The triangle inequality bounds the left side by $w\|\mathbf{u}\| + \tau w\|\mathbf{v}\|$, so $\mathbf{s}^\top \mathbf{v} \leq w\|\mathbf{v}\|$ for every $\mathbf{v}$. Taking $\mathbf{v} = \mathbf{s}$ gives $\|\mathbf{s}\| \leq w$.

If $\mathbf{u} = \mathbf{0}$, the two conditions say $\|\mathbf{s}\| \leq w$. If $\mathbf{u} \neq \mathbf{0}$, then $\mathbf{s}^\top \mathbf{u} = w\|\mathbf{u}\| \geq \|\mathbf{s}\|\|\mathbf{u}\|$ is equality in Cauchy–Schwarz, so $\mathbf{s}$ is a nonnegative multiple of $\mathbf{u}$ with norm w , that is, $\mathbf{s} = w\mathbf{u}/\|\mathbf{u}\|$. ■

Combining the two lemmas, $\hat{\boldsymbol{\beta}}$ is a lasso estimate iff $\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) = \lambda \text{sign}(\hat{\beta}_j)$ for every j with $\hat{\beta}_j \neq 0$ and $|\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})| \leq \lambda$ for every j with $\hat{\beta}_j = 0$, as in [Definition 27.4.1](#): active regressors

share the absolute correlation λ with the residual, and no inactive one exceeds it.

30.1.4 The Bayesian reading

Ridge regression is a posterior mean ([Proposition 7.6.3\(d\)](#)). For other penalties the matching statement is about the posterior *mode*; part (b) below restates, for completeness, the reading of the lasso found in [Exercise \(B2\)](#) ([Section 27.4](#)).

Proposition 30.1.4 — Penalized estimates as posterior modes

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$ with σ^2 known, and give $\boldsymbol{\beta}$ a prior density $\pi(\mathbf{b}) \propto \exp\{-(\lambda/\sigma^2)P(\mathbf{b})\}$, assumed integrable. Then the posterior density of $\boldsymbol{\beta}$ is proportional to $\exp\{-Q_\lambda(\mathbf{b})/\sigma^2\}$. So the penalized least squares estimates are exactly the posterior modes. In particular:

- (a) a normal prior $\boldsymbol{\beta} \sim N_p(\mathbf{0}, \tau^2\mathbf{I})$ gives ridge regression ([Theorem 27.2.2](#)) with $\lambda = \sigma^2/\tau^2$, and the posterior mode equals the posterior mean;
- (b) independent Laplace priors with density $(a/2)e^{-a|b_j|}$ give the lasso with $\lambda = a\sigma^2$.

Proof. By Bayes' theorem the posterior density is proportional to the likelihood times the prior, that is, to $\exp\{-\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2/(2\sigma^2)\} \exp\{-(\lambda/\sigma^2)P(\mathbf{b})\} = \exp\{-Q_\lambda(\mathbf{b})/\sigma^2\}$, and $t \mapsto e^{-t/\sigma^2}$ is decreasing. For (a), $\tau^{-2}\|\mathbf{b}\|^2/2 = (\lambda/\sigma^2)\|\mathbf{b}\|^2/2$ with $\lambda = \sigma^2/\tau^2$. The posterior is normal, so its mode and mean coincide ([Theorem 7.6.2](#) with σ^2 known, or [Proposition 7.6.3\(d\)](#)). For (b), as in [Exercise \(B2\)](#), $a\|\mathbf{b}\|_1 = (\lambda/\sigma^2)\|\mathbf{b}\|_1$ with $\lambda = a\sigma^2$. ■

Under squared error loss, though, a Bayesian reports the posterior mean, which under a Laplace prior is never sparse.

Example. (Posterior mode and posterior mean under a Laplace prior)

Take one observation $z \sim N(\theta, 1)$ and a Laplace prior on θ with rate $a = 1.5$. By [Proposition 30.1.4\(b\)](#) the posterior mode is the lasso estimate with $\lambda = 1.5$, which is soft thresholding at 1.5 ([Theorem 27.4.2](#)). The posterior mean, computed by numerical integration in the listing below, behaves differently:

z	0.5	1.0	2.0	4.0
posterior mode	0	0	0.500	2.500
posterior mean	0.174	0.364	0.859	2.509

The mode is zero for $|z| \leq 1.5$; the mean is zero only at $z = 0$, and approaches $z - 1.5$ for large z ([Figure 30.1.1\(c\)](#)). Exact zeros come from the mode, not from the prior; a prior that believes in exact zeros needs a point mass, as in the spike-and-slab priors of George and McCulloch (1993). [Chapter 39](#) returns to priors as regularizers ([Proposition 39.5.1](#)).

```
import numpy as np
from scipy import integrate
```

```

def soft(z, lam):
    return np.sign(z) * np.maximum(np.abs(z) - lam, 0.0)

def laplace_posterior_mean(z, rate):
    """E(theta | z) when z ~ N(theta, 1) and theta has density (rate/2) exp(-rate /
    theta)."""
    w = lambda t: np.exp(-0.5 * (z - t) ** 2 - rate * abs(t))
    num = integrate.quad(lambda t: t * w(t), -30, 30, points=[0.0, z])[0]
    den = integrate.quad(w, -30, 30, points=[0.0, z])[0]
    return num / den

rate = 1.5
for z in [0.5, 1.0, 2.0, 4.0]:
    print(f"z = {z}: posterior mode {float(soft(z, rate)):.3f}, "
          f"posterior mean {laplace_posterior_mean(z, rate):.3f}")

```

30.1.5 Penalties that are not convex

Under an orthonormal design the lasso subtracts λ from every surviving coefficient, however large (Theorem 27.4.2). Fan and Li (2001) asked for a rule that is **sparse**, **continuous** in the data, and **nearly unbiased** (large estimates left alone). Soft thresholding fails the third, and hard thresholding, the best-subset rule (Theorem 27.4.2(c)), the second. No convex penalty has all three, since one that is flat far from zero on both sides is constant. Two penalties $P(\mathbf{b}) = \sum_j \rho(b_j)$, with ρ concave on $[0, \infty)$, are in common use.

SCAD (the smoothly clipped absolute deviation of Fan and Li, 2001), with a parameter $a > 2$, is defined through its derivative on $t > 0$:

$$\rho'(t) = \lambda \left\{ \mathbf{1}(t \leq \lambda) + \frac{(a\lambda - t)_+}{(a-1)\lambda} \mathbf{1}(t > \lambda) \right\}, \quad \rho(0) = 0, \quad \rho(-t) = \rho(t).$$

It is the lasso penalty up to λ ; its slope then falls linearly to zero at $a\lambda$. Here λ sits inside ρ , and the criterion is $\frac{1}{2}\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \sum_j \rho(b_j)$. Fan and Li suggest $a = 3.7$.

MCP (the minimax concave penalty of Zhang, 2010), with a parameter $\gamma > 1$, is

$$\rho(t) = \begin{cases} \lambda|t| - t^2/(2\gamma), & |t| \leq \gamma\lambda, \\ \gamma\lambda^2/2, & |t| > \gamma\lambda. \end{cases}$$

Its slope $\lambda - |t|/\gamma$ starts to fall at once, rather than after λ as for SCAD.

Proposition 30.1.5 — MCP: convexity and firm thresholding

Let $Q(\mathbf{b}) = \frac{1}{2}\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \sum_j \rho(b_j)$ with ρ the MCP penalty.

- If the smallest eigenvalue of $\mathbf{X}^\top \mathbf{X}$ is at least $1/\gamma$, then Q is convex. If it exceeds $1/\gamma$, then Q is strictly convex and has a unique minimizer.
- If $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, the unique minimizer is $\hat{\beta}_j = \phi(z_j)$ with $\mathbf{z} = \mathbf{X}^\top \mathbf{y}$, where ϕ is **firm**

thresholding:

$$\phi(z) = \begin{cases} 0, & |z| \leq \lambda, \\ \text{sign}(z) \frac{|z| - \lambda}{1 - 1/\gamma}, & \lambda < |z| \leq \gamma\lambda, \\ z, & |z| > \gamma\lambda. \end{cases}$$

Proof.

(a) Write

$$Q(\mathbf{b}) = \left\{ \frac{1}{2} \mathbf{b}^\top (\mathbf{X}^\top \mathbf{X} - \gamma^{-1} \mathbf{I}) \mathbf{b} - \mathbf{y}^\top \mathbf{X} \mathbf{b} + \frac{1}{2} \mathbf{y}^\top \mathbf{y} \right\} \\ + \sum_j \left\{ \rho(b_j) + \frac{b_j^2}{2\gamma} \right\}.$$

The first brace is a quadratic with nonnegative definite matrix, hence convex, and strictly convex if the matrix is positive definite. Each term of the second sum is $\lambda|t|$ for $|t| \leq \gamma\lambda$ and $\gamma\lambda^2/2 + t^2/(2\gamma)$ beyond. On $t > 0$ its derivative is λ up to $\gamma\lambda$ and t/γ after. This derivative is continuous at $\gamma\lambda$ and nondecreasing, so the function is convex (it is even, with a corner at 0). A sum of convex functions is convex, and adding a strictly convex function makes the sum strictly convex. A strictly convex function that tends to infinity has exactly one minimizer, by the argument of [Theorem 30.1.1](#)(a) and (c).

(b) With $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, part (a) applies because $\gamma > 1$. Moreover $Q(\mathbf{b}) = \frac{1}{2} \|\mathbf{z} - \mathbf{b}\|^2 + \sum_j \rho(b_j) + \text{const}$, which separates into one problem per coordinate: minimize $g(\theta) = \frac{1}{2}(z - \theta)^2 + \rho(\theta)$. Take $z \geq 0$. For $\theta > 0$, $g(-\theta) - g(\theta) = 2z\theta \geq 0$, so we may restrict to $\theta \geq 0$. There

$$g'(\theta) = \begin{cases} (1 - 1/\gamma)\theta - (z - \lambda), & 0 < \theta \leq \gamma\lambda, \\ \theta - z, & \theta > \gamma\lambda, \end{cases}$$

a continuous nondecreasing function. If $z \leq \lambda$, then $g' \geq 0$ on $(0, \infty)$, and the minimizer is 0. If $\lambda < z \leq \gamma\lambda$, then g' vanishes at $\theta = (z - \lambda)/(1 - 1/\gamma)$, which is at most $\gamma\lambda$. If $z > \gamma\lambda$, then $g'(\gamma\lambda) = \gamma\lambda - z < 0$, and g' vanishes at $\theta = z$.

■

Firm thresholding has all three properties; it tends to soft thresholding as $\gamma \rightarrow \infty$ and to hard thresholding as $\gamma \downarrow 1$. The SCAD rule under an orthonormal design is (Fan and Li, 2001)

$$\phi_{\text{SCAD}}(z) = \begin{cases} \text{sign}(z)(|z| - \lambda)_+, & |z| \leq 2\lambda, \\ \frac{(a-1)z - \text{sign}(z)a\lambda}{a-2}, & 2\lambda < |z| \leq a\lambda, \\ z, & |z| > a\lambda, \end{cases}$$

which [Exercise \(B1\)](#) derives. The script checks each rule of [Figure 30.1.1](#) against brute-force minimization.

```
import numpy as np

def soft(z, lam):
    return np.sign(z) * np.maximum(np.abs(z) - lam, 0.0)
```

Figure 30.1.1: (a) The lasso, SCAD ($a = 3.7$), MCP ($\gamma = 3$) and ℓ_0 penalties with $\lambda = 1$. (b) The thresholding rules they induce under an orthonormal design (soft, SCAD, firm, and hard thresholding dashed); the grey line is the identity. (c) Posterior mode and posterior mean of θ given $z \sim N(\theta, 1)$ under a Laplace prior with rate 1.5 ([Example \(Posterior mode and posterior mean under a Laplace prior\)](#)).

```
def mcp_rule(z, lam, gam):
    # firm thresholding
    az = np.abs(z)
    mid = np.sign(z) * (az - lam) / (1 - 1 / gam)
    return np.where(az <= lam, 0.0, np.where(az <= gam * lam, mid, z))

def scad_rule(z, lam, a):
    az = np.abs(z)
    mid = ((a - 1) * z - np.sign(z) * a * lam) / (a - 2)
    return np.where(az <= 2 * lam, soft(z, lam), np.where(az <= a * lam, mid, z))

def hard_rule(z, lam):
    # penalty (lam^2 / 2) * 1{theta != 0}
    return np.where(np.abs(z) > lam, z, 0.0)
```

Without the eigenvalue condition there can be several local minima ([Exercise \(C1\)](#)). Replacing ρ by its tangent at a preliminary estimate gives a weighted lasso (Zou and Li, 2008), as does the adaptive lasso (Zou, 2006). Fan and Li (2001) proved an *oracle property*, which we state without proof: with p fixed, $\lambda_n/n \rightarrow 0$, $\lambda_n/\sqrt{n} \rightarrow \infty$ (in the scaling of [Eq. 30.1.1](#); Fan and Li write the penalty as $n \sum_j p_\lambda(|b_j|)$, where the conditions read $\lambda_n \rightarrow 0$, $\sqrt{n}\lambda_n \rightarrow \infty$) and regularity conditions, some local SCAD minimizer finds the zero coefficients with probability tending to one and estimates the rest as well as least squares on the true support. The convergence is not uniform in β (Leeb and Pötscher, 2005), and it does not justify oracle standard errors ([Chapter 29](#)).

30.1.6 Exercises

30.1.6.1 A. Check your understanding

Exercise A1.

With $\lambda = 1$, compute the lasso, ridge (penalty $\frac{1}{2}b^2$), hard, firm ($\gamma = 3$) and SCAD ($a = 3.7$) estimates of θ for a single observation $z = 2.5$ under an orthonormal design. Which rules shrink it, and by how much?

Solution. Lasso: $2.5 - 1 = 1.5$. Ridge: $2.5/2 = 1.25$. Hard: 2.5, since $|z| > 1$. Firm: $\lambda < z \leq \gamma\lambda = 3$, so $(2.5 - 1)/(1 - 1/3) = 2.25$. SCAD: $2 < z \leq 3.7$, so $(2.7 \cdot 2.5 - 3.7)/1.7 = 3.05/1.7 = 1.79$. Only hard thresholding leaves z alone. At $z = 4$ the firm and SCAD rules would leave it alone as well, since 4 exceeds both $\gamma\lambda = 3$ and $a\lambda = 3.7$.

Exercise A2.

Show that the firm thresholding rule ϕ of Proposition 30.1.5(b) is continuous at $|z| = \lambda$ and at $|z| = \gamma\lambda$, whereas the hard thresholding rule $z\mathbf{1}(|z| > \lambda)$ jumps by λ at $|z| = \lambda$. What is the largest slope of ϕ , and what happens to it as $\gamma \downarrow 1$?

Solution. Take $z \geq 0$. As $z \downarrow \lambda$ the middle branch $(z - \lambda)/(1 - 1/\gamma)$ tends to 0, the value below λ . At $z = \gamma\lambda$ it equals $(\gamma - 1)\lambda/\{(\gamma - 1)/\gamma\} = \gamma\lambda$, the value of the upper branch. Hard thresholding is 0 at $z = \lambda$ and tends to λ as $z \downarrow \lambda$. The slope of ϕ is 0, then $\gamma/(\gamma - 1)$, then 1; the largest is $\gamma/(\gamma - 1)$, which tends to infinity as $\gamma \downarrow 1$, where ϕ approaches the discontinuous hard rule.

30.1.6.2 B. Practice

Exercise B1.

Derive the SCAD thresholding rule displayed above. Minimize $g(\theta) = \frac{1}{2}(z - \theta)^2 + \rho(\theta)$ for $z \geq 0$ on the three pieces $[0, \lambda]$, $[\lambda, a\lambda]$ and $[a\lambda, \infty)$, and check that g is convex on $[0, \infty)$ when $a > 2$.

Solution. On $(0, \infty)$, $g'(\theta) = \theta - z + \rho'(\theta)$. This is $\theta - z + \lambda$ on $(0, \lambda]$, $\theta - z + (a\lambda - \theta)/(a - 1)$ on $(\lambda, a\lambda]$, and $\theta - z$ beyond. The middle piece has slope $1 - 1/(a - 1) = (a - 2)/(a - 1) > 0$ when $a > 2$, and the pieces agree at λ and at $a\lambda$. So g' is continuous and increasing, and g is strictly convex on $[0, \infty)$. As in the proof of Proposition 30.1.5, a negative θ is never better when $z \geq 0$. If $z \leq \lambda$, then $g'(0+) = \lambda - z \geq 0$ and $\hat{\theta} = 0$. If $\lambda < z \leq 2\lambda$, the root $z - \lambda$ lies in $(0, \lambda]$. If $2\lambda < z \leq a\lambda$, the middle piece vanishes at $\theta = \{(a - 1)z - a\lambda\}/(a - 2)$, which lies in $(\lambda, a\lambda]$ exactly for these z . If $z > a\lambda$, then $\hat{\theta} = z$.

Exercise B2.

Let P be any penalty on the slopes, and let the model have an unpenalized intercept. By Proposition 27.2.1, $(\hat{b}_0, \hat{\beta})$ minimizes $\frac{1}{2} \sum_i (y_i - b_0 - \mathbf{x}_{(i)}^\top \mathbf{b})^2 + \lambda P(\mathbf{b})$ iff $\hat{\beta}$ minimizes the centred criterion and $\hat{b}_0 = \bar{y} - \bar{\mathbf{x}}^\top \hat{\beta}$. Deduce that the fitted values of penalized regression with an intercept are unchanged when a constant is added to $\mathbf{y}$, and that the slopes are unchanged when a constant is added to a column of $\mathbf{X}$. Does the second statement survive standardizing the columns before fitting?

30.1.6.3 C. Going deeper

Exercise C1.

Let $n = p = 2$, $\mathbf{X}^\top \mathbf{X} = \begin{pmatrix} 1 & r \\ r & 1 \end{pmatrix}$ with $r \in (0, 1)$, and use MCP with $\gamma > 1$. For which r does [Proposition 30.1.5\(a\)](#) guarantee convexity? Find a response $\mathbf{y}$ for which the MCP criterion has two distinct local minima when r exceeds that bound.

30.2 The elastic net

When several regressors are near copies of one another (repeated measurements, genes in one pathway), the lasso tends to keep one and drop the rest, and which one can change with a small perturbation of the data. With two identical columns its solution is not even unique (Exercise B1 of [Section 27.4](#)). Ridge spreads the coefficient evenly over the copies but never sets anything to zero. Zou and Hastie (2005) proposed using both penalties.

30.2.1 Definition and basic properties

Definition 30.2.1 — Elastic net

For $\lambda_1, \lambda_2 \geq 0$, the **elastic net** criterion is

$$Q(\mathbf{b}) = \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda_1 \|\mathbf{b}\|_1 + \frac{1}{2} \lambda_2 \|\mathbf{b}\|^2, \quad (30.2.1)$$

and its minimizer $\hat{\boldsymbol{\beta}}^{\text{en}}$ is the (naive) **elastic net estimate**. An equivalent parameterization is $\lambda_1 = \alpha\lambda$, $\lambda_2 = (1 - \alpha)\lambda$, with a mixing parameter $\alpha \in [0, 1]$ and an overall level $\lambda \geq 0$.

With $\lambda_2 = 0$ this is the lasso, and with $\lambda_1 = 0$ ridge. Here the columns of $\mathbf{X}$ are centred with unit length and $\mathbf{y}$ is centred, so $\rho_{ij} = \mathbf{x}_i^\top \mathbf{x}_j$ is a sample correlation.

Proposition 30.2.1 — Elastic net: uniqueness, augmented data, grouping

Let $\lambda_2 > 0$.

- (a) The criterion [Eq. 30.2.1](#) has a unique minimizer, whatever the rank of $\mathbf{X}$. It is characterized by

$$\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) - \lambda_2 \hat{\beta}_j = \lambda_1 \text{sign}(\hat{\beta}_j) \quad (\hat{\beta}_j \neq 0), \quad |\mathbf{x}_j^\top (\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}})| \leq \lambda_1 \quad (\hat{\beta}_j = 0). \quad (30.2.2)$$

- (b) (*Augmented data.*) Let $\mathbf{X}^* = \begin{pmatrix} \mathbf{X} \\ \sqrt{\lambda_2} \mathbf{I}_p \end{pmatrix}$ and $\mathbf{y}^* = \begin{pmatrix} \mathbf{y} \\ \mathbf{0} \end{pmatrix}$. Then $\hat{\boldsymbol{\beta}}^{\text{en}}$ is the lasso estimate, with parameter λ_1 , for the data $(\mathbf{X}^*, \mathbf{y}^*)$. The matrix $\mathbf{X}^*$ has full column rank p .
- (c) (*Orthonormal design.*) If $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, then $\hat{\beta}_j^{\text{en}} = \text{sign}(z_j)(|z_j| - \lambda_1)_+ / (1 + \lambda_2)$, with $\mathbf{z} = \mathbf{X}^\top \mathbf{y}$.

(d) (*Grouping effect.*) If $\hat{\beta}_i \hat{\beta}_j > 0$, then

$$|\hat{\beta}_i - \hat{\beta}_j| \leq \frac{\|\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}\| \|\mathbf{x}_i - \mathbf{x}_j\|}{\lambda_2} \leq \frac{\|\mathbf{y}\| \sqrt{2(1 - \rho_{ij})}}{\lambda_2}. \quad (30.2.3)$$

(e) (*Identical columns.*) If $\mathbf{x}_i = \mathbf{x}_j$, then $\hat{\beta}_i = \hat{\beta}_j$.

Proof.

- (a) The penalty $\lambda_1 \|\mathbf{b}\|_1 + \frac{1}{2} \lambda_2 \|\mathbf{b}\|^2$ is strictly convex, because $\|\mathbf{b}\|^2$ is strictly convex and $\|\mathbf{b}\|_1$ is convex. It is at least $\frac{1}{2} \lambda_2 \|\mathbf{b}\|^2$, so $Q \rightarrow \infty$. Existence and uniqueness follow as in [Theorem 30.1.1](#)(a) and (c). By [Lemma 30.1.2](#) applied to the whole penalty, with the gradient $\lambda_2 \mathbf{b}$ of the smooth part moved to the left-hand side, and [Lemma 30.1.3](#), the minimizer is characterized by [Eq. 30.2.2](#).
- (b) $\|\mathbf{y}^* - \mathbf{X}^* \mathbf{b}\|^2 = \|\mathbf{y} - \mathbf{X} \mathbf{b}\|^2 + \lambda_2 \|\mathbf{b}\|^2$. So $\frac{1}{2} \|\mathbf{y}^* - \mathbf{X}^* \mathbf{b}\|^2 + \lambda_1 \|\mathbf{b}\|_1$ is [Eq. 30.2.1](#). The last p rows of $\mathbf{X}^*$ are $\sqrt{\lambda_2} \mathbf{I}_p$, which has rank p .
- (c) With $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, [Eq. 30.2.1](#) equals $\sum_j \{\frac{1}{2}(1 + \lambda_2)b_j^2 - z_j b_j + \lambda_1 |b_j|\}$ plus a constant. Dividing the j th term by $1 + \lambda_2$ gives $\frac{1}{2}\{b_j - z_j/(1 + \lambda_2)\}^2 + \{\lambda_1/(1 + \lambda_2)\}|b_j|$ plus a constant. By the univariate lasso solution ([Theorem 27.4.2](#)), this is minimized by soft thresholding $z_j/(1 + \lambda_2)$ at $\lambda_1/(1 + \lambda_2)$, which is the stated formula.
- (d) Both coefficients are nonzero with a common sign s , so [Eq. 30.2.2](#) gives $\mathbf{x}_i^\top \mathbf{r} - \lambda_2 \hat{\beta}_i = \lambda_1 s = \mathbf{x}_j^\top \mathbf{r} - \lambda_2 \hat{\beta}_j$, where $\mathbf{r} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}$. Subtracting, $\lambda_2(\hat{\beta}_i - \hat{\beta}_j) = (\mathbf{x}_i - \mathbf{x}_j)^\top \mathbf{r}$, and Cauchy–Schwarz gives the first inequality. For the second, $\|\mathbf{x}_i - \mathbf{x}_j\|^2 = 2 - 2\rho_{ij}$ for unit-length columns, and $\frac{1}{2}\|\mathbf{r}\|^2 \leq Q(\hat{\boldsymbol{\beta}}) \leq Q(\mathbf{0}) = \frac{1}{2}\|\mathbf{y}\|^2$.
- (e) Swapping coordinates i and j of $\hat{\boldsymbol{\beta}}$ changes neither $\mathbf{X}\hat{\boldsymbol{\beta}}$ nor the penalty. So the swapped vector is also a minimizer, and by uniqueness it equals $\hat{\boldsymbol{\beta}}$. ■

By (b), the elastic net is a lasso on $n + p$ observations with a full-rank design, so it can select all p regressors even when $p > n$; a unique lasso solution has at most $\min(n, p)$ nonzero coefficients ([Exercise \(C1\)](#)). Part (d) is the grouping effect of Zou and Hastie (2005): as $\rho_{ij} \rightarrow 1$, coefficients of the same sign are forced together at a rate set by λ_2 . No such bound holds for the lasso.

Example. (Three near-copies of one signal)

The script simulates $n = 50$ observations of $p = 10$ regressors. The first three are noisy copies of a common variable, with pairwise correlations between 0.93 and 0.95, and each has coefficient 2 (on the unit-length scale). The other seven are independent noise. With $\lambda_1 = 0.8$:

	$\hat{\beta}_1$	$\hat{\beta}_2$	$\hat{\beta}_3$	nonzero
lasso ($\lambda_2 = 0$)	2.335	0.000	2.522	2
elastic net	1.248	1.103	1.236	4
($\lambda_2 = 1$)				
rescaled elastic net	2.496	2.207	2.471	4

Figure 30.2.1: Coefficient paths for the data of [Example \(Three near-copies of one signal\)](#), plotted against $\log_{10} \lambda$, with λ decreasing to the right. The three correlated regressors are coloured and the seven noise regressors are grey. (a) The lasso. (b) The elastic net with $\alpha = \frac{1}{2}$, that is, $\lambda_1 = \lambda_2 = \lambda/2$.

The lasso drops the second copy. The elastic net keeps all three with similar coefficients (and one noise regressor, at 0.081). For the pair (1, 2), with correlation 0.927, the spread 0.144 is well inside [Eq. 30.2.3](#), whose middle term is 1.577 (residual norm 4.129) and right-hand side 2.532 ($\|y\| = 6.630$). Along the lasso path ([Figure 30.2.1](#)) the second copy enters only after λ has fallen by a factor of about 26; along the elastic net path all three enter at the same grid value.

30.2.2 Computing it: coordinate descent

Cyclic coordinate descent, used for the lasso in [Lemma 27.4.4](#), minimizes over one coordinate at a time, the others fixed, and sweeps until nothing changes.

Proposition 30.2.2 — Coordinate update

Fix all coordinates of $\mathbf{b}$ except b_j , and let $\mathbf{r}_{(j)} = \mathbf{y} - \sum_{k \neq j} \mathbf{x}_k b_k$ be the partial residual. The value of b_j that minimizes [Eq. 30.2.1](#) is

$$b_j = \frac{\text{sign}(\mathbf{x}_j^\top \mathbf{r}_{(j)}) (|\mathbf{x}_j^\top \mathbf{r}_{(j)}| - \lambda_1)_+}{\|\mathbf{x}_j\|^2 + \lambda_2}. \quad (30.2.4)$$

Proof. As a function of b_j alone, [Eq. 30.2.1](#) equals $\frac{1}{2}(\|\mathbf{x}_j\|^2 + \lambda_2)b_j^2 - b_j \mathbf{x}_j^\top \mathbf{r}_{(j)} + \lambda_1 |b_j|$ plus a constant. Divided by $\|\mathbf{x}_j\|^2 + \lambda_2$, this is a univariate lasso problem of the form in the proof of [Proposition 30.2.1\(c\)](#). Its solution is [Eq. 30.2.4](#). ■

Because the nonsmooth part is separable, every limit point of the iterates is a minimizer (Tseng, 2001; cited, not proved), so the iterates converge when the minimizer is unique, as for the elastic

net with $\lambda_2 > 0$. For a coupling penalty such as $\sum_j |b_j - b_{j-1}|$, coordinate descent can stall. Whole paths are computed on a decreasing grid of λ , each fit starting from the last (Friedman, Hastie, Höfling and Tibshirani, 2007; Friedman, Hastie and Tibshirani, 2010). The listing works through the Gram matrix, as the next proposition requires.

beta = np.r_[2.0, 2.0, 2.0, np.zeros(p - 3)]
y = X @ beta + 0.5 * rng.normal(size=n)
y -= y.mean()

lam1 = 0.8
b_lasso = elastic_net(X, y, lam1, 0.0)
b_naive = elastic_net(X, y, lam1, 1.0)
print("lasso          ", np.round(b_lasso[:5], 3))
print("naive EN       ", np.round(b_naive[:5], 3))
print("rescaled EN    ", np.round(2.0 * b_naive[:5], 3))    # (1 + lam2) * naive
```

30.2.3 Double shrinkage and the rescaled elastic net

By [Proposition 30.2.1\(c\)](#), under an orthonormal design the elastic net soft-thresholds and then divides by $1 + \lambda_2$: surviving coefficients are shrunk twice. Zou and Hastie (2005) proposed reporting $(1 + \lambda_2)\hat{\boldsymbol{\beta}}^{\text{en}}$ instead, which in general is a lasso with a modified Gram matrix.

Proposition 30.2.3 — The rescaled elastic net

Let the columns of $\mathbf{X}$ have unit length and let $\lambda_2 > 0$. Then $\tilde{\boldsymbol{\beta}} = (1 + \lambda_2)\hat{\boldsymbol{\beta}}^{\text{en}}$ is the unique minimizer of

$$\frac{1}{2} \mathbf{c}^\top \boldsymbol{\Sigma}_{\lambda_2} \mathbf{c} - \mathbf{y}^\top \mathbf{X} \mathbf{c} + \lambda_1 \|\mathbf{c}\|_1, \quad \boldsymbol{\Sigma}_{\lambda_2} = \frac{\mathbf{X}^\top \mathbf{X} + \lambda_2 \mathbf{I}}{1 + \lambda_2}. \quad (30.2.5)$$

Proof. Up to the constant $\frac{1}{2} \mathbf{y}^\top \mathbf{y}$, [Eq. 30.2.1](#) is $\frac{1}{2} \mathbf{b}^\top (\mathbf{X}^\top \mathbf{X} + \lambda_2 \mathbf{I}) \mathbf{b} - \mathbf{y}^\top \mathbf{X} \mathbf{b} + \lambda_1 \|\mathbf{b}\|_1$. Substitute $\mathbf{b} = \mathbf{c}/(1 + \lambda_2)$ and multiply by $1 + \lambda_2 > 0$. The result is [Eq. 30.2.5](#). The substitution is a bijection, so minimizers correspond, and the minimizer of [Eq. 30.2.1](#) is unique by [Proposition 30.2.1\(a\)](#). ■

The lasso has $\mathbf{X}^\top \mathbf{X}$ in place of $\boldsymbol{\Sigma}_{\lambda_2}$, whose correlations are divided by $1 + \lambda_2$: the rescaled elastic net is a lasso computed as if the regressors were less correlated. The rescaling is a heuristic; in [Example \(Three near-copies of one signal\)](#), where the true coefficients are 2, the naive estimates are about half that and the rescaled ones somewhat too large. The glmnet software (Friedman, Hastie and Tibshirani, 2010) fits the naive criterion.

30.2.4 Exercises

30.2.4.1 A. Check your understanding

Exercise A1.

Under an orthonormal design with $\mathbf{z} = \mathbf{X}^\top \mathbf{y} = (3, 0.5, -1.2)^\top$, $\lambda_1 = 1$ and $\lambda_2 = 1$, compute the lasso, ridge, naive elastic net and rescaled elastic net estimates.

Solution. Lasso ($\lambda = 1$): $(2, 0, -0.2)$. Ridge ($\lambda = 1$): $\mathbf{z}/2 = (1.5, 0.25, -0.6)$. Naive elastic net: the lasso divided by 2, $(1, 0, -0.1)$. Rescaled: multiply by $1 + \lambda_2 = 2$, which gives the lasso, $(2, 0, -0.2)$.

30.2.4.2 B. Practice

Exercise B1.

Show that if $\hat{\beta}_i \hat{\beta}_j < 0$, then $|\hat{\beta}_i + \hat{\beta}_j| \leq \|\mathbf{y}\| \sqrt{2(1 + \rho_{ij})}/\lambda_2$. Interpret this for two

regressors with correlation close to -1 .

Solution. With signs s and $-s$, Eq. 30.2.2 gives $\mathbf{x}_i^\top \mathbf{r} - \lambda_2 \hat{\beta}_i = \lambda_1 s$ and $\mathbf{x}_j^\top \mathbf{r} - \lambda_2 \hat{\beta}_j = -\lambda_1 s$. Adding, $\lambda_2(\hat{\beta}_i + \hat{\beta}_j) = (\mathbf{x}_i + \mathbf{x}_j)^\top \mathbf{r}$, and $\|\mathbf{x}_i + \mathbf{x}_j\|^2 = 2 + 2\rho_{ij}$. Bound $\|\mathbf{r}\| \leq \|\mathbf{y}\|$ as before. If $\rho_{ij} \approx -1$, then $\mathbf{x}_j \approx -\mathbf{x}_i$, and the bound forces $\hat{\beta}_j \approx -\hat{\beta}_i$. The two regressors are treated as one regressor with a sign flip.

Exercise B2.

Let $\mathbf{X} = [\mathbf{x}, \mathbf{x}]$ with $\|\mathbf{x}\| = 1$. Find the elastic net estimate in closed form and compare it with the ridge and lasso estimates.

30.2.4.3 C. Going deeper

Exercise C1.

Suppose $p > n$ and the lasso estimate $\hat{\boldsymbol{\beta}}$ is unique with active set A . Use the KKT conditions to show that the columns $\mathbf{X}_A$ are linearly independent, and deduce that $|A| \leq n$. (Hint: if $\mathbf{X}_A \mathbf{d} = \mathbf{0}$ with $\mathbf{d} \neq \mathbf{0}$, move along $\hat{\boldsymbol{\beta}} + \tau(\mathbf{d}, \mathbf{0})$ and use that the fit and the ℓ_1 norm are constant among minimizers.)

30.3 Group penalties

A factor with k levels enters a linear model as $k - 1$ indicator columns (Section 8.5, Definition 8.5.1), and a smooth effect as several basis columns. The question is whether *the factor* matters. The lasso on the indicator columns can keep some levels and drop others, and its answer depends on the coding. Yuan and Lin (2006) proposed a penalty that treats a block of columns as a unit.

30.3.1 The group lasso

Partition the columns of $\mathbf{X}$ into groups $g = 1, \dots, G$, with $\mathbf{X}_g$ the $n \times p_g$ block of group g and $\mathbf{b}_g$ the matching block of coefficients, so that $\mathbf{X}\mathbf{b} = \sum_g \mathbf{X}_g \mathbf{b}_g$.

Definition 30.3.1 — Group lasso

For weights $w_g > 0$, the **group lasso** criterion is

$$Q(\mathbf{b}) = \frac{1}{2} \left\| \mathbf{y} - \sum_{g=1}^G \mathbf{X}_g \mathbf{b}_g \right\|^2 + \lambda \sum_{g=1}^G w_g \|\mathbf{b}_g\|, \quad (30.3.1)$$

with Euclidean norms $\|\mathbf{b}_g\|$, not squared. The usual weights are $w_g = \sqrt{p_g}$. The columns of each group are usually centred and **orthonormalized within the group**

before fitting, so that $\mathbf{X}_g^\top \mathbf{X}_g = \mathbf{I}_{p_g}$. Different groups are not made orthogonal to each other.

With singleton groups and unit weights this is the lasso. In general it acts like the lasso *across* groups and like ridge *within* them: $\|\mathbf{b}_g\|$ has a corner only at $\mathbf{b}_g = \mathbf{0}$, so a group is either absent or present with, typically, all its coefficients nonzero.

Proposition 30.3.1 — Group lasso and block soft thresholding

- (a) A minimizer of Eq. 30.3.1 exists, and all minimizers have the same fitted vector.
 (b) (KKT conditions.) $\hat{\boldsymbol{\beta}}$ is a minimizer iff, with $\mathbf{r} = \mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}$, for every group g ,

$$\mathbf{X}_g^\top \mathbf{r} = \lambda w_g \frac{\hat{\boldsymbol{\beta}}_g}{\|\hat{\boldsymbol{\beta}}_g\|} \quad \text{if } \hat{\boldsymbol{\beta}}_g \neq \mathbf{0}, \quad \|\mathbf{X}_g^\top \mathbf{r}\| \leq \lambda w_g \quad \text{if } \hat{\boldsymbol{\beta}}_g = \mathbf{0}. \quad (30.3.2)$$

- (c) Let $\lambda > 0$. Then $\hat{\boldsymbol{\beta}} = \mathbf{0}$ iff $\lambda \geq \lambda_{\max} = \max_g \|\mathbf{X}_g^\top \mathbf{y}\| / w_g$.
 (d) (Orthonormal groups.) If $\mathbf{X}_g^\top \mathbf{X}_h = \mathbf{I}_{p_g}$ for $g = h$ and $\mathbf{0}$ for $g \neq h$, the unique minimizer is **block soft thresholding** of $\mathbf{z}_g = \mathbf{X}_g^\top \mathbf{y}$:

$$\hat{\boldsymbol{\beta}}_g = \left(1 - \frac{\lambda w_g}{\|\mathbf{z}_g\|}\right)_+ \mathbf{z}_g. \quad (30.3.3)$$

- (e) (Block update; compare Proposition 30.2.2.) If $\mathbf{X}_g^\top \mathbf{X}_g = \mathbf{I}_{p_g}$, then minimizing Eq. 30.3.1 over $\mathbf{b}_g$ with the other blocks fixed gives Eq. 30.3.3 with $\mathbf{z}_g$ replaced by $\mathbf{s}_g = \mathbf{X}_g^\top \mathbf{r}_{(g)}$, where $\mathbf{r}_{(g)} = \mathbf{y} - \sum_{h \neq g} \mathbf{X}_h \mathbf{b}_h$ is the partial residual.

Proof.

- (a) The penalty is convex and continuous. Since $\sum_g \|\mathbf{b}_g\| \geq \|\mathbf{b}\|$, it is at least $(\min_g w_g) \|\mathbf{b}\|$. Apply Theorem 30.1.1(a)(ii) and (b).
 (b) Combine Lemma 30.1.2 with Lemma 30.1.3, using the groups as the blocks.
 (c) At $\hat{\boldsymbol{\beta}} = \mathbf{0}$, the residual is $\mathbf{y}$, and Eq. 30.3.2 says that $\|\mathbf{X}_g^\top \mathbf{y}\| \leq \lambda w_g$ for every g . If this holds, $\mathbf{0}$ is a minimizer. Every minimizer then has fitted vector $\mathbf{0}$ and, by Theorem 30.1.1(b), penalty 0, so it is $\mathbf{0}$. If it fails, $\mathbf{0}$ is not a minimizer.
 (d) Under the assumption, $\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 = \|\mathbf{y}\|^2 - 2 \sum_g \mathbf{z}_g^\top \mathbf{b}_g + \sum_g \|\mathbf{b}_g\|^2$. So Eq. 30.3.1 separates into the problems $\min_{\mathbf{b}_g} \{\frac{1}{2} \|\mathbf{z}_g - \mathbf{b}_g\|^2 + \lambda w_g \|\mathbf{b}_g\|\}$, each strictly convex. Let $c = \lambda w_g$ and let $\mathbf{b}_g$ be given by Eq. 30.3.3. If $\|\mathbf{z}_g\| \leq c$, then $\mathbf{b}_g = \mathbf{0}$ and $\|\mathbf{z}_g - \mathbf{0}\| \leq c$. If $\|\mathbf{z}_g\| > c$, then $\mathbf{b}_g = (\|\mathbf{z}_g\| - c) \mathbf{z}_g / \|\mathbf{z}_g\| \neq \mathbf{0}$ and $\mathbf{z}_g - \mathbf{b}_g = c \mathbf{z}_g / \|\mathbf{z}_g\| = c \mathbf{b}_g / \|\mathbf{b}_g\|$. In both cases the one-group version of Eq. 30.3.2 holds.
 (e) As a function of $\mathbf{b}_g$, the criterion is $\frac{1}{2} \|\mathbf{r}_{(g)} - \mathbf{X}_g \mathbf{b}_g\|^2 + \lambda w_g \|\mathbf{b}_g\|$ plus a constant. With $\mathbf{X}_g^\top \mathbf{X}_g = \mathbf{I}$, this is the one-group problem of (d) with $\mathbf{z}_g$ replaced by $\mathbf{s}_g$.

■

Block soft thresholding keeps the direction of the least squares vector $\mathbf{z}_g$ and reduces its length by λw_g : the lasso rule applied to a length. The weights come from (c): for pure noise and orthonormal groups, $\|\mathbf{X}_g^\top \mathbf{y}\|^2 / \sigma^2 \sim \chi^2(p_g)$ has mean p_g , so without $\sqrt{p_g}$ large groups would enter merely for being large (Exercise (A1)). Block coordinate descent with update (e) has every limit point a minimizer because the penalty is separable across blocks (Tseng, 2001), so

it converges when the minimizer is unique; without orthonormality the block problem has no closed form ([Exercise \(C1\)](#)).

30.3.2 Factors as groups

Orthonormalizing within groups also makes the group lasso independent of how a factor is coded.

Proposition 30.3.2 — Invariance to the coding of a group

- (a) Let $\mathbf{U}_g$ be $p_g \times p_g$ orthogonal matrices, and replace every $\mathbf{X}_g$ by $\mathbf{X}_g \mathbf{U}_g$. Then $\hat{\boldsymbol{\beta}}$ minimizes the original criterion iff the vector with blocks $\mathbf{U}_g^\top \hat{\boldsymbol{\beta}}_g$ minimizes the new one. The fitted contributions $\mathbf{X}_g \hat{\boldsymbol{\beta}}_g$ are the same.
- (b) Suppose each group is orthonormalized within itself, so that $\mathbf{X}_g$ is an orthonormal basis of a subspace $\mathcal{V}_g$. Then the minimizers, expressed through the fitted contributions $\mathbf{X}_g \hat{\boldsymbol{\beta}}_g \in \mathcal{V}_g$, depend on the groups only through the subspaces $\mathcal{V}_g$. In particular, for a factor they do not depend on the choice of reference level or of contrasts.

Proof.

- (a) With $\mathbf{b}_g = \mathbf{U}_g \mathbf{c}_g$, we have $\mathbf{X}_g \mathbf{U}_g \mathbf{c}_g = \mathbf{X}_g \mathbf{b}_g$ and $\|\mathbf{c}_g\| = \|\mathbf{b}_g\|$. So the new criterion at $\mathbf{c}$ equals the old criterion at $\mathbf{b}$, and $\mathbf{b} \leftrightarrow \mathbf{c}$ is a bijection.
- (b) Two orthonormal bases $\mathbf{X}_g$ and $\mathbf{X}'_g$ of $\mathcal{V}_g$ satisfy $\mathbf{X}'_g = \mathbf{X}_g \mathbf{U}_g$ with $\mathbf{U}_g = \mathbf{X}_g^\top \mathbf{X}'_g$ orthogonal. Apply (a). For a factor with k levels, the centred indicator columns of any reference coding, and the centred columns of any other full-rank contrast coding, span the same $(k-1)$ -dimensional subspace: the vectors that are constant within levels and orthogonal to $\mathbf{1}$.

■

With orthonormalized groups $\|\mathbf{b}_g\| = \|\mathbf{X}_g \mathbf{b}_g\|$: the penalty is the total length of the groups' fitted contributions, a coding-free quantity. Simon and Tibshirani (2012) argue for this version.

Example. (Selecting factors)

The script simulates $n = 120$ observations of four factors A, B, C, D (with 4, 3, 5 and 3 levels) and three numeric regressors; the response depends on A , weakly on B , and on x_1 . The group lasso path starts at $\lambda_{\max} = 6.876$, and groups enter in the order x_1, A, B, D . At $\lambda = 2.0$ only A and x_1 are selected, with $\|\mathbf{X}_A \hat{\boldsymbol{\beta}}_A\| = 2.834$ and $\|\mathbf{X}_{x_1} \hat{\boldsymbol{\beta}}_{x_1}\| = 4.861$. Another reference level gives the same fitted contributions to machine precision. The lasso on the raw indicator columns does not: at $\lambda = 6.0$ its fit moves by 8.6 per cent of its length when the reference levels change. Along its path the columns of A enter at values of λ spread over a factor of 2.8, and it admits its first column of a null factor (C or D) at a residual sum of squares of 112.0, a worse fit than the 110.7 that the group lasso reaches with both null factors still excluded ([Figure 30.3.1](#)).

```
import numpy as np
```

Figure 30.3.1: (a) Group lasso path for [Example \(Selecting factors\)](#): the length of each group's fitted contribution $\|\mathbf{X}_g \hat{\mathbf{b}}_g\|$ against $\log_{10} \lambda$. Factors enter as wholes. (b) The lasso path for the same data, with each indicator column penalized separately, coloured by factor. The dashed curves are the numeric regressors.

    print(f"{name}: {Xg.shape[1]} columns, ||X_g b_g|| = {np.linalg.norm(Xg @ bg):.3f}")

```

The **sparse group lasso** adds an ℓ_1 term so that a selected group can have zero coefficients (Simon, Friedman, Hastie and Tibshirani, 2013).

30.3.3 Ordered coefficients: the fused lasso

When coefficients have a natural order (levels of an ordered factor, successive times), neighbours are expected to be similar. The **fused lasso** of Tibshirani, Saunders, Rosset, Zhu and Knight (2005) penalizes their differences:

$$Q(\mathbf{b}) = \frac{1}{2} \|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2 + \lambda_1 \sum_{j=1}^p |b_j| + \lambda_2 \sum_{j=2}^p |b_j - b_{j-1}|. \quad (30.3.4)$$

It produces exact zeros and exact ties $\hat{\beta}_j = \hat{\beta}_{j-1}$, so the coefficient sequence is piecewise constant. The penalty is convex but not separable, so coordinate descent can stall at a tie. For an ordered factor, fusion merges adjacent levels the data cannot distinguish (Gertheiss and Tutz, 2010). [Exercise \(B1\)](#) solves the smallest case.

30.3.4 Exercises

30.3.4.1 A. Check your understanding

Exercise A1.

Under orthonormal groups and $\mathbf{y} \sim N_n(\mathbf{0}, \sigma^2 \mathbf{I})$, show that $P(\hat{\boldsymbol{\beta}}_g \neq \mathbf{0}) = P\{\chi^2(p_g) > \lambda^2 w_g^2 / \sigma^2\}$. With $w_g = 1$, compare these probabilities for $p_g = 1$ and $p_g = 10$ when $\lambda = 2\sigma$. What do the weights $\sqrt{p_g}$ achieve, and what do they not achieve?

Solution. By [Eq. 30.3.3](#), $\hat{\beta}_g \neq \mathbf{0}$ iff $\|\mathbf{z}_g\| > \lambda w_g$. Here $\mathbf{z}_g = \mathbf{X}_g^\top \mathbf{y} \sim N_{p_g}(\mathbf{0}, \sigma^2 \mathbf{I})$, so $\|\mathbf{z}_g\|^2 / \sigma^2 \sim \chi^2(p_g)$. With $w_g = 1$ and $\lambda = 2\sigma$, the probabilities are $P\{\chi^2(1) > 4\} = 0.046$ and $P\{\chi^2(10) > 4\} = 0.947$, so a large null group almost always enters. With $w_g = \sqrt{p_g}$ the threshold is $4p_g$, four times the mean of $\chi^2(p_g)$. This removes the gross imbalance, but it does not equalize the probabilities: they are 0.046 and $P\{\chi^2(10) > 40\} = 1.7 \times 10^{-5}$. Equal null entry probabilities would need thresholds at a common quantile of $\chi^2(p_g)$.

30.3.4.2 B. Practice

Exercise B1.

Solve the fused lasso [Eq. 30.3.4](#) with $\mathbf{X} = \mathbf{I}_2$, $\lambda_1 = 0$ and $\lambda_2 = \lambda$. Show that $\hat{\beta}_1 = \hat{\beta}_2 = \frac{1}{2}(y_1 + y_2)$ if $|y_1 - y_2| \leq 2\lambda$. Otherwise, each estimate moves a distance λ from its observation towards the other.

Solution. The penalty is $\lambda|b_1 - b_2| = \lambda|\mathbf{a}^\top \mathbf{b}|$ with $\mathbf{a} = (1, -1)^\top$. Its subgradients are $\lambda s \mathbf{a}$ with $s \in \partial|\cdot|(b_1 - b_2)$. By [Lemma 30.1.2](#), $y_1 - b_1 = \lambda s$ and $y_2 - b_2 = -\lambda s$. If $b_1 = b_2 = b$, adding the equations gives $b = \frac{1}{2}(y_1 + y_2)$, and then $s = (y_1 - y_2)/(2\lambda)$ must lie in $[-1, 1]$. If $|y_1 - y_2| > 2\lambda$, then $b_1 \neq b_2$, $s = \text{sign}(b_1 - b_2)$, and $b_1 = y_1 - \lambda s$, $b_2 = y_2 + \lambda s$. This is consistent when $s = \text{sign}(y_1 - y_2)$, since then $b_1 - b_2 = y_1 - y_2 - 2\lambda s$ has the sign of s .

Exercise B2.

Under an orthonormal design, compare the group lasso (one group of size 3, $w = \sqrt{3}$) with the lasso on the same three columns, for $\mathbf{z} = (2, 0.3, -0.2)^\top$ and $\lambda = 1$. Which coefficients are zero in each? Show that, under an orthonormal design, the group lasso never sets a single coordinate of a selected group to zero unless the corresponding $z_j = 0$.

30.3.4.3 C. Going deeper

Exercise C1.

Drop the assumption $\mathbf{X}_g^\top \mathbf{X}_g = \mathbf{I}$. Show that a nonzero solution of the block problem $\min_{\mathbf{b}} \frac{1}{2} \|\mathbf{r} - \mathbf{X}_g \mathbf{b}\|^2 + c \|\mathbf{b}\|$ is $\mathbf{b} = (\mathbf{X}_g^\top \mathbf{X}_g + (c/t)\mathbf{I})^{-1} \mathbf{X}_g^\top \mathbf{r}$, where $t = \|\mathbf{b}\|$ is the root of a one-dimensional equation. Show that this equation has a unique root when $\|\mathbf{X}_g^\top \mathbf{r}\| > c$, so the block update is a ridge regression ([Theorem 27.2.2](#)) with a data-dependent parameter.

30.4 Componentwise boosting

Boosting is an algorithm, not a criterion: it improves the fit by many small steps, each changing the single coefficient that helps most, and the number of steps plays the part of a penalty. Begun as a way to combine classifiers (Freund and Schapire, 1997) and recast as gradient descent on a loss (Friedman, Hastie and Tibshirani, 2000; Friedman, 2001), with squared error and single regressors it is the L_2 boosting of Bühlmann and Yu (2003).

30.4.1 The algorithm

Let $\mathbf{y}$ and the columns of $\mathbf{X}$ be centred, and let no column be zero. For a vector $\mathbf{r}$, the least squares fit of $\mathbf{r}$ on the single column $\mathbf{x}_j$ has coefficient $\mathbf{x}_j^\top \mathbf{r} / \|\mathbf{x}_j\|^2$. It reduces the sum of squares by $(\mathbf{x}_j^\top \mathbf{r})^2 / \|\mathbf{x}_j\|^2$, by the one-column case of [Theorem 6.4.1](#).

Definition 30.4.1 — Componentwise L_2 boosting

Fix a **step size** $\nu \in (0, 2)$. Start from $\mathbf{b}^{(0)} = \mathbf{0}$ and $\mathbf{r}^{(0)} = \mathbf{y}$. For $m = 0, 1, 2, \dots$:

1. choose $j_m = \arg \max_j (\mathbf{x}_j^\top \mathbf{r}^{(m)})^2 / \|\mathbf{x}_j\|^2$, the column whose simple regression fits the current residual best;
2. set $b_{j_m}^{(m+1)} = b_{j_m}^{(m)} + \nu \mathbf{x}_{j_m}^\top \mathbf{r}^{(m)} / \|\mathbf{x}_{j_m}\|^2$, leave the other coordinates unchanged, and put $\mathbf{r}^{(m+1)} = \mathbf{y} - \mathbf{X}\mathbf{b}^{(m+1)}$.

The estimate after m steps is $\mathbf{b}^{(m)}$, and the **stopping iteration** m is the tuning parameter.

With unit-length columns, step 1 picks the column most correlated with the residual. The residual is the negative gradient of $\frac{1}{2}\|\mathbf{y} - \mathbf{f}\|^2$ in the fitted vector $\mathbf{f}$, so each step fits the negative gradient by the best single column and moves a fraction ν of the way. The theory below allows $\nu < 2$; with $\nu > 1$ a step overshoots the simple regression fit, and in practice $\nu \leq 1$, often $\nu = 0.1$. With $\nu = 1$ this is *matching pursuit* (Mallat and Zhang, 1993), which is not forward selection, since earlier coefficients are never refitted.

30.4.2 Convergence to least squares

Boosting converges to the least squares fit at a geometric rate, slow when the design is badly conditioned.

Theorem 30.4.1 — Convergence of componentwise L_2 boosting

Let $\nu \in (0, 2)$, let $Q(\mathbf{b}) = \frac{1}{2}\|\mathbf{y} - \mathbf{X}\mathbf{b}\|^2$ with minimum Q^* , let $s > 0$ be the smallest nonzero singular value of $\mathbf{X}$, and put

$$\kappa = \frac{\nu(2-\nu)s^2}{p \max_j \|\mathbf{x}_j\|^2}.$$

Then $0 < \kappa \leq 1$, and:

- (a) each step lowers the residual sum of squares by exactly

$$Q(\mathbf{b}^{(m)}) - Q(\mathbf{b}^{(m+1)}) = \nu \left(1 - \frac{\nu}{2}\right) \max_j \frac{(\mathbf{x}_j^\top \mathbf{r}^{(m)})^2}{\|\mathbf{x}_j\|^2}; \quad (30.4.1)$$

- (b) $Q(\mathbf{b}^{(m)}) - Q^* \leq (1 - \kappa)^m (Q(\mathbf{0}) - Q^*)$. Hence the fitted values converge geometrically to the least squares fit: $\|\mathbf{X}\mathbf{b}^{(m)} - \mathbf{M}\mathbf{y}\|^2 = 2\{Q(\mathbf{b}^{(m)}) - Q^*\} \rightarrow 0$;

- (c) the coefficients $\mathbf{b}^{(m)}$ converge to a least squares estimate. If $\mathbf{X}$ has full column rank, the limit is $\hat{\boldsymbol{\beta}}$.

Proof.

- (a) Write $\mathbf{r} = \mathbf{r}^{(m)}$, $j = j_m$ and $c = \mathbf{x}_j^\top \mathbf{r} / \|\mathbf{x}_j\|^2$. Then $\mathbf{r}^{(m+1)} = \mathbf{r} - \nu c \mathbf{x}_j$, and

$$\begin{aligned} \|\mathbf{r} - \nu c \mathbf{x}_j\|^2 &= \|\mathbf{r}\|^2 - 2\nu c \mathbf{x}_j^\top \mathbf{r} + \nu^2 c^2 \|\mathbf{x}_j\|^2 \\ &= \|\mathbf{r}\|^2 - (2\nu - \nu^2) \frac{(\mathbf{x}_j^\top \mathbf{r})^2}{\|\mathbf{x}_j\|^2}. \end{aligned}$$

Halving gives [Eq. 30.4.1](#), since j maximizes the ratio.

- (b) Let $\mathbf{u}_m = \mathbf{M}\mathbf{r}^{(m)} = \mathbf{M}\mathbf{y} - \mathbf{X}\mathbf{b}^{(m)}$, which lies in $\mathcal{C}(\mathbf{X})$. The residual splits orthogonally as $\mathbf{r}^{(m)} = (\mathbf{I} - \mathbf{M})\mathbf{y} + \mathbf{u}_m$, so $Q(\mathbf{b}^{(m)}) - Q^* = \frac{1}{2}\|\mathbf{u}_m\|^2$ and $\mathbf{X}^\top \mathbf{r}^{(m)} = \mathbf{X}^\top \mathbf{u}_m$. By the singular value decomposition ([Theorem 1.8.1](#)), $\|\mathbf{X}^\top \mathbf{u}\| \geq s\|\mathbf{u}\|$ for every $\mathbf{u} \in \mathcal{C}(\mathbf{X})$. A maximum is at least an average, so

$$\begin{aligned} \max_j \frac{(\mathbf{x}_j^\top \mathbf{r}^{(m)})^2}{\|\mathbf{x}_j\|^2} &\geq \frac{\sum_j (\mathbf{x}_j^\top \mathbf{u}_m)^2}{p \max_j \|\mathbf{x}_j\|^2} \\ &= \frac{\|\mathbf{X}^\top \mathbf{u}_m\|^2}{p \max_j \|\mathbf{x}_j\|^2} \geq \frac{s^2 \|\mathbf{u}_m\|^2}{p \max_j \|\mathbf{x}_j\|^2}. \end{aligned}$$

With (a), $Q(\mathbf{b}^{(m)}) - Q(\mathbf{b}^{(m+1)}) \geq \kappa\{Q(\mathbf{b}^{(m)}) - Q^*\}$, that is, $Q(\mathbf{b}^{(m+1)}) - Q^* \leq (1 - \kappa)\{Q(\mathbf{b}^{(m)}) - Q^*\}$. Iterating gives (b). Finally $\kappa > 0$, and $\kappa \leq 1$ because $\nu(2 - \nu) \leq 1$ and $s^2 \leq \text{tr}(\mathbf{X}^\top \mathbf{X}) = \sum_j \|\mathbf{x}_j\|^2 \leq p \max_j \|\mathbf{x}_j\|^2$.

- (c) The m th step changes one coordinate, by $\nu|\mathbf{x}_{j_m}^\top \mathbf{u}_m|/\|\mathbf{x}_{j_m}\|^2 \leq \nu\|\mathbf{x}_{j_m}\|\|\mathbf{u}_m\|/\|\mathbf{x}_{j_m}\|^2 \leq \nu\|\mathbf{u}_m\|/\min_j \|\mathbf{x}_j\|$, using Cauchy–Schwarz. By (b), $\|\mathbf{u}_m\| \leq (1 - \kappa)^{m/2}\|\mathbf{u}_0\|$, which is summable. So $\sum_m \|\mathbf{b}^{(m+1)} - \mathbf{b}^{(m)}\| < \infty$, the sequence is Cauchy, and it converges to some $\mathbf{b}^\infty$. By continuity, $\mathbf{X}\mathbf{b}^\infty = \lim \mathbf{X}\mathbf{b}^{(m)} = \mathbf{M}\mathbf{y}$, so $\mathbf{b}^\infty$ is a least squares estimate ([Theorem 6.4.1](#)). With full column rank there is only one. ■

The bound is crude, but it shows what controls the speed: the step size and the conditioning of $\mathbf{X}$.

Remark (When $p > n$). If $\text{rank } \mathbf{X} = n$, as is typical when $p > n$, boosting run long enough *interpolates* the data, so stopping early is a necessity. Its limit depends on the order in which columns were chosen and is in general not the least squares estimate of smallest norm ([Proposition 6.10.1](#)), which full gradient descent from zero does reach ([Exercise \(B2\)](#); this is the ridgeless estimator of [Theorem 28.1.1](#)).

30.4.3 Early stopping as shrinkage

For a base learner linear in the data, the effect of stopping early is exact. Let an $n \times n$ matrix $\mathbf{S}$ map a residual vector to its fitted values; boosting updates $\mathbf{f}^{(m+1)} = \mathbf{f}^{(m)} + \nu \mathbf{S}(\mathbf{y} - \mathbf{f}^{(m)})$ from $\mathbf{f}^{(0)} = \mathbf{0}$.

Proposition 30.4.2 — The boosting operator

- (a) $\mathbf{f}^{(m)} = \mathbf{B}_m \mathbf{y}$ with $\mathbf{B}_m = \mathbf{I} - (\mathbf{I} - \nu \mathbf{S})^m$.
 (b) Let $\mathbf{S}$ be symmetric with eigenvalues $d_k \geq 0$ and orthonormal eigenvectors $\mathbf{u}_k$, and let $\nu d_k \leq 1$ for every k . Then

$$\mathbf{B}_m = \sum_k \{1 - (1 - \nu d_k)^m\} \mathbf{u}_k \mathbf{u}_k^\top.$$

Each factor $1 - (1 - \nu d_k)^m$ lies in $[0, 1]$, is nondecreasing in m , and tends to 1 when $d_k > 0$. The trace $\text{tr } \mathbf{B}_m$ increases with m towards $\text{rank } \mathbf{S}$.

- (c) (*Least squares learner.*) If $\mathbf{S} = \mathbf{M}$, then $\mathbf{B}_m = \{1 - (1 - \nu)^m\} \mathbf{M}$. Early stopping shrinks the least squares fit by a single factor.
 (d) (*Gradient descent.*) The iteration $\mathbf{b}^{(m+1)} = \mathbf{b}^{(m)} + \nu \mathbf{X}^\top (\mathbf{y} - \mathbf{X} \mathbf{b}^{(m)})$ from $\mathbf{b}^{(0)} = \mathbf{0}$ is the case $\mathbf{S} = \mathbf{X} \mathbf{X}^\top$. If $\mathbf{X}$ has singular values σ_k and $\nu \sigma_k^2 \leq 1$, its fitted values shrink the k th singular component of the least squares fit by $1 - (1 - \nu \sigma_k^2)^m$. Ridge regression shrinks the same component by $\sigma_k^2 / (\sigma_k^2 + \lambda)$.

Proof.

- (a) $\mathbf{y} - \mathbf{f}^{(m+1)} = (\mathbf{I} - \nu \mathbf{S})(\mathbf{y} - \mathbf{f}^{(m)})$, so $\mathbf{y} - \mathbf{f}^{(m)} = (\mathbf{I} - \nu \mathbf{S})^m \mathbf{y}$. (b) $(\mathbf{I} - \nu \mathbf{S})^m = \sum_k (1 - \nu d_k)^m \mathbf{u}_k \mathbf{u}_k^\top$ by the spectral theorem (Theorem 1.7.2), and $0 \leq 1 - \nu d_k \leq 1$.
 (c) $\mathbf{M}$ has eigenvalues 0 and 1, and it is idempotent.
 (b) $\mathbf{X} \mathbf{b}^{(m+1)} = \mathbf{X} \mathbf{b}^{(m)} + \nu \mathbf{X} \mathbf{X}^\top (\mathbf{y} - \mathbf{X} \mathbf{b}^{(m)})$. The eigenvalues of $\mathbf{X} \mathbf{X}^\top$ are the σ_k^2 and zeros, and the eigenvectors for the σ_k^2 are the left singular vectors (Theorem 1.8.1). For ridge, see Theorem 27.2.2.

■

For small σ_k^2 , gradient descent keeps the fraction $1 - (1 - \nu \sigma_k^2)^m \approx m \nu \sigma_k^2$ of a component and ridge keeps $\approx \sigma_k^2 / \lambda$; for large σ_k^2 both keep nearly everything. So m steps behave like ridge with $\lambda \approx 1/(m \nu)$. Part (c) is the proportional shrinkage of Proposition 7.6.3(c).

Degrees of freedom. For a linear smoother the complexity is $\text{tr } \mathbf{B}_m$, which equals the covariance penalty $\sigma^{-2} \sum_i \text{Cov}(\hat{y}_i, y_i)$ (Theorem 29.1.1). Componentwise boosting is not linear, since the chosen columns depend on $\mathbf{y}$, but for a fixed sequence $j_0, \dots, j_{m-1}$ its fitted values are $\mathbf{B}_m \mathbf{y}$ with

$$\mathbf{B}_m = \mathbf{I} - (\mathbf{I} - \nu \mathbf{H}_{j_{m-1}}) \cdots (\mathbf{I} - \nu \mathbf{H}_{j_0}), \quad \mathbf{H}_j = \frac{\mathbf{x}_j \mathbf{x}_j^\top}{\|\mathbf{x}_j\|^2}, \quad (30.4.2)$$

by Proposition 30.4.2(a) applied step by step. Bühlmann (2006) used $\text{tr } \mathbf{B}_m$ along the observed sequence as the degrees of freedom in a corrected Akaike criterion for choosing m . That treats the selection as fixed in advance, and the next example shows how much it can understate.

Example. (Boosting a sparse regression)

The script draws $n = 60$ observations of $p = 30$ normal regressors with correlations

Figure 30.4.1: Componentwise boosting for [Example \(Boosting a sparse regression\)](#). (a) Coefficient paths with $\nu = 0.1$ (true nonzero coefficients in blue); the dashed line is the cross-validated stopping iteration. (b) Exact risk along the path for $\nu = 0.1$ and $\nu = 1$, with the least squares risk dashed. Both horizontal axes are linear up to 10 and logarithmic beyond. (c) Two degrees of freedom: the average trace of the boosting operator [Eq. 30.4.2](#), and the covariance degrees of freedom estimated from 2000 simulated responses.

$0.5^{|j-k|}$, five nonzero coefficients and $\sigma = 1.5$, and boosts on the standardized regressors. The expected squared error on a new case (the *risk*) is computed exactly from the design law; its floor is $\sigma^2 = 2.25$.

Convergence. For $\nu = 0.1$, $\kappa = 3.18 \times 10^{-4}$, and $\|\mathbf{b}^{(m)} - \hat{\boldsymbol{\beta}}\|/\|\hat{\boldsymbol{\beta}}\|$ is 0.497, 0.161 and 2.7×10^{-8} after 100, 1000 and 50000 steps; the script checks [Eq. 30.4.1](#) and the bound (b) at every step.

Early stopping. Least squares has risk 4.046. With $\nu = 0.1$ the risk is smallest, 2.981, after 108 steps (with 14 nonzero coefficients), and within 5 per cent of that from $m = 72$ to $m = 305$; five-fold cross-validation chooses $m = 229$, with risk 3.047. With $\nu = 1$ the best risk, 2.893, occurs at $m = 4$ and only there is the risk within 5 per cent of it: a needle that a data-based stopping rule is unlikely to hit ([Figure 30.4.1](#)).

Degrees of freedom. Over 2000 responses with the same design and mean, the covariance degrees of freedom after $m = 20$ steps are 3.1 against an average trace of 1.5, and after $m = 120$ steps 12.6 against 6.2. The trace does not see the adaptation of the chosen columns to the noise.

```
import numpy as np

def l2_boost(X, y, nu, steps):
    """Componentwise L2 boosting from b = 0; returns the coefficient path (steps +
    1) x p."""
    n, p = X.shape
    norms2 = np.sum(X ** 2, axis=0)
    b = np.zeros(p)
    r = y.astype(float).copy()
    path = [b.copy()]
    for _ in range(steps):
        corr = X.T @ r
        j = np.argmax(corr ** 2 / norms2)           # largest drop in the
        residual sum of squares
        step = nu * corr[j] / norms2[j]
        b[j] += step
```

```

print(f"m = {m_df}: mean trace {trace_df:.1f}, covariance df {cov_df:.1f}")

```

The gap is the optimism of selection ([Proposition 29.5.1](#)). For the lasso, by contrast, the covariance degrees of freedom equal the expected number of nonzero coefficients (Zou, Hastie and Tibshirani, 2007; we do not reproduce the proof): shrinkage offsets the cost of selection (compare [Exercise \(C1\)](#)). In practice m is chosen by cross-validation ([Chapter 29](#)), which needs no degrees of freedom.

30.4.4 Exercises

30.4.4.1 A. Check your understanding

Exercise A1.

Let $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, $\mathbf{z} = \mathbf{X}^\top \mathbf{y} = (3, -1, 0.5)^\top$ and $\nu = 0.1$. Carry out the first three boosting steps by hand. Show that under an orthonormal design the current residual correlations are $\mathbf{z} - \mathbf{b}^{(m)}$, so boosting always moves the coordinate whose remaining correlation is largest in absolute value, and removes one tenth of that correlation.

Solution. $\mathbf{X}^\top \mathbf{r}^{(m)} = \mathbf{X}^\top \mathbf{y} - \mathbf{X}^\top \mathbf{X} \mathbf{b}^{(m)} = \mathbf{z} - \mathbf{b}^{(m)}$, with unit column lengths. Step 1: coordinate 1, $b_1 = 0.3$, residual correlation 2.7. Step 2: coordinate 1 again, $b_1 = 0.3 + 0.27 = 0.57$, correlation 2.43. Step 3: coordinate 1, $b_1 = 0.57 + 0.243 = 0.813$. Coordinate 1 keeps being chosen until its remaining correlation $3(0.9)^m$ falls below 1, which first happens at $m = 11$. This is the approach to soft thresholding that [Section 30.5](#) makes precise.

30.4.4.2 B. Practice

Exercise B1.

Use [Eq. 30.4.1](#) to show that $\sum_{m \geq 0} \max_j (\mathbf{x}_j^\top \mathbf{r}^{(m)})^2 / \|\mathbf{x}_j\|^2 \leq \|\mathbf{y}\|^2 / \{\nu(2 - \nu)\}$. Deduce, without the singular value argument, that $\mathbf{X}^\top \mathbf{r}^{(m)} \rightarrow \mathbf{0}$ for every $\nu \in (0, 2)$.

Solution. Summing [Eq. 30.4.1](#) over $m = 0, \dots, M-1$ gives $\nu(1 - \nu/2) \sum_{m < M} \max_j (\dots) = Q(\mathbf{0}) - Q(\mathbf{b}^{(M)}) \leq \frac{1}{2} \|\mathbf{y}\|^2$. Multiply by $2/\{\nu(2 - \nu)\}$ and let $M \rightarrow \infty$. The terms of a convergent series tend to zero. So $\max_j |\mathbf{x}_j^\top \mathbf{r}^{(m)}| / \|\mathbf{x}_j\| \rightarrow 0$, and hence every coordinate of $\mathbf{X}^\top \mathbf{r}^{(m)}$ does.

Exercise B2.

For the gradient descent iteration of [Proposition 30.4.2\(d\)](#) with $0 < \nu < 2/\sigma_1^2$, show that every $\mathbf{b}^{(m)}$ lies in $\mathcal{C}(\mathbf{X}^\top)$, and that $\mathbf{b}^{(m)} \rightarrow \mathbf{X}^+\mathbf{y}$, the minimum-norm least squares estimate ([Proposition 6.10.1](#)). Why does this argument fail for componentwise boosting?

Solution. Each increment $\nu\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\mathbf{b}^{(m)})$ lies in $\mathcal{C}(\mathbf{X}^\top)$, and $\mathbf{b}^{(0)} = \mathbf{0}$. In the singular value basis, $\mathbf{b}^{(m)} = \sum_k \{1 - (1 - \nu\sigma_k^2)^m\} \sigma_k^{-1}(\mathbf{u}_k^\top \mathbf{y}) \mathbf{v}_k$, because the iteration acts on each component separately. With $|1 - \nu\sigma_k^2| < 1$ this converges to $\sum_k \sigma_k^{-1}(\mathbf{u}_k^\top \mathbf{y}) \mathbf{v}_k = \mathbf{X}^+\mathbf{y}$. Componentwise boosting adds multiples of coordinate vectors $\mathbf{e}_j$, which need not lie in $\mathcal{C}(\mathbf{X}^\top)$ when $\text{rank } \mathbf{X} < p$. So its limit can have a component in $\mathcal{N}(\mathbf{X})$.

30.4.4.3 C. Going deeper**Exercise C1.**

Under an orthonormal design with $\mathbf{y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{I})$, the lasso fit with parameter λ has covariance degrees of freedom $E \#\{j : |z_j| > \lambda\}$ (by Stein's lemma, [Lemma 27.5.1](#), applied coordinatewise). Show that hard thresholding at the same λ has covariance degrees of freedom $E \#\{j : |z_j| > \lambda\} + \sum_j (\lambda/\sigma) \{\phi((\lambda - \beta_j)/\sigma) + \phi((\lambda + \beta_j)/\sigma)\}$, where ϕ is the standard normal density. The extra term is the price of selecting without shrinking.

30.5 Boosting as regularization

The boosting path of [Figure 30.4.1\(a\)](#) looks like a lasso path, and not by coincidence. A close relative of boosting with tiny steps traces the lasso path exactly under a condition on the design (Efron, Hastie, Johnstone and Tibshirani, 2004, under their positive cone condition; Hastie, Taylor, Tibshirani and Walther, 2007, in terms of monotone paths). This section proves the simplest case, sketches the general one, compares the procedures, and ends with boosting beyond linear least squares. Throughout, $\mathbf{y}$ and the columns of $\mathbf{X}$ are centred and the columns have unit length.

30.5.1 Forward stagewise regression

Definition 30.5.1 — Incremental forward stagewise regression

Fix $\varepsilon > 0$. Start from $\mathbf{b}^{(0)} = \mathbf{0}$. At step k , with residual $\mathbf{r}^{(k)} = \mathbf{y} - \mathbf{X}\mathbf{b}^{(k)}$, choose $j = \arg \max_j |\mathbf{x}_j^\top \mathbf{r}^{(k)}|$ and set $b_j^{(k+1)} = b_j^{(k)} + \varepsilon \text{sign}(\mathbf{x}_j^\top \mathbf{r}^{(k)})$, leaving the other coordinates unchanged. Write FS_ε for this procedure, and FS_0 for the limit of its paths as $\varepsilon \rightarrow 0$, when the limit exists.

Stagewise and componentwise boosting choose the same coordinate; boosting moves it by ν times its correlation, stagewise by a fixed ε , so the ℓ_1 length of its path after k steps is exactly $k\varepsilon$.

30.5.2 The orthonormal case

Under an orthonormal design the lasso estimate at λ is $\text{sign}(z_j)(|z_j| - \lambda)_+$ with $\mathbf{z} = \mathbf{X}^\top \mathbf{y}$ (Theorem 27.4.2), and stagewise follows it to within one step.

Proposition 30.5.1 — Stagewise under an orthonormal design

Let $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, $\mathbf{z} = \mathbf{X}^\top \mathbf{y}$, and let $\tau_k = \max_j |z_j - b_j^{(k)}|$ be the largest absolute residual correlation after k steps of FS_ε . Let K be the last step before τ first falls below ε , so that $\tau_0, \dots, \tau_K \geq \varepsilon$. For every $k \leq K$:

- (a) $\tau_{k+1} \leq \tau_k$ (for $k < K$);
- (b) every coordinate satisfies $|b_j^{(k)} - \text{sign}(z_j)(|z_j| - \tau_k)_+| \leq \varepsilon$, that is, FS_ε is within ε of the lasso estimate at $\lambda = \tau_k$.

Consequently, the part of the stagewise path with $\tau_k \geq \varepsilon$ and the lasso path are within 3ε of each other, in the sense that every point of either is within 3ε of some point of the other in every coordinate. As $\varepsilon \rightarrow 0$ the stagewise path converges to the lasso path.

Proof. With $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, the residual correlations are $\mathbf{X}^\top (\mathbf{y} - \mathbf{X}\mathbf{b}) = \mathbf{z} - \mathbf{b}$. The coordinate chosen at step k has $|z_j - b_j^{(k)}| = \tau_k \geq \varepsilon$. Moving b_j by ε towards z_j reduces this distance to $\tau_k - \varepsilon$ without overshooting, and the other coordinates are unchanged. This proves (a). It also shows that every move of b_j made while $\tau \geq \varepsilon$ goes towards z_j without passing it. Starting from 0, the coordinate therefore stays on the segment from 0 to z_j , and $b_j^{(k)} = \text{sign}(z_j)(|z_j| - d_j)$ with $d_j = |z_j - b_j^{(k)}| \in [0, |z_j|]$.

Fix j and k . If j has not been chosen before step k , then $b_j^{(k)} = 0$ and $|z_j| = d_j \leq \tau_k$, so the lasso coordinate at τ_k is also 0. Otherwise, let $l < k$ be the last step at which j was chosen. Then $d_j = \tau_l - \varepsilon \geq \tau_k - \varepsilon$ by (a), and $d_j \leq \tau_k$ because τ_k is a maximum. If $|z_j| \geq \tau_k$, the difference from the lasso coordinate is $(|z_j| - d_j) - (|z_j| - \tau_k) = \tau_k - d_j \in [0, \varepsilon]$. If $|z_j| < \tau_k$, the lasso coordinate is 0 and $|b_j^{(k)}| = |z_j| - d_j \leq \tau_k - d_j \leq \varepsilon$. This proves (b).

For the last statement, (b) puts every stagewise point with $\tau_k \geq \varepsilon$ within ε of the lasso path. Conversely, with K as in the statement, each step lowers τ by at most ε , because $\tau_{k+1} \geq d_j = \tau_k - \varepsilon$ for the chosen j . Hence $\tau_K < 2\varepsilon$, and every $\lambda \in [\tau_K, \tau_0]$ is within ε of some τ_k with $k \leq K$. Soft thresholding is 1-Lipschitz in λ , so for such λ the lasso estimate is within 2ε of $\mathbf{b}^{(k)}$. For $\lambda \geq \tau_0 = \max_j |z_j|$ it is $\mathbf{0} = \mathbf{b}^{(0)}$. For $\lambda < \tau_K$ it is within $\tau_K - \lambda < 2\varepsilon$ of the lasso estimate at τ_K , hence within 3ε of $\mathbf{b}^{(K)}$. ■

For componentwise boosting the same argument gives tolerance $\nu\tau_k$ (Exercise (B1)).

30.5.3 The general relation

In general the lasso path is piecewise linear with explicit directions. Part (a) below restates the segment formula of Proposition 27.4.3 in the notation of this chapter; what is new is the reading in terms of tied correlations.

Proposition 30.5.2 — Stagewise and the lasso path

- (a) Suppose that for λ in an interval the lasso estimate is unique and has a fixed active set A and fixed signs $\mathbf{s}_A$, and $\mathbf{X}_A$ has full column rank. Then on that interval

$$\hat{\boldsymbol{\beta}}_A(\lambda) = (\mathbf{X}_A^\top \mathbf{X}_A)^{-1} (\mathbf{X}_A^\top \mathbf{y} - \lambda \mathbf{s}_A), \quad (30.5.1)$$

so as λ decreases the active coefficients move along the direction $\mathbf{d}_A = (\mathbf{X}_A^\top \mathbf{X}_A)^{-1} \mathbf{s}_A$, and all active variables keep the common absolute correlation λ with the residual.

- (b) (*Sketch; Efron, Hastie, Johnstone and Tibshirani, 2004, who prove it under their positive cone condition on the design; Hastie et al., 2007, for monotone paths.*) If along the whole lasso path every direction $\mathbf{d}_A$ has the signs $\mathbf{s}_A$ coordinatewise, that is, if every lasso coefficient is monotone in λ , then FS_0 exists and coincides with the lasso path.
- (c) (*Sketch; Hastie, Taylor, Tibshirani and Walther, 2007.*) In general FS_0 is the path of the *monotone lasso*. Write $\mathbf{b} = \mathbf{b}^+ - \mathbf{b}^-$ with $\mathbf{b}^\pm \geq \mathbf{0}$. Along the path, every coordinate of $\mathbf{b}^+$ and of $\mathbf{b}^-$ is nondecreasing, and the path lowers the residual sum of squares as fast as possible per unit of ℓ_1 arc length, subject to that constraint.

Proof.

- (a) The formula Eq. 30.5.1 is Proposition 27.4.3. By Lemma 30.1.2 and Lemma 30.1.3, the active coordinates satisfy $\mathbf{X}_A^\top (\mathbf{y} - \mathbf{X}_A \hat{\boldsymbol{\beta}}_A) = \lambda \mathbf{s}_A$, which says that the active correlations are $\lambda \mathbf{s}_A$.

Sketch of (b) and (c). Complete proofs need a careful limiting argument; see the papers cited. Choosing a variable of maximal absolute correlation lowers its correlation relative to the others, so in the limit the active correlations are tied, as for the lasso. The net movement is a direction $\mathbf{d}$ with $d_j s_j \geq 0$ on A , and the only direction keeping the correlations tied is $\mathbf{d}_A$. If $\mathbf{d}_A$ has the signs $\mathbf{s}_A$, stagewise follows it; that is (b). Otherwise the lasso shrinks a coefficient against the sign of its correlation, which stagewise cannot do. Stagewise instead holds it and moves along a nonnegative least squares fit of the residual on the sign-adjusted active columns. Efron et al. (2004) build this into a modified least angle regression and prove it gives FS_0 ; Hastie et al. (2007) identify the path with the monotone lasso. ■

The lasso at ℓ_1 norm t minimizes the residual sum of squares subject to $\|\mathbf{b}\|_1 \leq t$ (the constrained form of Definition 27.4.1); stagewise budgets the ℓ_1 arc length and never undoes a move. For monotone paths the two budgets coincide (Exercise (A2)).

Example. (Stagewise and lasso paths)

Orthonormal design. With 5 orthonormal columns and $\varepsilon = 0.01$, the largest distance from the lasso estimate at $\lambda = \tau_k$ over all steps is 0.0092.

A non-monotone lasso path. For $n = 40$ observations of $p = 6$ regressors sharing a common factor (correlations near 0.64), the lasso coefficient of regressor 6 grows to 0.308 at $\|\mathbf{b}\|_1 = 4.12$ and then shrinks back. FS_ε with $\varepsilon = 0.002$ agrees with the lasso to

Figure 30.5.1: (a) The lasso path and (b) the forward stagewise path ($\varepsilon = 0.002$) for the correlated design of [Example \(Stagewise and lasso paths\)](#), against $\|\mathbf{b}\|_1$. The thick purple curve is the coefficient that the lasso shrinks back after the dashed line; stagewise holds it. (c) Smallest risk along the path for 50 simulated data sets: forward stagewise and boosting ($\nu = 0.05$) against the lasso.

within 0.039 until then, and afterwards holds the coefficient: halfway to the least squares norm 7.53, the two differ by 0.165 there ([Figure 30.5.1](#)). At every ℓ_1 norm checked, the lasso has the smaller residual sum of squares, as it must; the excess of stagewise is at most 0.011.

Prediction. Over 50 data sets from the design of [Example \(Boosting a sparse regression\)](#), the average smallest risk along the path is 2.857 for the lasso, 2.857 for stagewise and 2.856 for boosting with $\nu = 0.05$, against 4.607 for least squares. Data set by data set the points lie close to the diagonal (panel (c)): the best risks of stagewise and boosting never differ from the lasso's by more than 6.6 per cent.

print("stagewise at the end: ", np.round(fs_path[-1], 3))

```

Near least squares, stagewise dithers, stepping back and forth by ε : its arc length grows while its ℓ_1 norm does not.

30.5.4 Beyond linear least squares

For a differentiable loss $\sum_i L(y_i, f_i)$, boosting fits the negative gradient $-\partial L(y_i, f_i)/\partial f_i$ in place of the residual (Friedman, 2001): absolute error gives residual signs, the Huber loss clipped residuals, and the exponential loss e^{-yf} , $y = \pm 1$, recovers AdaBoost (Friedman, Hastie and Tibshirani, 2000). Small regression trees as base learners give gradient tree boosting; penalized splines in one regressor at a time give componentwise boosting of an additive model (Bühlmann and Yu, 2003; Bühlmann and Hothorn, 2007), a topic for Chapters 43 and 44 (Definition 43.3.1, Definition 44.1.1).

Zhang and Yu (2005) prove consistency of early-stopped boosting for general convex losses over rich base classes; Bühlmann (2006) proves it for componentwise L_2 boosting with p growing almost exponentially in n under sparsity. We state this without proof; it says that some sequence

of stopping iterations works, not how to find it.

Warning. Early stopping is an implicit regularizer: the estimates minimize no stated criterion. For prediction, tune m like any smoothing parameter. For interpreting coefficients, boosting inherits every caution of [Chapter 29](#) about selection, and inference after boosting meets the obstacles of inference after the lasso ([Theorem 28.5.1](#)).

30.5.5 Exercises

30.5.5.1 A. Check your understanding

Exercise A1.

Let $\mathbf{X}^\top \mathbf{X} = \mathbf{I}$, $\mathbf{z} = (3, -1, 0.5)^\top$ and $\varepsilon = 0.5$. Run FS_ε by hand until the largest absolute residual correlation first falls below 1, and check [Proposition 30.5.1\(b\)](#) at each step.

Exercise A2.

Show that the ℓ_1 arc length of the FS_ε path after k steps is $k\varepsilon$, that it is at least $\|\mathbf{b}^{(k)}\|_1$, and that equality holds iff no coordinate has ever moved in both directions. Which of the two paths in [Figure 30.5.1](#) has equality up to the least squares region?

30.5.5.2 B. Practice

Exercise B1.

Adapt the proof of [Proposition 30.5.1](#) to componentwise boosting with step $\nu \in (0, 1]$ under an orthonormal design. Show that τ_k is nonincreasing and that $|b_j^{(k)} - \text{sign}(z_j)(|z_j| - \tau_k)_+| \leq \nu\tau_k$ for all j and k .

Solution. The chosen coordinate's remaining correlation changes from τ_k to $(1 - \nu)\tau_k$, with no overshoot since $\nu \leq 1$. So τ is nonincreasing, and each coordinate stays between 0 and z_j . If j was last chosen at step $l < k$, then $d_j = (1 - \nu)\tau_l \geq (1 - \nu)\tau_k$ and $d_j \leq \tau_k$. As in the proof, the distance from the lasso coordinate at τ_k is at most $\tau_k - d_j \leq \nu\tau_k$. A coordinate that has never been chosen is 0, and so is the lasso coordinate.

Exercise B2.

On a segment of the lasso path with active set A and signs $\mathbf{s}_A$, show that the correlation of an inactive regressor is $c_j(\lambda) = \mathbf{x}_j^\top (\mathbf{I} - \mathbf{M}_A) \mathbf{y} + \lambda \mathbf{x}_j^\top \mathbf{X}_A (\mathbf{X}_A^\top \mathbf{X}_A)^{-1} \mathbf{s}_A$, where $\mathbf{M}_A$ projects onto $\mathcal{C}(\mathbf{X}_A)$. Deduce the value of λ at which j joins the active set, and the value at which an active coefficient reaches zero. This is the lasso version of least angle regression.

Solution. By [Eq. 30.5.1](#), $\mathbf{y} - \mathbf{X}_A \hat{\boldsymbol{\beta}}_A(\lambda) = (\mathbf{I} - \mathbf{M}_A) \mathbf{y} + \lambda \mathbf{X}_A (\mathbf{X}_A^\top \mathbf{X}_A)^{-1} \mathbf{s}_A$. Take the inner product with $\mathbf{x}_j$. Regressor j joins when $|c_j(\lambda)|$ reaches λ . Since c_j is affine in λ , this happens at the largest λ below the current one solving $c_j(\lambda) = \pm\lambda$. An active coefficient

$\hat{\beta}_k(\lambda)$ is affine in λ by [Eq. 30.5.1](#), and it leaves when it reaches 0. The next breakpoint is the largest of these candidate values. At a breakpoint, A and $\mathbf{s}_A$ are updated, and the path continues linearly.

Exercise B3.

Show that for $p = 2$ (unit-length columns, correlation $\rho \in (-1, 1)$) the direction $\mathbf{d}_A$ always has the signs $\mathbf{s}_A$. Conclude, using [Proposition 30.5.2\(b\)](#), that FS_0 and the lasso path coincide for every data set with two regressors.

Solution. For $A = \{j\}$, $\mathbf{d}_A = s_j$. For $A = \{1, 2\}$, $(\mathbf{X}_A^\top \mathbf{X}_A)^{-1} = (1 - \rho^2)^{-1} \begin{pmatrix} 1 & -\rho \\ -\rho & 1 \end{pmatrix}$. So $\mathbf{d}_A = (1 - \rho^2)^{-1}(s_1 - \rho s_2, s_2 - \rho s_1)^\top$. If $s_1 = s_2 = s$, this is $s(1 - \rho)(1 - \rho^2)^{-1}(1, 1)^\top$, with the signs of s . If $s_2 = -s_1$, it is $(1 + \rho)(1 - \rho^2)^{-1}(s_1, s_2)^\top$. In both cases the signs are right, because $|\rho| < 1$.

30.6 Summary and Notes

30.6.1 Summary

Idea.

1. A penalized criterion ([Definition 30.1.1](#)) has a minimizer when it is coercive; with a convex penalty all minimizers share their fit and penalty, and strict convexity or full rank gives uniqueness ([Theorem 30.1.1](#)).
2. For convex penalties, $\mathbf{X}^\top(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}) \in \lambda \partial P(\hat{\boldsymbol{\beta}})$ characterizes minimizers ([Lemma 30.1.2](#), [Lemma 30.1.3](#)), and penalized estimates are posterior modes ([Proposition 30.1.4](#)).
3. SCAD and MCP are sparse, continuous and nearly unbiased; MCP is firm thresholding ([Proposition 30.1.5](#)).
4. The elastic net is unique, a lasso on augmented data, and groups correlated regressors ([Proposition 30.2.1](#), [Proposition 30.2.3](#)).
5. The group lasso selects whole groups by block soft thresholding ([Proposition 30.3.1](#)) and, orthonormalized, ignores the coding of factors ([Proposition 30.3.2](#)).
6. Componentwise boosting converges geometrically to least squares ([Theorem 30.4.1](#)); early stopping is a spectral filter like ridge ([Proposition 30.4.2](#)), and the operator trace understates its degrees of freedom.
7. Forward stagewise tracks the lasso path ([Proposition 30.5.1](#)); its limit is the lasso when paths are monotone and the monotone lasso otherwise ([Proposition 30.5.2](#)).

30.6.2 Notes and sources

Coverage. Fahrmeir, Kneib, Lang and Marx (2021, §4.2–4.3) treat penalties and componentwise boosting in applied terms; the theory and proofs are added here. Hastie, Tibshirani and

Friedman (2009, chapters 3, 10 and 16) cover the same ground from the machine-learning side.

Penalties. Ridge regression is due to Hoerl and Kennard (1970), the lasso to Tibshirani (1996) and bridge penalties to Frank and Friedman (1993); uniqueness of the lasso in general position is from Tibshirani (2013). Boyd and Vandenberghe (2004) cover subgradients, and Park and Casella (2008) develop the Bayesian lasso. SCAD and the oracle property are from Fan and Li (2001), MCP from Zhang (2010).

Elastic net and groups. The elastic net, its grouping effect and rescaling are from Zou and Hastie (2005); our grouping bound adds the residual-norm term. Pathwise coordinate descent is from Friedman, Hastie, Höfling and Tibshirani (2007) and Friedman, Hastie and Tibshirani (2010). The group lasso is due to Yuan and Lin (2006), its orthonormalized form is discussed by Simon and Tibshirani (2012), and the sparse group lasso is from Simon, Friedman, Hastie and Tibshirani (2013).

Boosting. AdaBoost is due to Freund and Schapire (1997); Friedman, Hastie and Tibshirani (2000) and Friedman (2001) gave the statistical and gradient view, and matching pursuit is from Mallat and Zhang (1993). L_2 boosting and the boosting operator are from Bühlmann and Yu (2003), componentwise boosting in high dimensions from Bühlmann (2006), and a survey is Bühlmann and Hothorn (2007). Our proof of [Theorem 30.4.1](#) is the standard argument for greedy coordinate descent on a quadratic. Efron, Hastie, Johnstone and Tibshirani (2004) proved that FS_0 is the lasso path under their positive cone condition, and Hastie, Taylor, Tibshirani and Walther (2007) described FS_0 in general as the monotone lasso; [Proposition 30.5.1](#) is a special case proved directly.

Chapter 31

The General Gauss–Markov Model

Every chapter so far has assumed that the errors are uncorrelated and equally variable. That assumption is a statement about the *geometry* of observation space: it says that Euclidean distance is the right way to measure how far the data are from the model. When observations share a common shock, follow one another in time, or are measured with different precision, Euclidean distance is the wrong ruler. This chapter replaces $\sigma^2\mathbf{I}$ by a general $\sigma^2\mathbf{V}$: first with $\mathbf{V}$ known and invertible, where the theory of Parts II and III survives a change of coordinates; then in the two places where it does not survive, when $\mathbf{V}$ is singular and some functions of $\boldsymbol{\beta}$ become known exactly, and when $\mathbf{V}$ has to be estimated from the data that produced the fit.

What you need. Chapter 6, especially Section 6.9: projection in the $\mathbf{V}^{-1}$ inner product (Definition 6.9.1, Theorem 6.9.1), oblique projections (Proposition 6.9.4) and Kruskal’s theorem (Theorem 6.9.3). Section 7.2 for the Gauss–Markov theorem (Theorem 7.2.1) and Aitken’s corollary (Corollary 7.2.3), which this chapter cites and does not reprove. From Chapter 1: generalized inverses, square roots (Theorem 1.7.6) and the Woodbury identity (Theorem 1.6.5). From Chapter 2: whitening (Proposition 2.2.4) and the support of a singular covariance (Theorem 2.2.3). Quadratic forms (Chapter 4), estimability (Chapter 8) and the F test (Chapter 11) are used throughout. Section 19.2 and Chapter 21 supply the diagnostic side: what a wrong covariance does (Theorem 19.2.2), how much efficiency it costs (Theorem 19.2.3), and the sandwich estimator (Theorem 21.4.2).

31.0.1 Roadmap

- Generalized least squares
- When ordinary least squares is best
- Singular covariance matrices
- Estimated covariance: feasible generalized least squares
- Summary and notes

31.1 Generalized least squares

The model of this chapter keeps the mean structure of every earlier chapter and loosens the second moments:

$$E(\mathbf{Y}) = \mathbf{X}\boldsymbol{\beta}, \quad \text{Cov}(\mathbf{Y}) = \sigma^2 \mathbf{V}, \quad (31.1.1)$$

where $\mathbf{X}$ is $n \times p$ of rank r , the matrix $\mathbf{V}$ is known and nonnegative definite, and $\sigma^2 > 0$ is unknown. This section and the next assume $\mathbf{V}$ nonsingular; [Section 31.3](#) removes that assumption.

31.1.1 What is assumed and what is not

The split of the covariance into a known matrix $\mathbf{V}$ and an unknown scalar σ^2 is a convention, not extra knowledge. Only the product $\sigma^2 \mathbf{V}$ enters [Eq. 31.1.1](#), so $(\sigma^2, \mathbf{V})$ and $(\sigma^2/c, c\mathbf{V})$ describe the same model for every $c > 0$; it is usual to normalize $\mathbf{V}$ so that $\text{tr}(\mathbf{V})/n = 1$, making σ^2 the variance of a single observation on a reference scale. What the model really assumes is that the *shape* of the covariance — the ratios of variances and all the correlations — is known.

That is exactly true only when the design forces the shape, as when an observation is the mean of m_i replicates and has variance σ^2/m_i ([Section 21.3](#)), or when the construction of the data does, as under the linear transformations of [Section 31.3](#). Otherwise $\mathbf{V}$ belongs to a family $\mathbf{V}(\boldsymbol{\theta})$ estimated first and then treated as known, and this section's exactness is a fiction whose price is computed in [Section 31.4](#).

31.1.2 The estimator and the whitened model

Generalized least squares was defined in [Definition 6.9.1](#) as projection in the $\mathbf{V}^{-1}$ inner product; we repeat it in the notation of this part.

Definition 31.1.1 — Generalized least squares

Under [Eq. 31.1.1](#) with $\mathbf{V}$ positive definite, a **generalized least squares estimate** is any $\hat{\boldsymbol{\beta}}_{\mathbf{V}}$ minimizing

$$Q_{\mathbf{V}}(\mathbf{b}) = (\mathbf{y} - \mathbf{X}\mathbf{b})^{\top} \mathbf{V}^{-1} (\mathbf{y} - \mathbf{X}\mathbf{b}),$$

equivalently any solution of the **generalized normal equations** $\mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{X} \mathbf{b} = \mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{y}$. The fitted vector is $\mathbf{X} \hat{\boldsymbol{\beta}}_{\mathbf{V}} = \mathbf{A}_{\mathbf{V}} \mathbf{y}$, where

$$\mathbf{A}_{\mathbf{V}} = \mathbf{X} (\mathbf{X}^{\top} \mathbf{V}^{-1} \mathbf{X})^{-} \mathbf{X}^{\top} \mathbf{V}^{-1} \quad (31.1.2)$$

for any generalized inverse, and the **generalized residual** is $\hat{\boldsymbol{\varepsilon}}_{\mathbf{V}} = \mathbf{y} - \mathbf{X} \hat{\boldsymbol{\beta}}_{\mathbf{V}}$.

Everything algebraic about $\mathbf{A}_{\mathbf{V}}$ is [Theorem 6.9.1](#) with $\mathbf{A} = \mathbf{V}^{-1}$: the choice of generalized inverse is immaterial, it is idempotent with column space $\mathcal{C}(\mathbf{X})$, and $\mathbf{V}^{-1} \mathbf{A}_{\mathbf{V}}$ is symmetric although $\mathbf{A}_{\mathbf{V}}$ is not — in the Euclidean geometry it is an oblique projection ([Proposition 6.9.4](#)). Everything statistical comes from one change of variables. Let $\mathbf{V}^{-1/2}$ be the symmetric positive definite square root of $\mathbf{V}^{-1}$ ([Theorem 1.7.6](#)) and set

$$\mathbf{Y}_* = \mathbf{V}^{-1/2} \mathbf{Y}, \quad \mathbf{X}_* = \mathbf{V}^{-1/2} \mathbf{X}. \quad (31.1.3)$$

By [Theorem 2.2.1](#), $E(\mathbf{Y}_*) = \mathbf{X}_*\boldsymbol{\beta}$ and $\text{Cov}(\mathbf{Y}_*) = \sigma^2\mathbf{I}$: the **whitened model** satisfies the assumptions of Part II exactly. Since $Q_{\mathbf{V}}(\mathbf{b}) = \|\mathbf{Y}_* - \mathbf{X}_*\mathbf{b}\|^2$, generalized least squares for $(\mathbf{Y}, \mathbf{X})$ is ordinary least squares for $(\mathbf{Y}_*, \mathbf{X}_*)$. Because $\mathbf{V}^{-1/2}$ is nonsingular, $\text{rank}(\mathbf{X}_*) = r$ and $\mathcal{C}(\mathbf{X}_*) = \mathcal{C}(\mathbf{X}^\top)$, so by [Theorem 8.3.1](#) the two models have the same estimable functions: nothing about identifiability changes. Any nonsingular $\mathbf{L}$ with $\mathbf{V} = \mathbf{L}\mathbf{L}^\top$ serves equally well, by [Proposition 2.2.4\(b\)](#); the Cholesky factor is the usual choice in computation.

Whitening is rarely carried out by forming $\mathbf{V}^{-1/2}$; structured $\mathbf{V}$ almost always has a shortcut. If the observations fall into G clusters of size m that share a random shock, so that $\mathbf{V} = (1 - \rho)\mathbf{I} + \rho\mathbf{Z}\mathbf{Z}^\top$ with $\mathbf{Z}$ the $n \times G$ matrix of cluster indicators, then [Theorem 1.6.5](#) gives

$$\mathbf{V}^{-1} = \frac{1}{1 - \rho} \left(\mathbf{I} - \frac{\rho}{1 + (m - 1)\rho} \mathbf{Z}\mathbf{Z}^\top \right), \quad (31.1.4)$$

and the whitening is the **quasi-demeaning**

$$y_{kj} \mapsto \frac{y_{kj} - c\bar{y}_k}{\sqrt{1 - \rho}}, \quad c = 1 - \sqrt{\frac{1 - \rho}{1 + (m - 1)\rho}}, \quad (31.1.5)$$

where $\bar{y}_k$ is the mean of cluster k ([Exercise \(B1\)](#)). At $\rho = 0$, $c = 0$ and nothing happens; at $\rho = 0.5$ with $m = 12$, $c = 0.723$; as $\rho \rightarrow 1$, $c \rightarrow 1$ and each cluster is fully centred, throwing away everything the shared shock contaminated. Generalized least squares interpolates, and [Chapter 32](#) will recognize [Eq. 31.1.5](#) as the transformation a random intercept induces.

31.1.3 Exact inference when the shape is known

Theorem 31.1.1 — Inference under a known covariance shape

Let $\mathbf{Y} \sim N_n(\mathbf{X}\boldsymbol{\beta}, \sigma^2\mathbf{V})$ with $\mathbf{V}$ known and positive definite, $r = \text{rank}(\mathbf{X}) < n$. Put

$$\text{SSE}_{\mathbf{V}} = \hat{\boldsymbol{\epsilon}}_{\mathbf{V}}^\top \mathbf{V}^{-1} \hat{\boldsymbol{\epsilon}}_{\mathbf{V}} = \mathbf{Y}^\top \mathbf{V}^{-1} (\mathbf{I} - \mathbf{A}_{\mathbf{V}}) \mathbf{Y}, \quad s_{\mathbf{V}}^2 = \frac{\text{SSE}_{\mathbf{V}}}{n - r}. \quad (31.1.6)$$

- (a) For $\boldsymbol{\lambda} \in \mathcal{C}(\mathbf{X}^\top)$, the statistic $\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}}$ is the same for every solution of the generalized normal equations, and

$$\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}} \sim N(\boldsymbol{\lambda}^\top \boldsymbol{\beta}, \sigma^2 \boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \boldsymbol{\lambda}).$$

It is the best linear unbiased estimator of $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ ([Corollary 7.2.3](#)).

- (b) $\text{SSE}_{\mathbf{V}}/\sigma^2 \sim \chi^2(n - r)$, independently of $\mathbf{X}\hat{\boldsymbol{\beta}}_{\mathbf{V}}$.
(c) $E(s_{\mathbf{V}}^2) = \sigma^2$ and $\text{Var}(s_{\mathbf{V}}^2) = 2\sigma^4/(n - r)$.
(d) For estimable $\boldsymbol{\lambda}^\top \boldsymbol{\beta}$ with $\boldsymbol{\lambda} \neq \mathbf{0}$,

$$\frac{\boldsymbol{\lambda}^\top \hat{\boldsymbol{\beta}}_{\mathbf{V}} - \boldsymbol{\lambda}^\top \boldsymbol{\beta}}{s_{\mathbf{V}} \sqrt{\boldsymbol{\lambda}^\top (\mathbf{X}^\top \mathbf{V}^{-1} \mathbf{X})^{-1} \boldsymbol{\lambda}}} \sim t(n - r).$$

- (e) Let $\mathcal{C}(\mathbf{X}_0) \subseteq \mathcal{C}(\mathbf{X})$ with $\text{rank}(\mathbf{X}_0) = r_0 < r$, and let $\text{SSE}_{\mathbf{V},0}$ be [Eq. 31.1.6](#) computed in the reduced model. Then

$$F = \frac{(\text{SSE}_{\mathbf{V},0} - \text{SSE}_{\mathbf{V}})/(r - r_0)}{s_{\mathbf{V}}^2} \sim F(r - r_0, n - r, \gamma), \quad (31.1.7)$$
